The chest radiograph of a subject with asthma is often normal. Severe asthma is associated with hyperinflation, as indicated by depression of the diaphragm and abnormally lucent lung fields. Complications of severe asthma, including pneumomediastinum or pneumothorax, may be detected radiographically. In mild to moderate asthma without adventitious sounds other than wheezing, a chest radiograph need not be obtained; if the asthma is of sufficient severity to merit hospital admission, a chest radiograph is advised.

Electrocardiographic Findings

The electrocardiogram, except for sinus tachycardia, is usually normal in acute asthma. However, right axis deviation, right bundle branch block, "P pulmonale," or even ST-T wave abnormalities may arise during severe asthma and resolve as the attack resolves.

Sputum Findings

The sputum of the asthmatic patient may be either clear or opaque with a green or yellow tinge. The presence of color does not invariably indicate infection, and examination of a Gram-stained and Wright-stained sputum smear is indicated. The sputum often contains eosinophils, Charcot-Leyden crystals (crystallized eosinophil lysophospholipase), Curschmann's spirals (bronchiolar casts composed of mucus and cells), or Creola bodies (clusters of airway epithelial cells with identifiable cilia that, in fresh samples, can often be seen to beat), which can affect color without the presence of infection.

DIAGNOSIS

Differential Diagnosis

Asthma is easy to recognize in a young patient without comorbid medical conditions who has exacerbating and remitting airway obstruction accompanied by blood eosinophilia. A rapid response to bronchodilator treatment is usually all that is needed to establish the diagnosis. However, in the patient with cryptic episodic shortness of breath, an elevated F_{ENO} can help establish a diagnosis of asthma. However, in the absence of an elevated F_{ENO}, other causes of wheezing (see Table 83-3 in Chapter 83) should be investigated.

PREVENTION AND TREATMENT

Rx

There is currently no way to prevent a patient from developing an asthmatic diathesis. For example, trials of allergen avoidance in childhood have not been successful. If a patient has such a diathesis with an allergic component, avoidance of allergens can reduce the frequency of asthma attacks. For example, removal of indoor mold can improve symptoms by 25% and reduce medication use by 50%.

The treatment of asthma is directed at the airway obstruction and the propensity for the airways to narrow too much and too easily in response to inhaled bronchoconstrictors. It is not acceptable practice to manage patients with asthma without objective measures of lung function. The best measure is FEV_1, but measures of PEFR can be substituted. Inexpensive and easy-to-use peak flowmeters make the measurement feasible in virtually all cases.

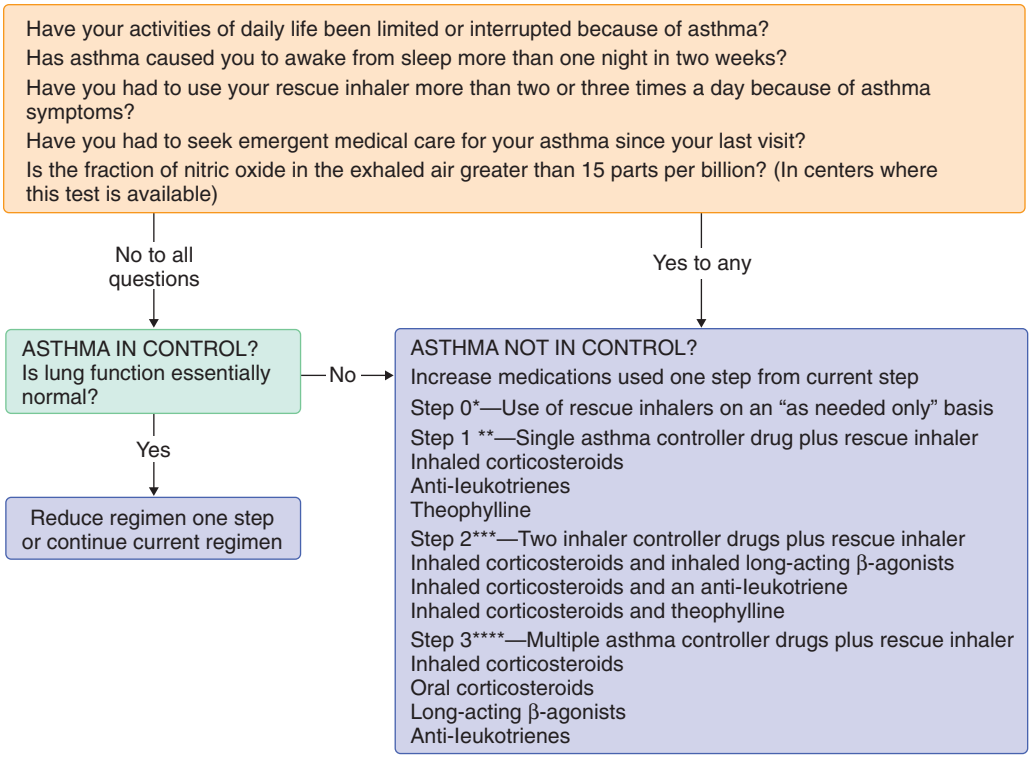

FIGURE 87-2. Approach to chronic control of asthma as well as to treatment of acute asthma symptoms. *Inhaled albuterol or, in patients predisposed to adverse effects from this treatment, inhaled ipratropium bromide. **The choice between these two agents as first-line therapy is up to the patient and provider. Inhaled corticosteroids are more potent for improving lung function but have adverse effects when used at high doses for extended periods. Efforts should be made to use the lowest doses possible. Although antileukotrienes are less effective, some patients prefer oral to inhaled treatment and wish to avoid the potential side effects of inhaled steroids. If a response to one treatment is not achieved, it makes sense to try the other. ***The best documented combination is a long-acting β-agonist plus an inhaled steroid, but the dose of inhaled steroids should be at least the median dose (see Table 87-2) before long-acting β-agonists are added. ****The use of multiple medications indicates asthma of substantial severity. Unless success is easily achieved, consultation with an asthma specialist may be appropriate.

Treatment of asthma has two components. The first is the use of acute reliever (rescue) agents (i.e., bronchodilators) for acute asthmatic airway obstruction. The second is the use of controller treatments, which modify the asthmatic airway environment so that acute airway narrowing, requiring rescue treatments, occurs much less frequently.

In a given individual, the intensity of asthma treatment is adjusted, for the most part, to achieve five goals:

1. Allow the patient to pursue the activities of his or her daily life without excessive interference from asthma
2. Allow the patient to sleep without awakening because of asthmatic symptoms
3. Minimize the use of rescue bronchodilator treatment
4. Prevent the need for unscheduled medical care
5. Maintain lung function reasonably near normal

A patient who meets these standards is said to be "in control," whereas a patient whose disease activities prevent these goals from being met is said to be "out of control." Treatment is titrated to achieve reasonable control in each patient. The recommendations given herein for chronic control of asthma are based on the Global Initiative for Asthma, 2009 revision (Fig. 87-2), but are not taken verbatim from them. Based on a directed history and physical examination, the patient's current degree of control can be determined, and then recommendations for future treatment can be made.

Rescue Treatments

All patients with asthma should be prescribed a rescue inhaler to use if they develop acute asthmatic airway obstruction.

β-Adrenergic Agents

Short-acting β-adrenergic agents given by inhalation are the mainstay of bronchodilator treatment of asthma. Constricted airway smooth muscle relaxes in response to stimulation of β_2-adrenergic receptors. β-Adrenergic agonists with varying degrees of β_2-selectivity are available for use in inhaled (by nebulizer or metered-dose inhaler; Fig. 87-3), oral, or parenteral preparations. Most patients with mild intermittent asthma should be treated with a short-acting β_2-selective inhaler (such as albuterol) on an as-needed basis. Regardless of the specific type of medication used, rescue treatment should consist of two "puffs" from the inhaler, with the first and second puffs separated by a 3- to 5-minute interval, which is thought to allow enough time for the first puff to dilate narrowed airways, thus giving the agent better access to affected areas of the lung. Patients should be instructed to exhale to a comfortable volume, to breathe in very slowly (such as they would when sipping hot soup), and to actuate the inhaler as they inspire. Inspiration to near total lung capacity is followed by holding the breath for 5 seconds to allow the deposition of smaller aerosol particles in more peripheral airways. This treatment can be repeated every 4 to 6 hours; patients should be instructed to "advance" their asthma treatment as noted in Figure 87-2 if they need to use more than 12 puffs of a β-agonist in a 72-hour period.

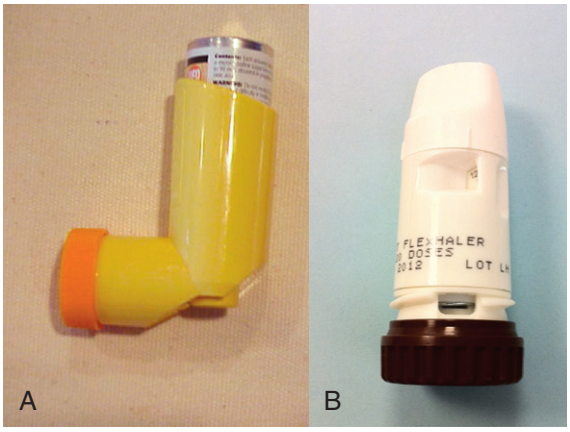

FIGURE 87-3. Commonly used inhalers. A, A pressurized metered-dose inhaler for a branded form of albuterol. Such inhalers propel the medication by means of a pressurized gas; many inhalers use propellants that do not harm the ozone layer. **B,** One of many types of dry powder inhalers; the one shown is a Flexhaler and dispenses budesonide. When this type of inhaler is activated, the active agent is released as a dry powder into a chamber. The patient creates the energy for airflow by means of an inspiratory effort that is directed through the device and that entrains medication into the inhaled airway.

Patients should receive specific instructions for correct inhaler use. Aerosol "spacers" are available from many manufacturers for patients who have difficulty coordinating their inspiratory effort and inhaler actuation. There is definitive evidence from prospective, randomized, placebo-controlled trials that the regularly scheduled use of prophylactic inhaled β-agonists has no deleterious effects in most patients with asthma.

In 2008, albuterol inhalers containing chlorofluorocarbon propellants were withdrawn from the market and replaced by inhalers powered by hydrofluoroalkanes. These inhalers have a lower velocity aerosol plume, so patients will notice a subjective difference in how the aerosol feels as it is dissipated into the mouth; nevertheless, clinical trials document that most hydrofluoroalkane inhalers will have nearly identical therapeutic effects.

Anticholinergics

Atropinic agents inhibit the effects of acetylcholine released from the intrapulmonary motor nerves that run in the vagus and innervate airway smooth muscle. Ipratropium bromide, the atropinic agent used therapeutically in asthma, is available in a metered-dose inhaler; the recommended dose is two puffs from a metered-dose inhaler every 4 to 6 hours. In adults with uncontrolled asthma, inhaled tiotropium (18 μg every morning) added to an

TABLE 87-2 ESTIMATED EQUIPOTENT DAILY DOSE FOR INHALED GLUCOCORTICOSTEROIDS FOR ADULTS

DRUG	LOW DAILY DOSE (μg)	MEDIAN DAILY DOSE (μg)	HIGH DAILY DOSE (μg)
Beclomethasone dipropionate	200-500	500-1000	>1000-2000
Budesonide*	200-400	400-800	>800-1600
Ciclesonide*	80-160	160-320	>320-1280
Flunisolide	500-1000	1000-2000	>2000
Fluticasone	100-250	250-500	>500-1000
Mometasone furoate*	200-400	400-800	>800-1200
Triamcinolone acetonide	400-1000	1000-2000	>2000

*Once-a-day dosing is acceptable.
Note: Some doses may be outside package labeling. Metered-dose inhaler doses are expressed as the amount of drug leaving the valve, not all of which is available to the patient. Dry powder inhaler doses are expressed as the amount of drug in the inhaler after activation.
Modified from 2010 Global Initiative for Asthma guidelines (*www.ginasthma.com*).

inhaled glucocorticoid is more effective than a double dose of glucocorticoids and similar in effect to salmeterol.[6]

Controller Treatments

Inhaled Corticosteroids

Inhaled corticosteroids (see Fig. 87-3), which have less systemic impact for a given level of therapeutic effect than systemic steroids, are effective controller treatments for improving lung function and preventing asthmatic exacerbations in patients with persistent asthma.[3] Accumulating data[6,7] indicate that treatment of patients whose disease can be categorized as "mild persistent asthma" can be limited to periods when the patients have increased asthma symptoms rather than requiring an inhaled corticosteroid on a regularly scheduled basis. However, inhaled corticosteroids do not change the natural history of asthma. A wide variety of inhaled corticosteroid products are on the market (Table 87-2). All available products are effective treatments of persistent asthma but differ in terms of cost, the magnitude of adrenal suppression, and the potential for systemic effects, including growth retardation in children, loss of bone mineralization, cataracts, and glaucoma. Overall, no convincing data are available to suggest that there is reason to prefer one corticosteroid over the others. Adverse effects common to all inhaled corticosteroids are oral thrush and hoarseness (attributed to myopathy of the laryngeal muscles); the risk and severity can be reduced by aerosol spacers and good oropharyngeal hygiene (i.e., rinsing out the mouth by gargling after dosing).

Antileukotrienes

Agents with the capacity to inhibit the synthesis of the leukotrienes (zileuton—controlled release [Zyflo-CR], 1200 mg twice daily) or the action of leukotrienes at the $CysLT_1$ receptor (montelukast [Singulair], 10 mg once a day; pranlukast [Onon, Ultair], 225 mg twice a day, not available in the United States; and zafirlukast [Accolate], 20 mg twice a day) are effective oral controller medications for patients with mild or moderate persistent asthma. In patients treatment with zileuton, function should be monitored for the first 3 to 6 months of treatment; if levels rise to more than three times the upper limit of normal, the drug should be stopped. Theophylline metabolism is slowed by zileuton, so monitoring of levels is indicated if both are prescribed. These treatments can be used on their own for mild persistent asthma or in combination with inhaled steroids for more severe asthma.

Long-Acting β-Agonists

In contrast to medium-acting β-agonists, long-acting β-agonists currently available in the United States (salmeterol [Serevent, 42 μg per puff; the same dose is labeled 50 μg per puff outside of the United States; one or two puffs should be delivered every 12 hours] and formoterol [Foradil, 12 μg through a proprietary dry powder inhaler every 12 hours]) have a duration of action of nearly 12 hours; they are considered a controller rather than a bronchodilator agent. Randomized controlled trials demonstrate that long-acting β-agonists should not be used as a sole controller agent. Other trials have shown that there are excess asthma deaths (about one for every 650 patient years of treatment) when long-acting β-agonists are used.[8] Therefore, long-acting β-agonists should be used only when they are given in concert with inhaled corticosteroids. Combination products with both inhaled steroids and long-acting β-agonists in the same aerosol device are available. These products prevent patients with asthma from using inhaled long-acting β-agonists without inhaled corticosteroids. When prescribing a combination inhaler, the physician should determine the inhaled dose of corticosteroids (fluticasone, budesonide, or beclomethasone) that the patient requires and then choose a combination product that will deliver a dose of long-acting β-agonist with the inhaled corticosteroid when given as two puffs twice per day. The dose of long-acting β-agonist varies with brand and type of inhaler used.

Theophylline

Theophylline and its more water-soluble congener aminophylline are moderately potent bronchodilators that are useful in both inpatient and outpatient management of asthma. The mechanism by which theophylline exerts its effects has not been established with certainty but is probably related to the inhibition of certain forms of phosphodiesterase. Theophylline is not widely used because of its toxicity and the wide variations in the rate of its metabolism, both in a single individual over time and among individuals in a population. Because blood levels need to be monitored for optimal dosing, most physicians have reserved theophylline for third- or fourth-line therapy. For most preparations, the starting dose should be about 300 mg/day; the frequency will depend on the preparation used.

Acceptable plasma levels for therapeutic effects are between 10 and 20 μg/mL; higher levels are associated with gastrointestinal, cardiac, and central nervous system toxicity, including anxiety, headache, nausea, vomiting, diarrhea, cardiac arrhythmias, and seizures. These last catastrophic complications may occur without antecedent mild side effects when plasma levels exceed 20 μg/mL. Because of these potentially life-threatening complications of treatment, plasma levels need to be measured with great frequency in hospitalized patients receiving intravenous aminophylline and less frequently in stable outpatients receiving one of the long-acting theophylline preparations. Most asthma care providers use dosing amounts and intervals to achieve steady-state theophylline levels of 10 to 14 μg/mL, thereby avoiding the toxicity associated with decrements in metabolism. Treatment with theophylline is recommended only for patients who have moderate or severe persistent asthma and who are receiving controller medications, such as inhaled steroids or antileukotrienes, but whose asthma is not adequately controlled.

Systemic Corticosteroids

Systemic corticosteroids are effective for the treatment of moderate to severe persistent asthma as well as for occasional severe exacerbations of asthma in a patient with otherwise mild asthma, but the mechanism of their therapeutic effect has not been established. No consensus has been reached on the specific type, dose, or duration of corticosteroid to be used in the treatment of asthma. In nonhospitalized patients with asthma refractory to standard therapy, a steroid "pulse" with initial doses of prednisone on the order of 40 to 60 mg/day, tapered to zero during 7 to 14 days, is recommended. For patients who cannot stop taking steroids without having recurrent uncontrolled bronchospasm despite the addition of multiple other controller treatments, alternate-day administration of oral steroids is preferable to daily treatment. For patients whose asthma requires in-hospital treatment but is not considered life-threatening, an initial intravenous bolus of 2 mg/kg of hydrocortisone, followed by continuous infusion of 0.5 mg/kg/hour, has been shown to be beneficial within 12 hours. In attacks of asthma that are considered life-threatening, the use of intravenous methylprednisolone (125 mg every 6 hours) has been advocated. In each case, as the patient improves, oral steroids are substituted for intravenous steroids, and the oral dose is tapered during 1 to 3 weeks; addition of inhaled steroids to the regimen is strongly recommended when oral steroids are started.

Monoclonal Antibody Treatment

Omalizumab

Subcutaneous administration of omalizumab, a humanized murine monoclonal antibody that binds circulating IgE, is associated with decreased serum free (not total) IgE levels. In patients who have moderate to severe allergic asthma with elevated levels of serum IgE and who are receiving inhaled corticosteroids, omalizumab treatment improves asthma control even as doses of inhaled steroids are decreased. Dosing is guided by weight and by pretreatment IgE levels: a monthly subcutaneous dose of 0.016 mg × body weight (kg) × IgE level (IU/mL). For example, in a patient weighing 70 kg with a pretreatment total IgE level of 300 IU/mL, 336 mg of omalizumab would be administered monthly by subcutaneous injection. Dosing calculators can be found online (e.g., *http://www.xolairhcp.com/xolairhcp/determining-the-dose.html*). Anti-IgE antibodies can reduce exacerbations and improve quality of life in patients with severe allergic asthma, but their place in treatment schema has not been established. Because of the potential for anaphylaxis, all patients need to be monitored after injection; the duration of the monitoring period is not specified by the U.S. Food and Drug Administration (FDA), but most physicians monitor for 30 to 60 minutes.

Mepolizumab

Mepolizumab is a monoclonal antibody directed against IL-5. Although it is not approved for clinical use, in small randomized trials it reduced asthma exacerbations among relatively rare patients with moderately severe asthma who still had sputum eosinophilia despite treatment with oral and inhaled corticosteroids. Among patients with more conventional asthma, however, mepolizumab treatment did not have a salutary effect.

Other Controller Drugs

Cromolyn sodium (one or two puffs from a metered-dose inhaler three or four times a day) and nedocromil sodium (two puffs from a metered-dose inhaler three or four times a day) are nonsteroid inhaled treatments that have proved beneficial in the management of mild to moderate persistent asthma. They appear to be most useful in pediatric populations or when an identifiable stimulus (such as exercise or allergen exposure) elicits an asthmatic response.

The use of systemic gold (as in rheumatoid arthritis), methotrexate, or cyclosporine has been suggested as adjunctive treatment of patients with severe chronic asthma who cannot otherwise discontinue high-dose corticosteroid treatment. However, these agents are experimental, and their routine use is not advocated. Despite initial encouraging trials, agents that inhibit the action of tumor necrosis factor-α do not benefit patients with asthma and should not be used.

Based on the concern that asthma could be caused by silent gastroesophageal reflux disease, treatment with a proton pump inhibitor has been advocated in patients with mild to moderate asthma even if in the absence of gastrointestinal symptoms. Adequately powered clinical studies suggest that this approach provides no benefit for asthma control.[9]

Vaccination for Seasonal Influenza and Pneumococcal Disease

Vaccination of patients for seasonal influenza is safe and not associated with enhanced asthma exacerbations. Vaccination against seasonal influenza and pneumococcal disease is recommended in patients with asthma.

Radio Frequency Ablation of Airway Smooth Muscle

A proprietary system to ablate airway smooth muscle by delivering radio frequency energy through a bronchoscopically placed probe has reduced asthma exacerbations in sham controlled trials among patients whose asthma remained out of control despite the use of multiple controller medications. A device for such treatment was recently approved by the FDA.

Control-Driven Asthma Therapy

Because all asthma treatment is symptomatic (i.e., no current treatment changes the disease history), the approach to the management of asthma is to titrate treatment to achieve an adequate level of control. If a patient's asthma is well controlled, treatment can be continued or "stepped down" (see Fig. 87-2).[10] If a patient's asthma is poorly controlled, treatment intensity should be stepped up. At the mild end of the spectrum, a patient who has rare limitations in activities of daily life, has nearly normal lung function, and sleeps without interruption from asthma can be prescribed nothing more than inhaled rescue treatment on an as-needed basis. In general, if a patient can control his or her asthma with the use of a single metered-dose inhaler of rescue treatment dispensed every 7 to 8 weeks or less frequently, there is no need for background controller treatment. If a patient has a requirement for more rescue treatment, has symptoms that interfere with sleeping through the night, or has moderately deranged lung function, controller therapy should be added.

Single-agent controller therapy should consist of an inhaled corticosteroid or an antileukotriene. If control is not achieved with one of these agents, the patient can be switched to the other or have a second agent added. The best studied two-agent combination is inhaled corticosteroids and a long-acting inhaled β_2-adrenergic agonist, available in a single inhaler under the trade names of Symbicort and Advair in the United States. These combinations provide excellent disease control and often allow a reduction in the dose of inhaled corticosteroids. Data indicate that another combination, an antileukotriene and inhaled steroid, is more effective than either treatment alone, but this regimen does not have as substantial an evidence base as the combination of inhaled corticosteroids and a long-acting β-agonist.

Specific Treatment Scenarios

Concurrent Pulmonary Infection

In some patients, acute exacerbations of asthma may be due to concurrent infection, which requires targeted therapy (Chapters 88, 90, and 97).

Aspirin-Exacerbated Respiratory Disease (Previously Termed Aspirin-Induced Asthma)

Approximately 5% of patients with moderate to severe persistent asthma develop asthma when they ingest agents that inhibit cyclooxygenase, such as aspirin and other nonsteroidal anti-inflammatory drugs (Chapter 36). Inhibitors of cyclooxygenase 2 are less likely to cause these reactions, but aspirin-type reactions have been reported in sensitive patients treated with selective cyclooxygenase 2 inhibitors. Although the physiologic manifestations of laboratory-based aspirin challenge can be blocked by leukotriene pathway inhibitors, these agents do not prevent clinical aspirin-exacerbated respiratory disease. Thus, patients with this form of asthma must avoid aspirin and other nonsteroidal anti-inflammatory drugs.

Asthma in the Emergency Department

When a patient with asthma presents for acute emergency care, objective measures of the severity of the attack, including quantification of pulsus paradoxus and measurement of airflow rates (PEFR or FEV_1), should be evaluated in addition to the usual vital signs. If the attack has been prolonged and failed to respond to treatment with bronchodilators (e.g., albuterol by metered-dose inhaler, two puffs every 2 to 3 hours) and high-dose inhaled steroids (e.g., more than 2000 μg per day of beclomethasone or half that amount of fluticasone) before arrival at the emergency department, intravenous steroids (40 to 60 mg of methylprednisolone or its equivalent) should be administered. If the patient has not been receiving treatment with a leukotriene receptor antagonist, such agents should be administered (10 mg of montelukast or 20 mg of zafirlukast) as soon as possible.[11] Treatment with inhaled β-agonists (either nebulized albuterol, 0.5 mL of a 0.5% solution—repeated at 20- to 30-minute intervals, or albuterol by metered-dose inhaler, two puffs every 30 minutes) should be used until the PEFR or FEV_1 increases to greater than 40% of the predicted values. If this point is not reached within 2 hours, admission to the hospital for further treatment is strongly advocated.

When patients have PEFR and FEV_1 values that are greater than 60% of their predicted value on arrival in the emergency department, treatment with inhaled β_2-agonists alone, albuterol (0.5 mL of an albuterol 0.083% solution) or equivalent, is likely to result in an objective improvement in airflow rates. If significant improvement takes place in the emergency department, such patients can usually be treated as outpatients with inhaled β_2-agonists and a controller agent (see Fig. 87-2). A good strategy is to add inhaled corticosteroids if the patient has not been receiving this treatment or has been using a single controller therapy.

For patients whose PEFR and FEV_1 values are between 40% and 60% of the values predicted at the time of initial evaluation in the emergency care setting, a plan of treatment varying in intensity between these two plans is indicated. Failure to respond to treatment by objective criteria (PEFR or FEV_1) within 2 hours of arrival at the emergency department is an indication for the use of systemic corticosteroids.

Status Asthmaticus

The asthmatic subject whose PEFR or FEV_1 does not increase to greater than 40% of the predicted value with treatment, whose $PaCO_2$ increases without improvement of indices of airflow obstruction, or who develops major complications such as pneumothorax or pneumomediastinum should be admitted to the hospital for close monitoring. Frequent treatments with inhaled β-agonists (0.5 mL of an albuterol 0.083% solution every 2 hours), intravenous aminophylline (at doses to yield maximal acceptable plasma levels, that is, 15 to 20 μg/mL; 500- to 1000-mg loading dose given during an hour followed by an infusion of 30 to 60 mg/hour), and high-dose intravenous steroids (methylprednisolone, 40 to 60 mg every 4 to 6 hours) are indicated. Oxygen should be administered by face mask or nasal cannula in amounts sufficient to achieve SaO_2 values between 92 and 94%; a higher FIO_2 promotes absorption atelectasis and provides no therapeutic benefit. If objective evidence of an infection is present, appropriate treatment should be given for that infection. If no improvement is seen with treatment and if respiratory failure appears imminent, bronchodilator treatment should be intensified to the maximum tolerated by the patient as indicated by the maximum tolerated heart rate, usually 130 to 140 beats per minute. If indicated, intubation of the trachea and mechanical ventilation can be instituted; in this case, the goal should be to provide a level of ventilation just adequate to sustain life but *not sufficient to normalize arterial blood gases*. For example, a $PaCO_2$ of 60 to 70 mm Hg, or even higher, is acceptable for a patient in status asthmaticus.

Asthma in Pregnancy

Asthma may be exacerbated, remain unchanged, or remit during pregnancy (Chapter 247). There need not be substantial departures from the ordinary management of asthma during pregnancy. However, no unnecessary medications should be administered; systemic steroids should be used sparingly to avert fetal complications, and certain drugs should be avoided, including tetracycline (as a treatment of intercurrent infection), ipratropium bromide (which may cause fetal tachycardia), terbutaline (which is contraindicated during active labor because of its tocolytic effects), and iodine containing mucolytics (such as saturated solution of potassium iodide). Moreover, use of prostaglandin $F_2\alpha$ as an abortifacient should be avoided in asthmatic patients.

PROGNOSIS

Asthma is a chronic relapsing disorder. Most patients have recurrent attacks without a major loss in lung function for many years. A minority of patients experience a significant irreversible loss in lung function over and above the normal pulmonary senescence. Methods to distinguish these various clinical phenotypes have not been developed.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

DENNIS E. NIEWOEHNER

DEFINITIONS

Chronic obstructive pulmonary disease (COPD) is now the preferred term for a condition that is characterized by progressive, largely irreversible airflow obstruction, usually with clinical onset in middle-aged or elderly persons with a history of cigarette smoking, and which cannot be attributed to another specific disease, such as bronchiectasis (Chapter 90) or asthma (Chapter 87). Commonly used terms for this condition in the past included *chronic bronchitis* and *emphysema*. That terminology is outdated because nearly all patients with a clinical diagnosis of COPD have both air space destruction (i.e., emphysema) and pathologic changes of the conducting airways consistent with chronic bronchitis.

Emphysema is defined pathologically by abnormal enlargement of the air spaces owing to destruction and deformation of alveolar walls. The severity of emphysema may vary widely in COPD patients with similar degrees of airflow obstruction. Chronic bronchitis is defined clinically as persistent cough and sputum production and pathologically as abnormal enlargement of the mucous glands within the central cartilaginous airways. Chronic bronchitis was once thought to be a key element in the pathogenesis of chronic airflow obstruction, but it is now known that increased airflow resistance in COPD can be attributed principally to a variety of pathologic changes within the distal airways of the lung ("small airways disease").

EPIDEMIOLOGY

COPD represents a growing global public health problem, although estimates vary widely according to the definition used. Cigarette smoking (Chapter 31) is the principal risk factor for COPD, so prevalence tends to reflect societal smoking habits with a lag phase of 20 to 30 years. Cigarette consumption has leveled off or decreased in large segments of North America and Europe, but the prevalence of COPD may continue to increase as these populations age. A greater future burden of COPD may be anticipated in Asia and other regions of the world because of rapidly increasing cigarette consumption.

More than 10% of the population older than 45 years in the United States has airflow obstruction of at least moderate severity as judged by spirometric criteria. COPD is the fourth leading cause of death in the United States, with mortality in women now exceeding that in men. COPD is projected to become the third leading cause of death worldwide by 2020. In 2007, medical costs and lost productivity attributable to COPD exceeded $40 billion in the United States. Direct medical costs rise precipitously as COPD becomes more severe, with hospitalization for exacerbations accounting for more than one half of the total.

Cigarette Smoking

Cigarette smoking is the principal cause of COPD, but the relationship between smoking and COPD is complex and incompletely understood. Airflow obstruction is the sentinel physiologic disturbance in COPD, and the forced expiratory volume in the first second (FEV_1) is the single best indicator of severity. Cigarette smoking causes declines in lung function that exceed those expected from aging alone, and the magnitude of loss is dependent on both the intensity and duration of exposure to cigarette smoke. Thus, the cumulative effects of smoking largely account for the increasing prevalence of COPD with advancing age.

Individual losses of lung function vary widely, even after adjustment for smoking intensity. After age 30 years, everyone loses lung function on a yearly basis, but smoking further impacts the rate of lung function loss. The mean annual reduction in the FEV_1 (Chapter 85) in normal nonsmoking white men is about 25 mL per year, but the loss increases to an average of about 40 mL per year among smokers (Fig. 88-1). A small minority of smokers, "susceptible smokers," suffer annual FEV_1 losses of 100 mL or more and may develop clinically significant airflow obstruction in the fourth and fifth decades of life. Factors that distinguish the susceptible smoker from the average smoker remain largely unknown.

Adverse effects of cigarette smoke on lung function may extend as far back as fetal development. Maternal smoking during pregnancy, secondhand cigarette smoke exposure during early childhood, and active smoking during adolescence impair lung growth. As a consequence, the lower lung function in early adulthood constitutes a significant risk factor for COPD later in life.

Other Environmental Exposures

Workers exposed to dust in certain workplace environments, such as mines, cotton mills, and grain-handling facilities, commonly develop respiratory symptoms and may suffer permanent loss of lung function (Chapter 93). In some regions of the world, repeated exposures to biomass combustion in confined living quarters causes airflow obstruction. Current urban air pollution in economically advanced countries appears to have little effect on the prevalence of airflow obstruction, but this factor may be more important in heavily polluted urban centers in industrializing countries.

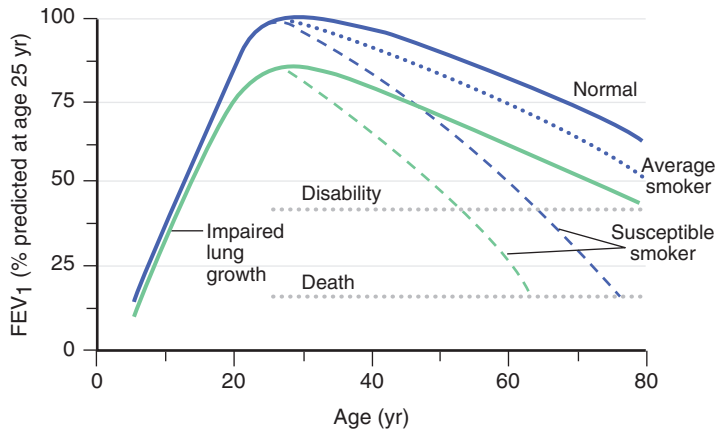

FIGURE 88-1. Lung growth occurs during childhood and adolescence with the forced expiratory volume in one second (FEV_1) reaching a maximum at about 25 years of age. Thereafter, the FEV_1 steadily declines owing to normal aging effects. Lung function declines more rapidly in smokers, but the average effect is so small that clinically significant airflow obstruction would never develop. However, a proportion of "susceptible smokers" lose lung function much faster than the average, so they develop disabling chronic obstructive pulmonary disorder (COPD). If lung growth is impaired, lung function reserve is less as a young adult, and a susceptible smoker will develop disabling COPD at an earlier age.

Respiratory Infections

Recurrent respiratory infections were once thought to be a major factor in the development of airflow obstruction, but longitudinal cohort studies have yielded inconclusive findings. An effect, if present, appears weak relative to cigarette smoking. Whether childhood respiratory infections leave residual effects on adult lung function is similarly unclear.

Airway Responsiveness

Acute bronchoconstriction after inhalation of dilute concentrations of methacholine or histamine, termed *bronchial hyperresponsiveness* (Chapter 87), is a defining feature of asthma but is also present in many COPD patients. Bronchial hyperresponsiveness independently predicts accelerated loss of lung function in persons with mild to moderate COPD, especially among persons who continue to smoke.

Genetic Factors

A severe deficiency of α_1-antitrypsin, which is the only proven genetic risk factor for COPD, is found in about 1-2% of patients with an established diagnosis of COPD. Alpha-1-antitrypsin, which is a serine protease inhibitor that is secreted into the circulation from the liver, is thought to protect lung tissue against digestion by neutrophil elastase and related serine proteinases that have been implicated in the pathogenesis of human emphysema. The most common allele at the α_1-antitrypsin genetic locus is M, and MM homozygotes have what are considered normal levels of α_1-antitrypsin (100 to 300 mg/dL). Numerous variant alleles have been identified, but severe deficiency is most commonly found in persons who are homozygous for the Z allele, in whom serum levels are generally less than 20 to 30% of the lower range of normal. Affected persons are very susceptible to cigarette smoke–induced damage and may develop severe COPD at a relatively early age. The risk for clinically important emphysema appears to be much less if patients with the risk alleles do not smoke. Emphysema associated with severe α_1-antitrypsin deficiency is characteristically of the panacinar type with a predominant basal distribution.

About 2 to 3% of northern European populations possess the MZ heterozygote serum and have α_1-antitrypsin levels about half of normal. Whether these individuals are at greater risk for developing COPD remains unclear. Familial aggregations of COPD not attributed to α_1-antitrypsin deficiency states suggest additional genetic risks. Women with severe COPD appear to have relatively more airway disease and less emphysema compared with men with similar airflow obstruction.

PATHOBIOLOGY

Pathology

Emphysema

Emphysema is characterized by abnormal enlargement of the air spaces distal to the terminal bronchiole, with destruction of the alveolar walls but without obvious fibrosis. The terminal bronchiole, which is the most distal nonalveolated airway within the bronchial tree, supplies ventilation to a lung unit that is termed the *acinus*. Distal to the terminal bronchiole are two or three generations of partially alveolated respiratory bronchioles, and then the alveolar zone, where most gas exchange occurs. Air spaces may enlarge throughout the alveolated zone owing to destruction or rearrangement of their walls.

Human emphysema consists of two major subtypes. Centriacinar emphysema localizes to the respiratory bronchioles just distal to the terminal bronchiole, whereas the remainder of the acinus is largely spared. Individual lesions, which may be up to 10 mm in diameter, tend to be more prominent in the upper lobe. Severe centriacinar emphysema is almost always related to cigarette smoking, but mild centriacinar emphysema can occur from other environmental exposures. Focal areas of inflammation, fibrosis, and carbonaceous pigment are commonly present in adjacent alveolar and bronchiolar walls.

In panacinar emphysema, alveolar ducts are diffusely enlarged; adjacent alveoli may become effaced to the extent that individual units can no longer be identified. With progression of the disease, individual lesions can coalesce to form large bullae. Panacinar emphysema, which is typical of severe α_1-antitrypsin deficiency, also commonly occurs in patients in whom the major risk factor for COPD is cigarette smoking. Most patients with severe COPD appear to have mixed elements of centriacinar and panacinar emphysema, and individual subtypes cannot be reliably distinguished in advanced disease.

Chronic Bronchitis and Bronchiolitis

Mucous glands, located between the epithelial basement membrane and the cartilage plates within the central bronchial tree, and goblet cells in the airway epithelium secrete mucus into the bronchial lumen to aid in host defenses. Enlargement of the bronchial mucous glands and expansion of the epithelial goblet cell population, which occur commonly in COPD, are correlated with clinical symptoms of cough and excess sputum production but not with airflow obstruction. A low-grade inflammatory response, consisting of neutrophils, macrophages, and $CD8^+$ T lymphocytes, may also be seen in the cartilaginous airways of COPD patients.

The principal sites of increased airflow resistance in COPD are the small distal airways that have an internal diameter near the lung's functional residual capacity of less than 2 mm. The earliest pathologic changes identified in young cigarette smokers consist of focal collections of brown-pigmented macrophages in the respiratory bronchiole and a sparse infiltrate of neutrophils and lymphocytes in the walls of the terminal bronchiole. In older patients with established COPD, the inflammatory response is more intense, but still with a similar mix of neutrophils, macrophages, and lymphocytes. Other pathologic changes in the distal airways include fibrosis, goblet cell and squamous cell metaplasia of the lining epithelium, smooth muscle enlargement within the airway walls, and scattered regions of mucous plugging. Compared with normal subjects, distal airways in patients with COPD have thicker airway walls and smaller lumens.

Pulmonary Vasculature

Hypoxemia causes vasoconstriction in small pulmonary arteries and a consequent increase in pulmonary vascular resistance. Vascular remodeling in response to chronic hypoxemia results in irreversible pulmonary hypertension (Chapter 68). Medial smooth muscle enlargement and intimal fibrosis in small pulmonary arteries are the most important vascular changes. Additionally, a substantial portion of the capillary bed may be destroyed by severe emphysema.

Pathogenesis

Emphysema appears to be caused by an elastase-antielastase imbalance in the lung, due either to elastase excess or to antielastase deficiency. Human lungs contain a rich network of elastin-containing fibers and other matrix proteins that confer structural integrity and elasticity to alveolar walls. Intratracheal instillation of proteinases, particularly those capable of hydrolyzing native elastin, induce lesions with morphologic and functional features of human emphysema in experimental animals. Chronic inflammation induced from cigarette smoke increases the burden of inflammatory cell-derived proteinases within lung parenchyma. Severe deficiencies of α_1-antitrypsin, a potent inhibitor of neutrophil elastase and other serine proteinases, is associated with development of severe panacinar emphysema in humans. In addition to neutrophil elastase, other neutrophil-derived serine proteinases, such as proteinase 3 and cathepsin G, and matrix metalloproteinases degrade elastin and other matrix components, including collagen, proteoglycans, and fibronectin. A macrophage-derived metalloproteinase, MMP-12, is essential to the development of cigarette smoke–induced emphysema in an animal model, and genetic studies show a linkage with the region of the genome containing DNA encoding MMP-12.

Relatively less is understood about the pathogenesis of distal airways disease. Particulate matter and toxic gases from inhaled cigarette smoke initiate an inflammatory response composed primarily of macrophages and neutrophils. This early inflammatory response may be mediated by the innate defense system as a response to cell injury. In more advanced disease, inflammation persists even after the patient has stopped smoking. At this stage, humoral and cellular components of the adaptive immune system may predominate, possibly in response to infection or specific antigens from other sources. Infiltration of airway walls with $CD4^+$, $CD8^+$, and B lymphocytes is a prominent feature of more advanced COPD. Repair from either type of immune response might cause airway remodeling by stimulating connective tissue matrix synthesis and smooth muscle formation and by increasing the proportion of mucus-secreting goblet cells within the epithelial layer.

Pathophysiology

Lung and Heart Mechanics

Elastic recoil refers to the lung's intrinsic tendency to deflate following inflation. A dense labyrinth of elastic fibers and other matrix elements within the

lung parenchyma, along with surface tension at the alveolar air-liquid interface, confers this important mechanical property. Elastic recoil maintains the patency of small airways through radial alveolar attachments, similar to the way a tent is held up by its guy ropes, and provides a portion of the driving pressure during expiration. Age-related loss of lung elasticity largely explains the normal decline in FEV_1 with advancing age. In emphysema, loss of lung elastic recoil results from damage to elastic fibers and loss of alveolar surface area.

An increase in bronchial airflow resistance is another sentinel feature of lung mechanics in COPD. The increased resistance in COPD is due primarily to changes in the small airways of less than 2 mm diameter. Compared with normal lungs, peripheral airflow resistance of COPD is larger by an order of magnitude or more. In contrast, airflow resistance in the central airways of lungs from COPD patients differs little from that of normal lungs. One of the key physiologic aspects of COPD is limitation of this expiratory airflow (Fig. 88-2) owing to loss of lung elastic recoil and increased viscous resistance to airflow in the small airways (Chapter 85). The severity of emphysema and airflow obstruction is directly related to impaired left ventricular filling, reduced stroke volume, and lower cardiac output without reducing the ejection fraction.

Gas Exchange

Mild hypoxemia may be detected in the early stages of COPD, and hypoxemia often becomes more prominent as airflow obstruction worsens. Hypercapnia usually appears only with severe COPD but is sometimes absent even in late-stage disease. Ventilation-perfusion mismatching, owing to changes in both the airways and pulmonary vessels, is largely responsible for hypoxemia, with uneven ventilation being the primary event. Gas exchange is most efficient when the ratio of ventilation to perfusion is uniform in all lung regions. In COPD, there is "wasted ventilation" because some lung regions have inadequate pulmonary blood flow for the ventilation. The calculated A-a gradient for oxygen is larger than anticipated for the patient's age (Chapter 103). Thus, in most cases of COPD, modest increases in the fraction of inspired oxygen result in a resolution of clinical hypoxemia.

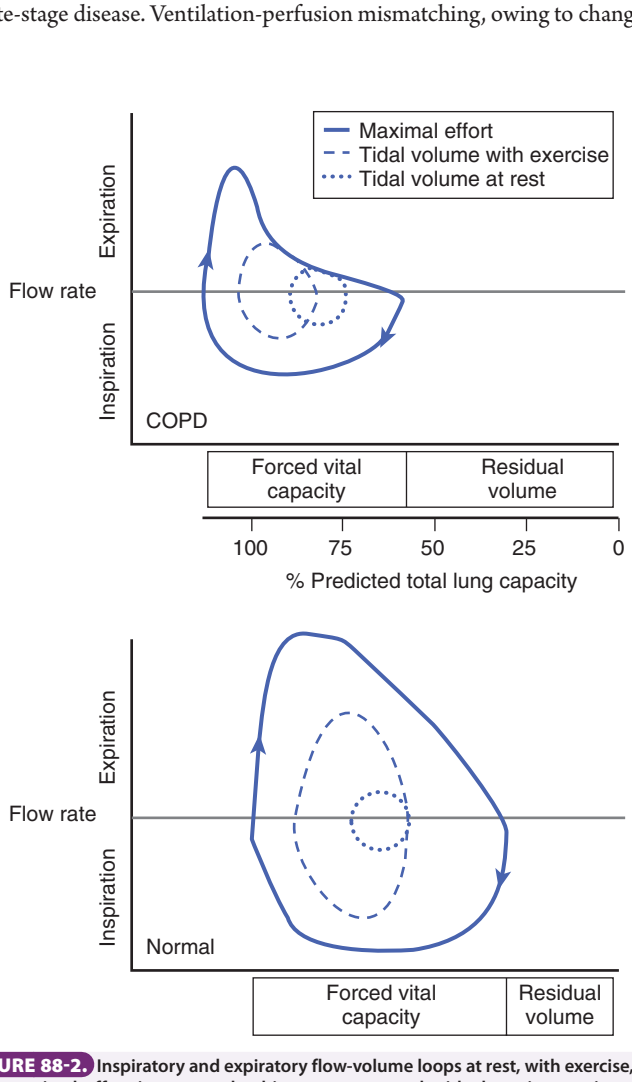

FIGURE 88-2. Inspiratory and expiratory flow-volume loops at rest, with exercise, and with maximal effort in a normal subject are compared with those in a patient with chronic obstructive pulmonary disorder (COPD). The normal subject can easily increase both tidal volume and breathing frequency to match the metabolic requirements of vigorous exercise. In contrast, the COPD patient exhibits maximal expiratory flow limitation even at rest and must breathe at larger lung volumes to optimize expiratory airflow. Lung hyperinflation requires greater respiratory work because the lung and chest wall become stiffer at larger volumes. This effect is accentuated during exercise, which causes end-expiratory lung volume to increase further. This phenomenon is described as *dynamic hyperinflation* and is an important mechanism in limiting exercise and causing dyspnea.

CLINICAL MANIFESTATIONS

History and Physical Examination

COPD should be suspected in all adults who complain of chronic respiratory symptoms, particularly dyspnea (Chapter 83) that limits activities of daily living. Clinical features that increase the likelihood of COPD include older age, current or past cigarette use, insidious onset of dyspnea with slow progression, history of acute bronchitis for which medical care is sought, and symptoms of chronic cough, sputum production, or wheezing. Symptoms of cough and sputum may antedate dyspnea by many years. Some patients date the onset of dyspnea to a respiratory infection, but careful questioning usually elicits some history of impaired exercise tolerance before that event. Absence of cigarette smoking does not preclude a diagnosis of COPD because a few persons develop severe irreversible airflow obstruction without smoking history and even without known genetic predispositions. Some nonsmokers may relate a history of occupational dust or noxious gas exposure (Chapter 94), but sometimes no putative cause can be discerned.

The physical examination is usually normal in patients with mild to moderate disease, and characteristic physical signs may be absent even in severe disease. Physical examination findings commonly present in severe COPD include the appearance of a barrel-shaped chest, low diaphragm detected by percussion, prolonged expiratory phase, and use of accessory muscles of respiration. Heart sounds are usually distant, and auscultation of the chest may reveal diminished breath sounds or a variety of rhonchi, wheezes, and rattles. Auscultatory wheezes may be prominent, particularly during exacerbations, but this physical sign does not reliably differentiate COPD from asthma. With severe hypoxemia, cyanosis may be clinically evident. Clubbing is not associated with COPD, and its presence should suggest another diagnosis. Pedal edema, distended jugular veins, and hepatic congestion are signs of pulmonary hypertension and cor pulmonale (Chapter 68). Patients with advanced COPD may be cachectic, with loss of muscle mass and subcutaneous fat.

Clinical Phenotypes

One of the more enduring efforts to categorize COPD into subtypes is the description of the patients as either "pink puffers" or "blue bloaters." The pink puffer is described as a cachectic individual with unrelenting dyspnea, clinical and radiographic signs of severe lung hyperinflation, and normal or near-normal arterial blood gases at rest. Salient features of the blue bloater are a stout body habitus, chronic cough and sputum, less troubling dyspnea, and severe hypoxemia and hypercapnia resulting in polycythemia and signs of cor pulmonale. In the original description of these phenotypes, the pink puffer phenotype was equated with severe emphysema, whereas the blue bloater was thought to have predominant chronic bronchitis.

Selected COPD patients do fit one or the other of these clinical subtypes, but most cannot be simply categorized. Limited information from clinical and pathologic correlative studies fails to show a consistent association of either clinical subtype with distinguishing pathologic features in lung parenchyma or airways. The blue bloater phenotype may now be less common, possibly because hypoxemia is recognized and treated earlier or because some COPD patients once described as blue bloaters may have had coexisting obstructive sleep apnea (Chapter 100).

COPD patients with similar degrees of airflow obstruction vary greatly with respect to severity of dyspnea, impairment of exercise tolerance, frequency of exacerbations, body habitus, and severity of arterial blood gas disturbances. There is limited understanding about the mechanisms underlying these clinical characteristics.

DIAGNOSIS

Pulmonary Function Tests

Airflow obstruction can be determined only by spirometry. If the ratio of FEV_1 to FVC is less than 0.70 (Chapter 85) after administration of an inhaled bronchodilator, an obstructive defect is present (Table 88-1). A large improvement of perhaps 30 to 40% in FEV_1 after treatment with an inhaled

bronchodilator may help identify a patient with predominant asthma, but the test otherwise has little clinical utility and cannot reliably identify patients who will benefit from any particular form of therapy.

Lung volume measurements may help distinguish obstructive and restrictive lung diseases in selected patients, but they are unnecessary in most COPD patients. The diffusing capacity for carbon monoxide (DLCO; Chapter 85) measures the uptake of carbon monoxide between inspired air and the blood stream. Decreases in the DLCO reflect the loss of alveolar surface area that is available for gas transfer and roughly correspond to the severity of emphysema. However, the test provides information of no practical value in the customary management of COPD.

After the diagnosis is established, follow-up spirometry may help determine whether worsening breathlessness is due to COPD, as indicated by a decrease in FEV_1, or to another cause, such as heart failure (Chapter 58). However, repeated spirometry should not be used as a guide to drug therapy because the background variability of the measurement is large relative to treatment effects.

Oximetry

Hypoxemia and hypercapnia become increasingly common as COPD worsens. Because treatment with supplemental oxygen improves mortality, patients with severe COPD should be tested for hypoxemia at regular intervals. Hypoxemia can be detected and quantified by oximetry or arterial blood gases. Oximetry is generally preferred because it is simpler, cheaper, and causes no discomfort. The added information from a set of arterial blood gases (Chapter 103) is most helpful in COPD patients with severe exacerbations.

TABLE 88-1 STAGE AND SEVERITY OF COPD ACCORDING TO POSTBRONCHODILATOR SPIROMETRY

STAGE AND SEVERITY	DEFINITION
I: Mild	$FEV_1/FVC < 0.70$, $FEV_1 \geq 80\%$ of predicted
II: Moderate	$FEV_1/FVC < 0.70$, $50\% \leq FEV_1 < 80\%$ of predicted
III: Severe	$FEV_1/FVC < 0.70$, $30\% \leq FEV_1 < 50\%$ of predicted
IV: Very severe	$FEV_1/FVC < 0.70$, $FEV_1 < 30\%$ of predicted or $FEV_1 < 50\%$ of predicted plus chronic respiratory failure

Data from the Global Initiative for Chronic Obstructive Lung Disease. http://www.goldcopd.com.

Radiographic Studies

Common signs of severe COPD on a chest radiograph include hyperinflated lungs, flattened diaphragms, and increased retrosternal clear space (Fig. 88-3). The walls of large emphysematous bullae may be visualized as thin curvilinear lines, and severe emphysema may appear as regions of relative hyperlucency. Chest radiographs are usually normal in mild to moderate COPD and sometimes in severe COPD. Hence, a chest radiograph is not an adequate diagnostic test for COPD, and it is used mostly to exclude other pulmonary diseases. Chest computed tomography (CT), which is a superior imaging modality to assess the magnitude and distribution of emphysema (Fig. 88-4), is not helpful in the usual management of COPD.

Other Studies

Measurement of the serum level of α_1-antitrypsin deficiency may be considered, particularly if the patient has a strong family history of COPD or if the onset of airflow obstruction occurs at an early age. If the α_1-antitrypsin level is less than 20 to 30% of normal, further testing with specialized phenotyping and genotyping studies is required to confirm the diagnosis.

Differential Diagnosis

COPD is most commonly confused with asthma (Chapter 87), particularly in older patients. Clinical features that favor asthma over COPD include onset of disease at an early age, presence of atopy, lack of a smoking history, substantial variability of symptoms over time, and largely reversible airflow obstruction. However, new onset of asthma may occur in elderly people, some asthmatics smoke, an atopic history is not a requisite for developing asthma, and airflow obstruction may become fixed in patients with severe, long-standing asthma. Because treatment is much the same, distinguishing asthma from COPD may not be so important.

Bronchiectasis (Chapter 90) is characterized by chronic inflammation and abnormal dilation of airways associated with chronic cough and expectoration of purulent sputum. It can be distinguished from COPD with a predominant bronchitis component by chest CT imaging.

Bronchiolitis obliterans is characterized by cicatricial narrowing of the distal airways with severe irreversible airflow obstruction. The condition may occur in association with collagen vascular diseases (Chapters 272 and 274) and is commonly seen after lung transplantation (Chapter 101). A similar

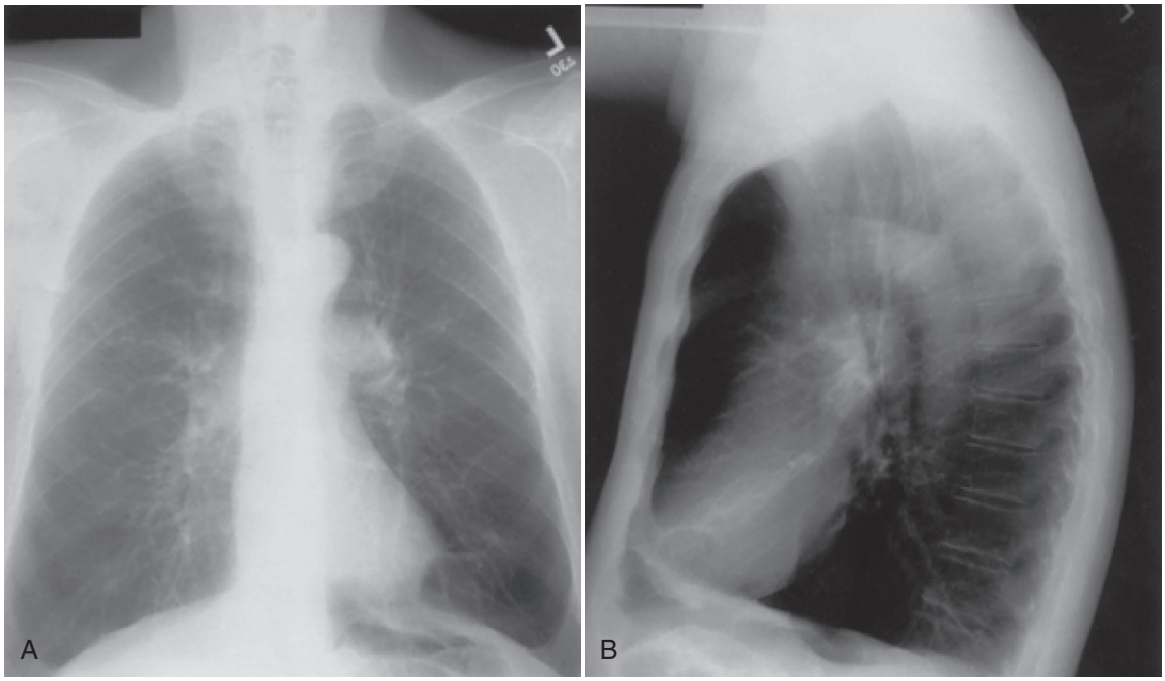

FIGURE 88-3. Posteroanterior (A) and lateral (B) radiographs of the thorax in a patient with emphysema. The most obvious abnormalities are those associated with increased lung volume. The lungs appear dark because of their increased air relative to tissue. The diaphragms are caudal to their normal position and appear flatter than normal. The heart is oriented more vertically than normal because of caudal displacement of the diaphragm, and the transverse diameter of the rib cage is increased; as a result, the width of the heart relative to the rib cage on the posteroanterior view is decreased. The space between the sternum and heart and great vessels is increased on the lateral view.

disorder has been described with certain industrial inhalants, such as diacetyl, a butter-like flavoring manufactured for use with microwavable popcorn (Chapter 93). In nonsmokers, the diagnosis of bronchiolitis obliterans can be reliably inferred from history, the presence of irreversible airflow obstruction, and the absence of emphysema or other explanatory conditions on chest CT images. Attribution of cause in smokers is more difficult because the airway pathology with diacetyl exposure is similar to that found with cigarette smoke.

TREATMENT

Rx

Stable Disease

Smoking Cessation

Smoking cessation (Chapter 31) reduces symptoms of cough and sputum production in many patients with COPD, but it improves lung function to only a small extent (Fig. 88-5). Most important, after smoking cessation, the rate of decline of FEV_1 in patients with mild to moderate disease reverts back to that seen in lifelong nonsmokers, thereby making it unlikely that these former smokers will ever develop severe COPD. Smoking cessation in patients with mild to moderate COPD also improves long-term mortality by reducing both respiratory and cardiovascular deaths.[1] It is not known whether smoking cessation slows the decline in lung function or improves mortality in patients with severe COPD.

Limited information indicates that counseling and pharmacotherapy achieve the same low success rates in COPD patients as in the general population. COPD patients tend to quit smoking as the disease progresses, possibly because they have greater awareness of their disease or because cigarette smoke makes their respiratory symptoms worse. Information regarding abnormal spirometry does not motivate patients to quit smoking.

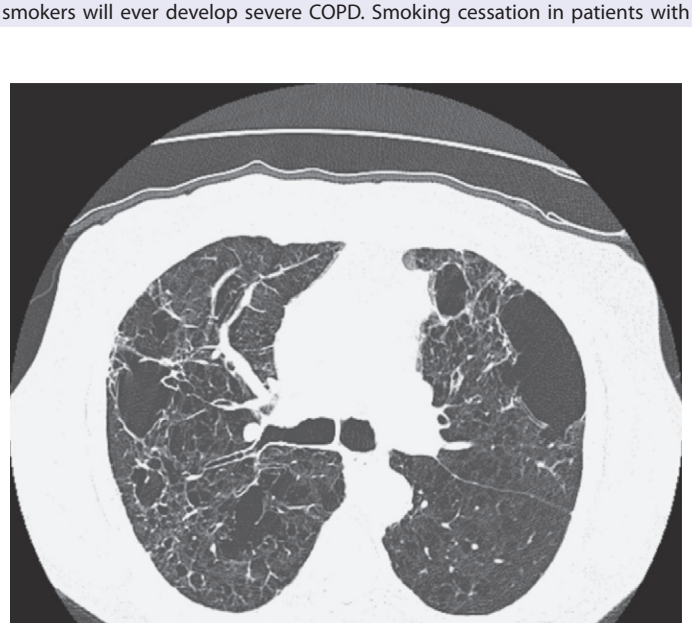

FIGURE 88-4. High-resolution axial computed tomography scan of a 1-mm section of the thorax of a patient with emphysema at the level of the tracheal carina. The right lung is on the *left*. Multiple large bullae—black holes—are evident. Many smaller areas of similar tissue destruction are also present in both lungs. The right upper lobe bronchus is seen entering the lung; its walls are thickened, suggesting chronic inflammation. (Courtesy of Dr. Bruce Maycher.)

Bronchodilators

Both β_2-adrenergic agonists and anticholinergics are widely used to treat COPD (Table 88-2). Short-acting β_2-adrenergic agonists, such as albuterol and the short-acting anticholinergic ipratropium bromide, can be administered either by oral inhaler devices or by nebulization, with little objective superiority of one delivery device over the other if a spacer is used with oral inhaler devices. Longer-acting bronchodilators have largely replaced shorter-acting drugs, but a short-acting bronchodilator, such as albuterol, is still recommended for "rescue" or "as-needed" use in patients who experience bothersome dyspnea.

The inhaled long-acting bronchodilators widely used for COPD include the β_2-adrenergic agonists salmeterol and formoterol, both administered by one inhalation twice daily, and the anticholinergic tiotropium, administered by one inhalation once or twice daily. Compared with placebo, they consistently provide clinically meaningful improvement in respiratory health status in only about 10 to 15% of patients.[2] Tiotropium (18 µg once daily) appears to be superior to salmeterol (50 µg twice daily) for reducing exacerbations.[3]

Compared with placebo, both classes of long-acting bronchodilators reduce exacerbation rates by about 15 to 20% in relative terms. Because the average patient with severe COPD has about one serious exacerbation per year, the number of patients that need to be treated to prevent one exacerbation is about six.

Adverse symptomatic events of both classes of long-acting bronchodilators in COPD patients are generally minor. Despite concerns about their long-term safety, the largest and longest trials to date have shown no serious safety issues when long-acting β_2-adrenergic agonists or long-acting anticholinergics are used to treat COPD.

Theophylline is a poor bronchodilator that largely has been replaced with inhaled drugs, but its effect is additive when given along with inhaled bronchodilators. Theophylline may also reduce exacerbations. To be used effectively and safely, it should be started with an oral daily dose of between 150 and 300 mg and titrated to achieve serum levels of 8 to 12 µg/mL. Higher levels are poorly tolerated, especially in older patients. Theophylline interacts with numerous other drugs (e.g., allopurinol, diazepam, cimetidine, ciprofloxacin), and conditions such as heart failure and liver disease may reduce its elimination rates. Patients' drug levels must be monitored on a regular basis, and even a patient on a stable dose can develop toxic levels. Oral roflumilast, a phosphodiesterase-4 inhibitor at 500 µg once daily, can increase FEV_1 by 50 mL and reduce moderate to severe exacerbations of COPD, even in patients already treated with tiotropium.[4]

Corticosteroids

Inhaled corticosteroids produce marginal improvements in lung function and respiratory health status in COPD patients, and they reduce COPD exacerbation rates by about 15 to 20% in relative terms.[5] Inhaled corticosteroids combined with an inhaled long-acting β_2-agonist provide added benefit over that seen with either monotherapy. However, multiple large trials found little effect of inhaled corticosteroids on FEV_1 loss over periods of several years.

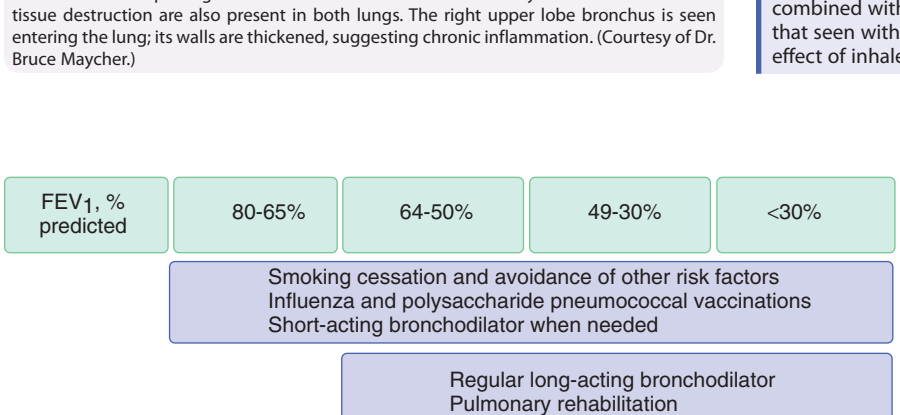

FIGURE 88-5. The flow diagram illustrates step management of stable COPD; more therapies are added as the disease becomes more severe. The percent predicted FEV_1 provides only a rough guide to the severity of the disease so other factors, such as exercise limitations and the frequency of exacerbations, should also be considered in the global assessment.

TABLE 88-2 COMMONLY USED MEDICATIONS FOR STABLE COPD

	MODE OF DELIVERY	DOSE AND FREQUENCY	POSSIBLE ADVERSE REACTIONS
SHORT-ACTING INHALED BRONCHODILATORS			
Albuterol (β_2-adrenergic agonist)	Inhaler	100 μg per inhalation; 1-2 inhalations every 4-6 hours, as needed	Palpitations, tachycardia, tremor, hypersensitivity reaction
	Nebulizer	2.5 mg; every 4-6 hours, as needed	
Ipratropium (anticholinergic)	Inhaler	17 μg per inhalation; 2 inhalations 4 times daily, up to 12 inhalations a day	Dry mouth, cough, blurred vision, hypersensitivity reaction
	Nebulizer	0.5 mg; every 6-8 hours	
Albuterol, ipratropium	Inhaler device	90 μg/18 μg per inhalation; 2 inhalations 4 times daily, up to 12 inhalations per day	All those occurring with either albuterol or ipratropium
	Nebulizer	2.5 mg/0.5 mg; 4 times daily, up to 2 additional doses daily	
LONG-ACTING INHALED BRONCHODILATORS			
Formoterol (β_2-adrenergic agonist)	Inhaler	12 μg; 1 inhalation twice daily	Dizziness, tremor, throat irritation, hypersensitivity reaction
	Nebulizer	20 μg; twice daily	
Salmeterol (β_2-adrenergic agonist)	Inhaler	50 μg; 1 inhalation twice daily	Headache, tremor, throat irritation, hypersensitivity reaction
Tiotropium (anticholinergic)	Inhaler	18 μg; one inhalation each morning	Dry mouth, urinary retention, symptoms of narrow-angle glaucoma, hypersensitivity reaction
INHALED CORTICOSTEROIDS			
Fluticasone powder	Inhaler	250 μg; 1-2 inhalations twice daily	Sore throat, dysphonia, headache, hypersensitivity reaction
Budesonide	Inhaler	160 μg; 1-2 inhalations twice daily	Nasopharyngitis, thrush, hypersensitivity reactions
COMBINATION β-ADRENERGIC AGONIST BRONCHODILATOR AND INHALED CORTICOSTEROID			
Fluticasone/salmeterol	Inhaler	250 μg/50 μg; 1 inhalation twice daily	All those occurring with either fluticasone or salmeterol
Budesonide/formoterol	Inhaler	160 μg/4.5 μg; 2 inhalations twice daily	All those occurring with either budesonide or formoterol
METHYLXANTHINES			
Theophylline (24-hour sustained release)	Pill	200-800 mg, once daily; start with daily dose of 150-300 mg and titrate to blood level of 8-12 μg/mL	Nausea and vomiting, seizures, tremor, insomnia, multifocal atrial tachyarrhythmia, hypersensitivity reaction

The most common adverse effects of inhaled corticosteroids are dysphonia and upper airway thrush. Observational studies suggest that inhaled corticosteroids may cause osteoporosis (Chapter 251) and cataracts (Chapter 431).

A few COPD patients are prescribed systemic corticosteroids on a regular basis, usually in doses of 10 to 15 mg per day of prednisone or its equivalent. These patients are sometimes considered "prednisone dependent" because it is frequently difficult to wean them completely off drug. There are no proven benefits of chronic, low-dose prednisone in COPD, and adverse effects involving bone, eyes, and other organs are well documented (Chapter 34). Consequently, efforts should be made to reduce or discontinue chronic systemic corticosteroids while optimizing other treatment.

Oxygen

Chronic hypoxemia in patients with COPD can induce irreversible pulmonary hypertension and cor pulmonale (Chapter 68). Long-term oxygen therapy extends life in patients who are persistently hypoxemic.■ The principal qualifying criteria are an arterial Pa_{O_2} of less than 56 mm Hg or an arterial oxygen saturation of less than 89%, both while breathing ambient air at rest in a stable clinical state. Patients should also be considered for home oxygen if their Pa_{O_2} is less than 60 mm Hg in the presence of right heart failure or polycythemia. Treatment should consist of home oxygen to be used for at least 18 hours daily, to include sleep time. To determine an appropriate prescription, the oxygen flow rate should be adjusted in 1-L/minute increments at 15-minute intervals until the resting oxygen saturation remains above 90%. In qualifying patients, long-term oxygen may also decrease polycythemia and pulmonary hypertension and improve neuropsychiatric function. Oxygen does not improve mortality in patients with similarly severe airflow obstruction but milder hypoxemia.

Many patients with severe COPD may be normoxemic at rest while breathing ambient air but exhibit oxygen desaturation with exercise. Physicians commonly prescribe ambulatory oxygen in this setting, with the expectation that it will improve exercise tolerance and increase daily activity. Ambulatory oxygen modestly improves exercise endurance for such patients in a laboratory setting, but efforts to show benefit during activities of daily living have been mostly unsuccessful. It is also unclear whether COPD patients with isolated nocturnal hypoxemia benefit from oxygen therapy.

Immunizations

An annual influenza vaccination (Chapter 17) is recommended for all patients with COPD, although few trials have targeted this patient population. Observational studies suggest that influenza vaccination substantially reduces hospitalization and mortality rates in COPD patients. Polysaccharide pneumococcal vaccination (Chapter 17) is also recommended, although supporting evidence is weak.

Pulmonary Rehabilitation

COPD patients become increasingly sedentary as their disease progresses. Lack of physical activity causes muscular and cardiovascular deconditioning, which further complicates the ability to perform routine tasks. The principal goal of pulmonary rehabilitation is to reverse this process with a program of exercise endurance training. Educational and behavior modification elements are usually included in an effort to improve coping skills and psychological functioning. Most programs are hospital based and consist of 3- to 4-hour sessions, three times a week, over a 6- to 12-week period. Patients who become breathless with minimal activity or who have exercise limiting comorbidities are not suitable candidates.

Numerous randomized, controlled trials have shown that pulmonary rehabilitation confers substantial improvements in respiratory health status and in walking distance and possibly in reduction of health care use.■ Unfortunately, the benefits of pulmonary rehabilitation erode rapidly in the absence of a continuation plan after completion of the initial program. Pulmonary rehabilitation is also not accessible to most patients for a variety of reasons.

Surgical Options

In lung volume reduction surgery (Chapter 101), severely emphysematous tissue is resected from the upper lobes of both lungs to permit less diseased portions of unresected lung to expand and function more normally. Patients who are severely disabled from COPD and who have no other major comorbid conditions may be candidates for this procedure if CT imaging shows that severe emphysema is mostly localized to the upper lobes. Compared with controls receiving no surgical treatment, lung volume reduction surgery improves lung function, exercise capacity, and respiratory health status in COPD patients with severe emphysema.■ There is no mortality benefit from this procedure, with a possible exception in the subset of patients with both predominant upper lobe emphysema and low exercise capacity.

Lung transplantation is an option for patients who are severely incapacitated from COPD and have no major comorbid conditions (Chapter 101). Median survival after lung transplantation is only about 5 years, primarily because of the development of bronchiolitis obliterans, a form of chronic graft rejection causing severe airflow obstruction in the peripheral airways. It is

unclear whether lung transplantation extends survival in patients with COPD, but patients who are fortunate enough to avoid complications are able to resume normal daily activities.

Exacerbations

Exacerbations represent an important element in the natural history of COPD. An exacerbation is defined as some combination of dyspnea, cough, and productive sputum, each of which has worsened from the stable state or has newly appeared. Exacerbations may also be associated with symptoms of rhinorrhea, sore throat, fever, and chest congestion. A symptom-based clinical event, as described previously, coupled with administration of an antibiotic or a systemic corticosteroid or admission to a hospital, is a definition that has been widely used in clinical trials.

Patients with severe COPD experience an average of about one such exacerbation per year along with additional milder exacerbations that meet the symptomatic definition but do not require a medical intervention. Exacerbations are acute in onset, but recovery may require several weeks. Severe exacerbations have a major adverse impact on health status and may cause permanent loss of lung function. Hospitalization for exacerbations consumes more than half of total medical costs for COPD. For poorly understood reasons, some patients suffer frequent exacerbations, whereas others have very few, despite similar degrees of airflow obstruction. Independent risk factors include low lung function, older age, history of frequent exacerbations and hospitalizations, presence of productive cough, and presence of cardiovascular comorbidities.

Respiratory infections are thought to cause most exacerbations, although many of these implicated microorganisms may be recovered from sputum during periods of stable disease. Bacteria commonly implicated include *Haemophilus influenzae* (Chapter 308), *Streptococcus pneumoniae* (Chapter 297), and *Moraxella catarrhalis* (Chapter 308). *Pseudomonas aeruginosa* (Chapter 314) and enteric gram-negative bacilli (Chapters 312 and 313) are less common but are seen in patients with very severe COPD who were recently hospitalized or intubated. Putative viral pathogens include rhinoviruses (Chapter 369), influenza (Chapter 372), parainfluenza (Chapter 371), and respiratory syncytial virus (Chapter 370). Periods of increased airborne pollution with diesel particulates, sulfur dioxide, ozone, and nitrogen dioxide are associated with more COPD hospitalizations, but no cause can be assigned to many exacerbations.

Evaluation and management of a patient with a suspected exacerbation varies according to severity. Mild exacerbations encountered in an office setting can be diagnosed and treated on the basis of a brief history and physical examination. Patients seen in emergency department or hospital settings generally are sicker and require a more extensive evaluation (Table 88-3). A chest radiograph should be obtained to look for signs of pneumonia (Chapter 97), pneumothorax (Chapter 99), and heart failure (Chapter 58). If pulmonary embolism (Chapter 98) is suspected, spiral CT of the chest is the test of choice. Arterial blood gases should be measured if there is any suspicion of hypercarbia because this information influences subsequent therapy. Sputum cultures need not be done routinely because they are unproven guides to antibiotic therapy. During seasonal outbreaks of influenza (Chapter 372), type A and B viruses can be identified with rapid commercially available assays. However, the sensitivity of these assays is only about 50 to 70%, so they should not be relied on to withhold antiviral therapy if there is a strong clinical suspicion of influenza.

Cardiac disease is a common comorbidity in COPD patients, and distinguishing a COPD exacerbation from left ventricular failure (Chapter 58) by history and physical examination alone is often problematic. Dyspnea (Chapter 83) is common to both conditions. Peripheral edema (Chapter 50) and elevated jugular venous pressure may occur with either left ventricular failure or with cor pulmonale secondary to COPD. Echocardiography (Chapter 55) and serum brain natriuretic peptide (BNP) levels (Chapter 58) are very useful in this clinical setting, although echocardiography is more difficult to perform in patients with severe COPD. BNP levels may be modestly elevated in both stable and exacerbated COPD in the absence of left ventricular dysfunction. A normal BNP level excludes a diagnosis of left heart failure with a high level of confidence, but an elevated level does not confirm its presence unless markedly elevated.

Decisions about the need for hospitalization rely mostly on clinical judgment because there are no well-validated guidelines. Clinical assessment should consider intensity of dyspnea, use of accessory muscles of respiration, arterial blood gas disturbances, hemodynamic stability, and mental alertness.

TABLE 88-3 GUIDELINE RECOMMENDATIONS FOR HOSPITAL MANAGEMENT OF COPD EXACERBATIONS

	GLOBAL INITIATIVE FOR CHRONIC OBSTRUCTIVE LUNG DISEASE*	AMERICAN THORACIC SOCIETY/ EUROPEAN RESPIRATORY SOCIETY†	NATIONAL INSTITUTE FOR CLINICAL EXCELLENCE‡
Date of statement	2010	2004	2010
Diagnostic testing	Chest radiograph, oximetry, ABGs, and ECG. Other testing as warranted by clinical indication.	Chest radiograph, oxygen saturation, ABGs, ECG, sputum Gram stain and culture.	Chest radiograph, ABG, ECG, complete blood count, sputum smear and culture, blood cultures if febrile.
Bronchodilator therapy	Inhaled short-acting β_2-agonist is recommended. Consider ipratropium if inadequate clinical response. Consider theophylline or aminophylline as second-line intravenous therapy.	Inhaled short-acting β_2-agonist and/or ipratropium with spacer or nebulizer, as needed.	Administer inhaled drugs by nebulizer or hand-held inhaler. Specific agents and dosing regimens not specified. Consider theophylline if inadequate response to inhaled bronchodilators.
Antibiotics	Recommended if (1) increases in dyspnea, sputum volume, and sputum purulence all are present; (2) increase in sputum purulence along with increase in either dyspnea or sputum volume; or (3) need for assisted ventilation. See original document for complex treatment algorithm.	Base choice on local bacterial resistance patterns. Consider amoxicillin/clavulanate or respiratory fluoroquinolones. If *Pseudomonas* species and/or other Enterobacteriaceae are suspected, consider combination therapy.	Administer only if history of purulent sputum. Initiate with an aminopenicillin, a macrolide, or a tetracycline, taking into account local bacterial resistance patterns. Adjust therapy according to sputum and blood cultures.
Systemic corticosteroids	Daily prednisolone 30-40 mg (or its equivalent) orally for 7-10 days.	Daily prednisone 30-40 mg orally for 10-14 days. Equivalent dose intravenously if unable to tolerate oral intake. Consider inhaled corticosteroids.	Daily prednisolone 30 mg (or its equivalent) orally for 7-14 days.
Supplemental oxygen	Maintain oxygen saturation >90%. Monitor ABGs for hypercapnia and acidosis.	Maintain oxygen saturation >90%. Monitor ABGs for hypercapnia and acidosis.	Maintain oxygen saturation within the individualized target range. Monitor ABGs.
Assisted ventilation	Indications for NPPV include severe dyspnea, acidosis (pH ≤ 7.35) and/or hypercapnia (P_{CO_2} > 45 mm Hg), and respiratory rate >25 breaths/min. Contraindications to NPPV include respiratory arrest, hemodynamic instability, impaired mental status, copious bronchial secretions, and extreme obesity. Intubate if contraindication to NPPV or failure of NPPV (worsening ABGs or clinical status). Consider likelihood of recovery and patient's wishes and expectations before intubation.	Consider with pH < 7.35 and P_{CO_2} > 45-60 mm Hg and respiratory rate > 24 breaths/min. Institute NPPV in a controlled environment, unless there are contraindications (e.g., respiratory arrest, hemodynamic instability, impaired mental status, copious bronchial secretions, and extreme obesity). Intubate if contraindication to NPPV or failure of NPPV (worsening ABGs or clinical status).	NPPV treatment of choice for persistent hypercapnic respiratory failure. Consider functional status, body mass index, home oxygen, comorbidities, prior ICU admissions, age, and FEV_1 when assessing suitability for intubation and ventilation.

‡Data from http://www.nice.org.uk.
ABGs, arterial blood gases; ECG, electrocardiogram; ICU, intensive care unit; NPPV, noninvasive positive pressure ventilation.

Guideline recommendations (see Table 88-3) for treatment of patients hospitalized for COPD exacerbations emphasize that antibiotics hasten recovery.[8] Antibiotics are most effective when cough and purulent sputum are present, but there are no well-validated methods for determining which patients should be treated. If patients are sufficiently ill to seek medical attention for an exacerbation, most should probably receive an antibiotic.

Most randomized placebo-controlled trials evaluated first-generation antibiotics, such as amoxicillin, trimethoprim-sulfamethoxazole, and tetracyclines, and it is unclear whether newer classes of antibiotics, such as macrolides and fluoroquinolones, are more effective. Choice of an antibiotic should be made with considerations to cost, safety, and local patterns of antibiotic resistance among the bacterial species commonly isolated from sputa during exacerbations. Doxycycline, 100 mg twice daily for 7 to 10 days, or trimethoprim/sulfamethoxazole, 160–800 mg twice daily for 7 to 10 days, would be reasonable choices for initial therapy in many locales.

Systemic corticosteroids improve lung function, shorten the recovery period, and prevent relapse when given to patients who are hospitalized or present to an emergency department with a COPD exacerbation.[10] Severely symptomatic patients seen in other clinical settings are also likely to benefit. Prednisone, 40 mg once daily for 10 to 14 days, is appropriate for most patients. Longer courses of systemic corticosteroid therapy are strongly discouraged because they are no more effective and they increase the likelihood of adverse effects. Parenteral corticosteroids should be given if gastrointestinal absorption is thought to be impaired. The major adverse effect of systemic corticosteroids is transient hyperglycemia, which may require treatment, particularly in patients with known diabetes mellitus (Chapter 237).

Patients should be encouraged to increase their use of short-acting bronchodilators during outpatient treatment of an exacerbation. For hospitalized patients, a short-acting bronchodilator should be administered on a regular schedule, every 4 to 6 hours and more frequently as needed. Anticholinergic and β_2-agonist agents are similarly effective, and a few small trials found no significant additive effect during exacerbations. Some patients express a preference for a nebulizer delivery system, although equivalent objective results can be achieved when inhalers are used with a spacer.

Sufficient oxygen should be provided to maintain arterial oxygen saturations just above 90%, usually with oxygen flow rates of 2 to 3 L/minute delivered through a nasal cannula. Even at low flow rates, oxygen therapy can be expected to increase $Paco_2$ by an average of about 5 to 10 mm Hg in patients with chronic hypercapnia. It is prudent to use the lowest flow of oxygen that achieves the desired result. If oxygen is prescribed for hypoxemia during an exacerbation, it is important to retest the patient several weeks later after recovery to determine when long-term oxygen is needed.

The introduction of noninvasive positive-pressure ventilation (NIPPV) has significantly improved the care of patients with severe COPD exacerbations who have respiratory failure. With NIPPV, the patient wears a tightly fitting nasal or full facial mask that is attached to a positive-pressure ventilator, avoiding the need for an endotracheal tube or a tracheostomy (Chapter 105). Compared with usual care, treatment with NIPPV is associated with fewer intubations, a shorter hospital stay, and improved all-cause mortality.

PROGNOSIS

Severe COPD is associated with excess mortality, and lung function, usually expressed as the percent of predicted FEV_1, is the single strongest predictor of death. Only about one half of patients with an FEV_1 that is about 40% of predicted will survive 5 years. Additional risk factors include the severity of dyspnea, weight loss, limited walking distance, hospitalization for exacerbation, hypoxemia, hypercapnia, and impaired quality of life. The only interventions shown to reduce mortality are smoking cessation in patients with mild to moderate COPD and home oxygen therapy for the subset of patients with chronic hypoxemia.

CYSTIC FIBROSIS

FRANK J. ACCURSO

DEFINITION

Cystic fibrosis is an autosomal recessive disease largely caused by mutations in the gene that encodes the cystic fibrosis transmembrane conductance regulator (CFTR) protein. Cystic fibrosis affects the lungs, pancreas, intestines, liver, sweat glands, sinuses, and vas deferens, and it results in substantial morbidity and premature mortality, with progressive lung disease as the cause of death in 90% of patients.

EPIDEMIOLOGY

The incidence of cystic fibrosis in the United States, Europe, and Australia is 1 in 3000 to 5000 births. Cystic fibrosis is most common in the non-Hispanic white population but also occurs in significant numbers in Hispanics (1 in 7000), African Americans (1 in 12,000), and some Native American populations. It also occurs rarely in individuals of Asian origin.

Approximately 30,000 persons in the United States have cystic fibrosis, so the prevalence is approximately 1 in 10,000. Worldwide, an estimated 100,000 individuals are affected. Exacerbations, particularly those requiring hospitalization, are associated with enormous social and monetary costs.

PATHOBIOLOGY

Lung and Sinus

The pathobiology of cystic fibrosis is based on the ion transport functions of the CFTR, which is a membrane glycoprotein that functions as a chloride channel but is also involved in the regulation of transepithelial sodium and bicarbonate transport. In the airway, CFTR dysfunction reduces chloride secretion from the epithelial lining cell into the airway lumen. In addition, sodium absorption from the lumen into the cell is markedly increased. The net effect is a thinning of the airway surface's liquid lining layer, thereby crucially impairing mucociliary clearance. The subsequent chronic infection leads to an intense neutrophil-dominated inflammatory response. Neutrophil products, including proteolytic enzymes and oxidants, are thought to mediate the subsequent pathologic changes in the airway, including bronchiectasis, bronchiolectasis, bronchial stenosis, and fibrosis. Mucous plugging of airways, likely from chronic infection and inflammation, is another prominent feature of airway disease. Because CFTR is expressed in relatively high concentration in the ductal portions of submucosal glands, speculation exists that mucus is abnormal in cystic fibrosis, but no abnormality has been identified.

The origin of sinus disease is believed to be similar to that in the lung. Impaired mucociliary clearance leads to chronic infection and inflammation. Nasal and sinus polyps are common, but their cause is poorly understood.

Pancreas

Pathologic studies of the pancreas in infants demonstrate ductal obstruction and dilation as well as acinar dilation. The CFTR is expressed in ductal tissue, suggesting that impairment of chloride and bicarbonate secretion into the lumen of the ducts leads to the viscous secretions that obstruct the ducts and cause acinar dilation. The exposure of pancreatic tissue to proteolytic enzymes of acinar origin leads to a cystic and fibrotic pancreas in the first few years of life. Unlike the lung, injury to the exocrine pancreas does not involve infection. Almost complete exocrine pancreatic insufficiency is seen in 85% of patients and is related to genotype.

Intestine and Liver

CFTR is expressed throughout the intestine. In approximately 15% of cases, cystic fibrosis is accompanied by meconium ileus as a manifestation of severe intestinal obstruction at birth. The incidence of jejunal and ileal stenoses and atresias is greatly increased compared with normal individuals. It is unclear how these severe abnormalities arise, but mucous obstruction in intestinal crypts is frequently seen at birth and suggests that abnormalities in CFTR lead to viscous meconium that interferes with normal intestinal development.

In the liver, bile duct obstruction is the first pathologic change noted. Focal areas of sclerosis ensue, probably owing to obstructed bile ducts. Infection is not involved in hepatic injury.

Sweat Gland

In the sweat gland, CFTR dysfunction leads to a failure of chloride absorption from the lumen into the sweat ductal lining cell. In contrast, the abnormality in the lung involves chloride secretion. The failure to absorb chloride and, by electroneutrality, sodium results in marked elevations in the chloride and sodium content of sweat. This abnormality is not accompanied by tissue destruction. The histology of the sweat gland is normal.

Male Reproductive Tract

The vas deferens appears to be the organ that is most sensitive to CFTR dysfunction. It often becomes obstructed in the fetus or in infancy. Resorption of the vas deferens occurs very early in life, and the vas is ultimately not identifiable in most males.

Other Organ Involvement

The primary abnormalities in cystic fibrosis result in secondary involvement of a number of other systems. Diabetes (Chapters 236 and 237), which is increasingly common in adolescents and adults, is thought to result when extensive scarring of the exocrine pancreas extends to the islets of Langerhans. Osteopenia and osteoporosis (Chapter 251), which are common in adults, result from a combination of malnutrition and chronic infection. Delayed puberty (Chapters 242 and 243) is also common. Patients can experience recurrent vasculitis and/or arthralgias that are believed to be caused by the host response to chronic infection. Exocrine pancreatic insufficiency leads to impaired growth and to a multitude of potential nutritional complications, including deficiencies in fat-soluble vitamins and trace elements (Chapter 225).

Genetics

The gene that encodes the CFTR spans more than 250,000 base pairs on the long arm of chromosome 7. The CFTR (ABCC7), which is a protein of 1480 amino acids, belongs to the ATP-binding cassette transporter family. More than 1500 mutations of five different classes have been described (Table 89-1). In the United States, only five mutations are present in more than 1% of cases. The F508δ mutation is by far the most common and is present in approximately 90% of patients in the United States. The next most common mutation, G542X, is present in only 4 to 5% of patients.

In class 1 mutations, protein is not produced because of nonsense mutations. Class II mutations lead to defective protein processing; in the case of 508δF, protein trafficking to the cell membrane is disrupted because the protein is recognized as being defective by cellular quality-control mechanisms, which direct it to the proteasome for degradation. In class III mutations, a protein is produced and processed correctly, but the channel remains closed in response to physiologic stimuli. Class IV mutations are present in the membrane and result in a channel that opens only partially in response to stimuli. In class V mutations, normal CFTR is produced, but in reduced amounts because of defective splicing.

Different mutations lead to differing levels of CFTR dysfunction. Severe mutations may reduce CFTR activity to 1 to 3% of normal, whereas mild mutations may be associated with CFTR activity that is 10 to 20% of normal. An important clinical correlation of CFTR activity is in the exocrine pancreas: patients with severe mutations almost always have pancreatic insufficiency, whereas some patients with milder mutations may retain pancreatic sufficiency. Patients with mild mutations tend, on average, to have less severe lung disease as well.

The clinical course of cystic fibrosis is variable, however, even after controlling for the type of mutation in CFTR, suggesting additional heritable and environmental influences. The genes that code for transforming growth factor-β, mannose-binding lectin, and interferon-related developmental regulator 1 have been identified as modifier genes. Each appears to modify the host response to infection and/or the development of fibrosis, rather than modifying the ion transport function of CFTR.

CLINICAL MANIFESTATIONS

Without specific supportive care, most patients succumb in infancy or early childhood because of malnutrition or lung disease. With the use of pancreatic enzyme replacement therapy, better pulmonary care, and the establishment of specialized centers of expertise, most patients live into the third or fourth decade of life.

TABLE 89-1 CLASSES OF CFTR MUTATIONS

CLASS	MECHANISM	GENETIC AND MOLECULAR ABNORMALITIES	REPRESENTATIVE GENOTYPE
I	Defective protein production	Unstable mRNA Truncated protein Premature stop mutations Frameshift Splicing variants	 W1282X Del394TT 1717-1G to A
II	Defective protein processing	Trafficking abnormality Protein degraded in proteasome Deletion	 F508del
III	Defective regulation	Protein at membrane Failure of gating Amino acid substitution	 G551D
IV	Defective conductance	Protein at membrane Decreased gating Amino acid substitution	 R117H
V	Decreased active CFTR	CFTR has normal activity at membrane but is decreased in amount Splice variant Substitution	 3849+10kb C to T A455E

LUNG DISEASE

Cough, often persistent after viral infections, is the most prominent early feature of the disease. Viral infection may require more frequent hospitalization in children with cystic fibrosis than in normal children.

Although the lung disease begins in infancy, pulmonary function is often preserved until adolescence, when a steep decline frequently begins; at this time, pulmonary exacerbations become common. Most patients with cystic fibrosis have a daily productive cough by late adolescence or young adulthood.

Cystic fibrosis causes obstructive lung disease, initially with decreased flows at low lung volumes. Forced expiratory volume in 1 second (FEV_1) (Chapter 85) is the best correlate of outcome and starts to differ markedly from normal during adolescence. The rate of decline in FEV_1 often predicts the clinical course.

Early in the disease, the chest radiograph demonstrates hyperinflation and peribronchial thickening. Computed tomography can demonstrate bronchiectasis (Chapter 90) early in the course of the disease.

Airway infection, which is the key clinical manifestation, can be detected by sputum culture or bronchoalveolar lavage. *Pseudomonas aeruginosa* (Chapter 314) is the primary pathogen, although its prevalence is decreasing in the United States, likely owing to improved treatment. *Staphylococcus aureus* (Chapter 296), which is another prominent pathogen, can be methicillin resistant and exist in a small-colony variant form that makes antibiotic treatment difficult.

Most infections remain endobronchial and rarely cause invasive disease, although *Burkholderia* infection can result in sepsis that leads to death. *Burkholderia* infection can also lead to an accelerated decline in lung function and result in death over months to years. Nontuberculous mycobacterial infection can cause granulomatous disease in the airway. *Aspergillus* (Chapter 347) and other fungal species, which are often identified in sputum samples, can cause allergic bronchopulmonary mycoses, but whether they contribute to endobronchitis apart from allergy is unknown.

The polymicrobial nature of airway disease is increasingly appreciated. *Stenotrophomonas maltophilia, Achromobacter xylosoxidans,* and *Inquilinus limosus* are frequently identified serially in airway cultures. Anaerobic infection may also be important.

Individuals with cystic fibrosis are subject to acute exacerbations characterized by cough, dyspnea, decreased exercise tolerance, fatigue, increased sputum production, and change in sputum color that may last days to weeks. Frequently crackles are increased on physical examination, and both the resting oxygen saturation and lung function may decline. Increasing evidence suggests that the permanent loss of lung function is accelerated during periods of exacerbation.

Pulmonary complications can also include pneumothorax (Chapter 99), hemoptysis (Chapter 83), and pulmonary hypertension (Chapter 68). Some patients with more advanced disease exhibit acute ventilatory failure with infection.

GASTROINTESTINAL DISEASE

Exocrine pancreatic insufficiency, which is apparent in the first year of life in most patients, results in impaired growth and lifelong difficulty in maintaining normal weight. Patients at all ages may exhibit signs of malabsorption, including bulky, foul-smelling stools and flatulence. Fat-soluble vitamin and trace element deficiencies are not uncommon and are difficult to diagnose without regular laboratory monitoring.

About 15% of patients retain exocrine pancreatic sufficiency, most of whom have mild mutations associated with 10 to 20% of CFTR function. About one sixth of these patients are subject to recurrent episodes of pancreatitis (Chapter 146) that can lead to pancreatic pseudocysts or ultimately result in exocrine pancreatic insufficiency.

Intestinal obstruction can occur at any age. Frequently the blockage is at the ileocecal valve, but generalized chronic constipation (Chapter 138) is even more common. Intussusception of the appendix can also occur. Inflammatory bowel disease (Chapter 143) and gastrointestinal malignancies (Chapters 198 and 199) appear to be more common than in the general population. Chronic abdominal pain can occur at any time of life, and its cause is often difficult to identify.

Most patients who develop liver disease do so in childhood or adolescence. Liver abnormalities are often first appreciated when a physical examination reveals splenomegaly or a palpable, firm liver. Occasionally, hematemesis leads to the identification of esophageal or gastric varices that are indicative of portal hypertension. Splenic sequestration can lead to neutropenia or thrombocytopenia. Decreased hepatic production of clotting factors can also contribute to bleeding. Occasionally, jaundice is a presenting sign of hepatobiliary disease. Except for γ-glutamyl transpeptidase (GGT) levels, liver enzymes are frequently normal, even in patients with advanced disease. Gallstones (Chapter 158) are common and may or may not lead to symptoms. The hepatopulmonary syndrome (Chapter 157) can occur.

OTHER ORGAN INVOLVEMENT

Although most patients have radiographic evidence of sinus disease, acute or chronic sinusitis occurs in only a minority of individuals. Sinusitis can be accompanied by debilitating headache and anosmia. Nasal or sinus polyposis can lead to obstructed breathing during sleep.

Hypoelectrolytemia can occur at any age. Symptoms range from nausea, vomiting, and decreased appetite to seizures and circulatory collapse with fatal consequences. Sweat electrolyte loss is often an underappreciated problem in cystic fibrosis.

Almost all males are sterile because of the changes in the vas deferens. Spermatogenesis is normal, however.

Cystic fibrosis–related diabetes (Chapter 236) increases in frequency with age. By 30 years of age, approximately one third of patients have diabetes. Although patients rarely develop ketoacidosis, the microvascular and macrovascular complications of diabetes can occur. In addition, patients with diabetes appear to have an accelerated decline in lung function. Osteoporosis (Chapter 251), osteopenia, and increased fractures also increase in frequency with age. Vasculitis accompanied by rash or arthralgia can occur at any time of life. Chronic pain and depression are other important complications that increase with age.

DIAGNOSIS

Newborn Screening and Diagnosis

In the United States, all 50 states require newborn screening to allow early diagnosis and immediate treatment. All newborn screening programs currently measure immunoreactive trypsinogen, a marker of pancreatic injury, from a dried blood spot taken during the first few days of life as the first step in the screening process. This biochemical screen identifies a large number of infants, only a fraction of whom have cystic fibrosis. Most programs perform genetic mutation analysis as the next step. Sweat testing is required to establish the diagnosis if suspected patients carry only one identifiable mutation, but most programs perform confirmatory sweat testing even if two mutations are present.

Sweat testing measures the chloride concentration in sweat that is stimulated by pilocarpine iontophoresis. The result is considered abnormal in adults and children when the concentration of chloride in the sweat is greater than 60 mmol/L; in infants, a concentration greater than 40 mmol/L is considered diagnostic. A family history of cystic fibrosis also provides supportive evidence. In parts of the world where genetic testing is not readily available, the appearance in infancy or childhood of intestinal obstruction or recurrent pulmonary problems should prompt sweat testing.

Diagnosis in Adulthood

Five percent of patients are diagnosed after 18 years of age, mostly on the basis of recurrent pancreatitis, nasal polyposis, chronic sinusitis, bronchiectasis, male infertility, allergic bronchopulmonary mycoses, and nontuberculous mycobacterial infection (Table 89-2). If the predominant symptoms are respiratory, the differential diagnosis includes primary ciliary dyskinesia, immune deficiency, or postinfectious bronchiectasis (Chapter 90). If the predominant symptom is recurrent pancreatitis (Chapter 146), the differential diagnosis includes hereditary pancreatitis with abnormalities in the *SPINK* gene. Transepithelial potential differences are altered in cystic fibrosis because of abnormal transport of sodium and chloride. The measurement of nasal potential difference, therefore, can sometimes be used as a diagnostic tool, particularly in adults.

It is increasingly recognized that some patients appear to have cystic fibrosis on clinical grounds but do not meet the criteria for diagnosis, usually because their sweat test is in the normal range or two genetic mutations cannot be identified. These patients are sometimes diagnosed as having atypical cystic fibrosis, nonclassical cystic fibrosis, or variant cystic fibrosis. Full analysis of the CFTR coding and flanking regions may be helpful in making the diagnosis. Such patients should be followed at a cystic fibrosis center so that their lung disease can be treated and they can be monitored for other complications of cystic fibrosis.

TABLE 89-2 APPROACH TO DIAGNOSIS OF CYSTIC FIBROSIS IN ADULT PATIENTS

CONDITIONS SUGGESTING THE DIAGNOSIS OF CYSTIC FIBROSIS IN ADULTS
Recurrent pancreatitis
Male infertility
Chronic sinusitis
Nasal polyposis
Nontuberculous mycobacterial infection
Allergic bronchopulmonary mycosis
Bronchiectasis
RECOMMENDED DIAGNOSTIC STUDIES
Sweat electrolyte determination
Extended CFTR mutation analysis
Nasal potential difference
High-resolution CT scan to identify bronchiectasis
CT scan of sinuses for polyposis
Sputum induction or bronchoalveolar lavage to identify bacterial and fungal pathogens

CFTR = cystic fibrosis transmembrane conductance regulator; CT = computed tomography.

TREATMENT

Rx

The general consensus is that treatment is best conducted at specialized centers that use a team approach. Much of their success is based on the education of patients and families with regard to the range of symptoms and complications, as well as the close monitoring of pulmonary function and rapid intervention for any detected abnormalities.

Pulmonary Infections

Pulmonary infections can be treated with oral, inhaled, or systemic antibiotics. Increase in cough or other respiratory symptoms should be addressed with the introduction of antibiotics or a change in antibiotics within a few days. Nebulized antibiotics (4 weeks of either aztreonam 75 mg two or three times a day[1] or tobramycin 300 mg twice daily[2]), alone or in combination with oral antibiotics, improve lung function and decrease exacerbations in patients with chronic *Pseudomonas* infection.[3] Chronic oral macrolide treatment (e.g., azithromycin 5 to 15 mg/kg/day, 500 mg three times per week, or 1250 mg once per week[4,5]) can reduce exacerbations for up to 6 months. It is not yet clear whether the chronic use of antibiotics in this setting leads to the development of more resistant organisms.

More severe changes in symptoms or an acute fall in lung function requires intravenous antibiotics aimed at the cultured pathogen (Chapter 97). Nontuberculous mycobacterial infections are treated for 6 months or longer using multiple antibiotic agents (Chapter 333). Allergic bronchopulmonary mycoses are treated with corticosteroids and antifungal agents (Chapter 339).

Agents to alter the viscosity of respiratory secretions include inhaled hypertonic (7%) saline, which can increase pulmonary function and reduce exacerbations.[3] Daily use of inhaled rhDNase (2.5 mg) is associated with improvement in lung function and fewer exacerbations.[3] Conversely, nebulized thiol derivatives do not appear to be beneficial.[3]

Many patients have hyper-reactive airways and may benefit from inhaled bronchodilators (Chapter 87). Inhaled corticosteroids are controversial and do not have proven benefit.[3] Oral corticosteroid "bursts" (e.g., 5 days of prednisone, 1 mg/kg twice a day in children and 30 mg/kg twice a day in adults) are often useful, but chronic administration of oral corticosteroids can result in severe complications, including diabetes and stunted growth. Most patients perform physical means of airway secretion clearance one or more times a day.

Even passive smoke exposure is deleterious. Oxygen therapy is often required to maintain saturation and prevent the development of pulmonary hypertension. Noninvasive ventilation is used mainly in patients with more advanced disease. Pneumothorax almost always requires pleurodesis. Persistent or recurrent hemoptysis is treated with bronchial artery embolization. Occasionally, lobectomy is required. Patients in acute ventilatory failure should receive mechanical ventilation unless they have decided against such treatment. The possible need for ventilation should be addressed in patients with advanced disease before the need arises.

Lung transplantation (Chapter 101) is an option for many adult patients. Individuals with cystic fibrosis have survival rates after transplantation comparable to or better than those of other patients.

Gastrointestinal Diseases

Pancreatic enzyme replacement (Chapter 146) is the mainstay of treatment for exocrine pancreatic insufficiency. Because gastric acid decreases enzyme activity, H_2-blockers (e.g., ranitidine 150 mg twice daily in children weighing >30 kg and in adults) or proton pump inhibitors (e.g., lansoprazole 30 mg orally once daily in children weighing >30 kg and in adults) are often used. Children and adolescents frequently use multiple nutritional supplements every day to maintain weight. Fat-soluble vitamin replacement therapy is necessary in most patients. Between 10 and 20% of patients may require gastrostomy feeding to aid growth or maintain weight.

To prevent intestinal obstruction, dietary fiber should be increased, and polyethylene glycol at varying doses (e.g., 17 mg orally with 8 ounces of water one to three times per day) is frequently used on a daily basis. Acute obstructions can be treated with more intensive use of polyethylene glycol or Gastrografin enema. Occasionally, refractory constipation (Chapter 138) requires surgical approaches that can result in loss of intestine.

Other Organ Systems

A combination of nasal rinses and topically applied corticosteroids and antibiotics is used to treat sinus disease (Chapter 434). Surgery is often required, however, especially for polyps.

Many pediatric patients receive daily salt supplementation. Adults should be counseled on the symptoms of salt depletion and encouraged to increase the amount of salt in their diet if there are no medical contraindications to doing so.

Regular screening for the onset of impaired glucose homeostasis or frank diabetes is required in all patients older than 10 years. Diabetes is treated with insulin (Chapter 236) because the safety and efficacy of oral antihyperglycemic agents have not been demonstrated in cystic fibrosis. Bone health is addressed through vitamin D supplementation, calcium supplementation, and oral bisphosphonate therapy (Chapter 251). Delayed puberty and short stature require consultation with endocrinologists and sometimes hormonal administration. Most clinics believe that both aerobic exercise and strength training can have beneficial effects, although the implementation of exercise programs has been difficult in clinical practice. Males with cystic fibrosis can father children through the use of epididymal aspiration to retrieve sperm, followed by in vitro fertilization.

General Care

Given all the pulmonary, nutritional, and other therapies prescribed for individuals with cystic fibrosis, their care amounts to several hours a day. This burden has a major influence on the quality of life in patients and their families and may contribute to the increasing incidence of depression observed in this population.

End-of-life care encompasses many complex issues. Patients are often depressed and experience chronic pain. They are asked to perform increasingly intense therapeutic regimens. They may have changed locations to await transplantation. Family, medical, and professional relationships are disrupted. Excellent communication with caregivers about advance directives and other planning is necessary.

PREVENTION

Prenatal carrier screening, which is offered in many countries, can decrease the incidence of cystic fibrosis by approximately 25%. Newborn screening programs may also help decrease the incidence by influencing the future reproductive decisions of parents of an affected child.

PROGNOSIS

Prognosis is now greatly improved compared with the natural history of the disease. The median expected survival in the United States is 37 years, but the peak age at death is 26 years, demonstrating that some patients are particularly vulnerable to devastating lung disease. Late adolescence and early adulthood are high-risk times for pulmonary insufficiency. Patients who survive to their 30s and beyond are often more stable, with a very slow decline in lung function.

This variability in prognosis is related to patients' ability to sustain lung function, recognizing that those with severe mutations succumb in adolescence or young adulthood, whereas patients with "milder" mutations often live longer.

BRONCHIECTASIS, ATELECTASIS, CYSTS, AND LOCALIZED LUNG DISORDERS

ANNE E. O'DONNELL

BRONCHIECTASIS

DEFINITION

Bronchiectasis is an abnormal permanent dilatation of the bronchi and bronchioles caused by repeated cycles of airway infection and inflammation. The distal airways become thickened; the mucosal surfaces develop edema, inflammation, and suppuration; ultimately, there is neovascularization of the adjacent bronchial arterioles. Bronchiectasis, which can be focal or diffuse, is triggered by a variety of genetic, anatomic, and systemic processes. Abnormalities of cilia, mucus clearance, mucus rheology, airway drainage, and host defenses can result in bronchiectasis. Regardless of the cause, patients with bronchiectasis develop chronic infections, which may lead to progressive lung destruction.

EPIDEMIOLOGY

Based on insurance claims reviews, it is estimated that there are at least 110,000 persons in the United States receiving treatment for bronchiectasis that is not related to cystic fibrosis (Chapter 89). The prevalence in the United States has been reported as 4.2 per 100,000 persons age 18 to 34 years and 272 per 100,000 among those older than 75 years. In the older age category, women are disproportionally represented. In Hong Kong, bronchiectasis results in a hospital admission rate of 14.4 per 100,000 persons. Other epidemiologic surveys suggest that there is increased risk for the development of bronchiectasis in individuals with reduced access to health care and higher rates of pulmonary infection in childhood.

PATHOBIOLOGY

In up to one third of cases, the cause of bronchiectasis is not identified. Other cases are related to pulmonary infections, genetic causes, anatomic abnormalities, and immune and autoimmune diseases.

Pulmonary Infections

Approximately one third of patients with bronchiectasis have an infectious trigger, usually years before the onset of the disease. Childhood viral infections, such as pertussis (Chapter 321) and bacterial infection, can cause permanent damage to the airways, leading to bronchiectasis years after the initial infection. Mycobacterial tuberculosis with its resultant granulomatous inflammation of the airway, lung parenchyma, and lymph nodes can cause subsequent bronchiectasis (Chapter 332), and *Mycobacterium avium-intracellulare* (MAI) infections have been recognized as an increasing cause and complication of bronchiectasis, particularly in white women older than 55 years (Chapter 333). MAI-related bronchiectasis typically involves the right middle lobe and lingula and can be associated with the "tree-in-bud" pattern of bronchiolar infection as well.

Genetics

Cystic fibrosis (Chapter 89) is characterized by bilateral diffuse bronchiectasis. Although many cystic fibrosis patients are diagnosed in childhood with multisystem disease, older patients may present with only pulmonary or pulmonary and sinus manifestations.

In primary ciliary dyskinesia, abnormalities in the dynein arms prevent normal ciliary beating. Patients with primary ciliary dyskinesia generally have significant sinopulmonary disease and infertility, and approximately half of these patients have Kartagener's syndrome with situs inversus (Chapter 69). Patients with α_1-antitrypsin deficiency also may develop bronchiectasis.

Anatomic Causes

Patients with chronic abnormalities of their swallowing mechanism or with esophageal dysfunction may develop focal or diffuse bronchiectasis with lower lobe predominance (Chapter 140). Direct lung injury due to acid or particulate matter aspiration or recurrent pneumonia may lead to bronchiectasis.

Chronic obstructive pulmonary disease is sometimes complicated by bronchiectasis (Chapter 88). Patients with chronic lower airway bacterial colonization and increased airway inflammation may develop areas of bronchiectasis. Rarely, patients with asthma (Chapter 87) have been found to have bronchiectasis. Allergic bronchopulmonary aspergillosis (Chapter 347) can cause a distinct "finger-in-glove" central bronchiectasis owing to chronic inflammation and mucous plugging. Airway abnormalities such as endobronchial tumors (Chapter 197), extrinsic compression by lymph nodes (right middle lobe syndrome), and foreign bodies are also rare causes of focal bronchiectasis. Tracheobronchomegaly (Mounier-Kuhn syndrome) is associated with distal bronchiectasis.

Immune and Autoimmune Diseases

Primary hypogammaglobulinemia (Chapter 258) leads to recurrent pulmonary infections that may result in bronchiectasis. Patients with immunoglobulin G subclass deficiencies may develop bronchiectasis if the deficiency leads to reduction in antibody production. Defects of neutrophil adhesion and chemotaxis (Chapter 172) have been found to cause bronchiectasis. Patients with human immunodeficiency virus infection (Chapter 394) have a higher prevalence of bronchiectasis than individuals with a normally functioning immune system.

Bronchiectasis is an increasingly recognized complication of collagen vascular diseases, particularly rheumatoid arthritis (Chapter 272) and Sjögren's syndrome (Chapter 276). The airway injury is likely due to chronic inflammation or esophageal dysfunction. Inflammatory bowel disease (Chapter 143) also causes bronchiectasis by undetermined mechanisms.

CLINICAL MANIFESTATIONS

Patients present with chronic cough and usually have mucopurulent or purulent sputum production. Occasionally, a dry nonproductive cough is the primary manifestation. Other symptoms include dyspnea, intermittent hemoptysis, and pleuritic chest pain. Weight loss, malaise, and fatigue sometimes develop. When patients have infectious exacerbations, they may develop fever as well as an increase in their baseline symptoms. Physical findings in patients with bronchiectasis are nonspecific: an abnormal chest examination with wheezing or crackles, or both. Clubbing of the digits is rare.

The clinical course of patients with bronchiectasis is variable. Some patients have few to no symptoms, others have daily cough with sputum production, and some patients have occasional to frequent exacerbations. A slow decline in pulmonary function is seen with bronchiectasis; decline is more rapid in patients infected with *Pseudomonas aeruginosa* (Chapter 314) and in patients who have more frequent exacerbations.

DIAGNOSIS

Imaging Studies

Although the diagnosis may be suspected by plain chest radiography, high-resolution computed tomography (HRCT) is the current "gold standard" for confirming bronchiectasis. The characteristic computed tomography (CT) findings are lack of bronchial tapering, bronchi visible in the peripheral 1 cm of the lungs, and an internal bronchial diameter greater than the diameter of the accompanying bronchial artery. Other associated HRCT findings are

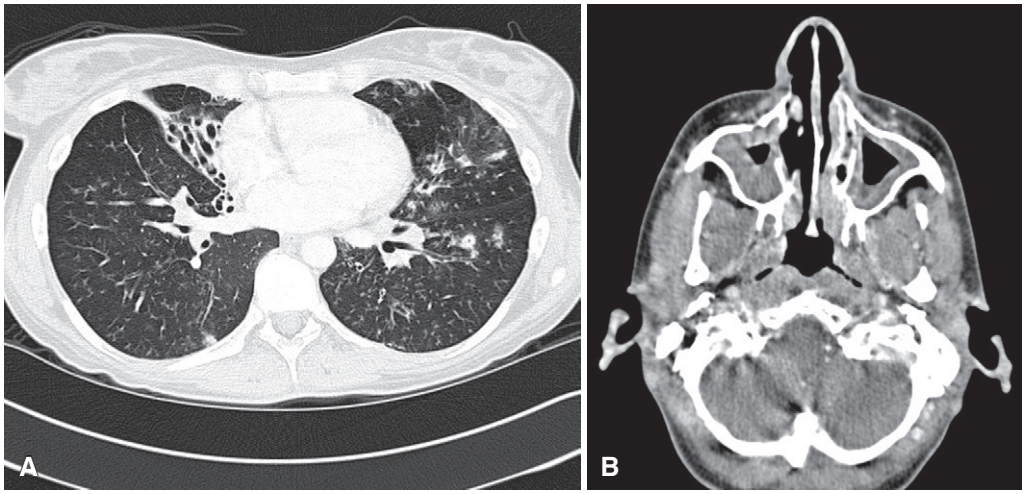

FIGURE 90-1. A and B, High-resolution computed tomographic images of bilateral bronchiectasis in a patient with primary ciliary dyskinesia.

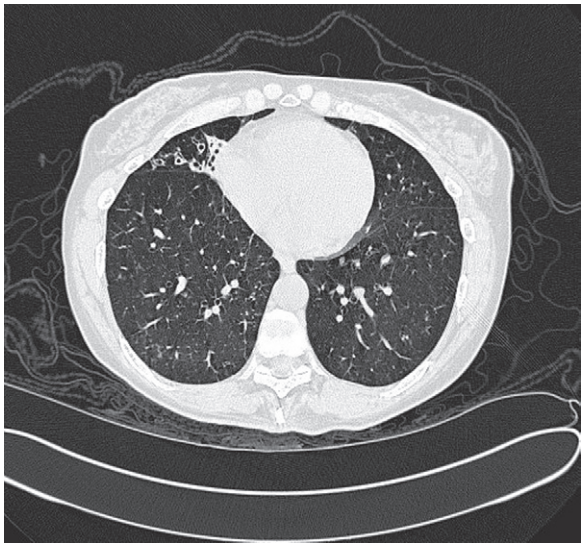

FIGURE 90-2. High-resolution computed tomographic image of nodular bronchiectasis due to nontuberculous mycobacterium infection.

cysts off the end of a bronchus, tree-in-bud irregular branching lines indicating mucus impaction, and occasionally associated consolidation (Fig. 90-1). The location of the bronchiectatic airways may suggest the cause: upper lobe predominance is seen in cystic fibrosis; lower lobe predominance in aspiration syndromes. Right middle lobe and lingula involvement suggests the presence of nontuberculous mycobacterial infection (Fig. 90-2), whereas central bronchiectasis is seen with allergic bronchopulmonary aspergillosis (Fig. 90-3).

Pulmonary function testing, which should be performed on all patients with suspected bronchiectasis, usually shows airflow obstruction as measured by the ratio between the forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) (Chapter 85). The severity of the airflow obstruction and the rate of decline correlate with radiographic extent of disease and frequency of exacerbation. Bronchoscopy will detect airway abnormalities including tumors, structural deformities, and foreign bodies and hence should be considered in the evaluation of localized bronchiectasis.

Cultures of sputum and of bronchoalveolar lavage when expectorated sputum is not available have an important role in assessing the infectious complications of bronchiectasis. The presence of *P. aeruginosa* portends a worse prognosis and more frequent exacerbations. Patients with no identifiable pathogens have the mildest disease. The presence of *Staphylococcus aureus* in the airway may suggest cystic fibrosis as the cause of the bronchiectasis. Nontuberculous mycobacteria are found with increasing frequency in the airways of patients with bronchiectasis, usually as a complication of preexisting bronchiectasis but occasionally as its primary cause. The laboratory evaluation of patients with bronchiectasis should be individualized. All patients should have sputum cultures for bacterial and mycobacterial testing. Other tests that should be considered include measurement of serum immunoglobulin levels and screening for genetic diseases, particularly in patients with diffuse bronchiectasis. Cystic fibrosis (Chapter 89) is diagnosed by elevated sweat chloride levels and by genetic testing. Primary ciliary dyskinesia is confirmed by electron microscopic evaluation of airway mucosal cilia. α_1-Antitrypsin deficiency is diagnosed by measuring levels and performing phenotyping (Chapter 88). Screening for rheumatoid arthritis (Chapter 272) or Sjögren's syndrome (Chapter 276) also may be reasonable in patients with diffuse bronchiectasis.

TREATMENT

Rx

The goals of treatment are to reduce the numbers of exacerbations and potentially to improve quality of life, reduce symptoms, and alter the natural history of the disease (Table 90-1). Currently, maintenance treatment is considered for patients with more advanced disease or more frequent exacerbations. Exacerbations are treated based on clinical acuity. Because patients are heterogeneous and therapeutic trials are few, therapy is commonly individualized in patients with bronchiectasis.

Preventing Exacerbations

The 23-valent pneumococcal vaccination is recommended for patients with bronchiectasis. Routine seasonal influenza vaccination is also standard. At present, no vaccines are available for prevention of the other infectious complications of bronchiectasis.

Treatment of the Underlying Etiology

For treatable conditions, such as immunoglobulin deficiency, replacement therapy (Chapter 258) should be considered even though there are few data on whether that alters the natural history of the lung disease. Patients with allergic bronchopulmonary aspergillosis (Chapter 347) should be treated with steroids to mitigate the inflammatory process that leads to the bronchiectasis.

Antimicrobial Therapy

Nebulized gentamicin (80 mg twice daily) for 12 months can provide sustained bacteriologic and clinical benefit.[1] Clinical trials have demonstrated microbiologic benefits with inhaled tobramycin, 300 mg twice per day as a 4-week trial for one cycle and a 2-week-on/2-week-off trial for three cycles,[2] but clinical benefit was not firmly established, and some patients experienced unacceptable respiratory side effects. Antimicrobial resistance is also a concern. In a retrospective study, radiographic stability was achieved in a limited number of patients who received cycles of alternating antibiotics, including a quinolone, over 6 to 84 months. At present, there is no firm evidence to support the use of routine maintenance antibiotics, although such therapy may be considered in patients with frequent exacerbations and progressive lung destruction. When mycobacterial species are cultured from patients with bronchiectasis, decisions regarding whether to treat and which antimicrobial agents to use are based on published guidelines (Chapters 332 and 333).

Reduction of Airway Inflammation

In two randomized trials of patients treated for 3 and 12 months, inhaled fluticasone, 500 µg twice daily, improved clinical status compared with placebo.[3,4] Small pilot trials of twice- or thrice-weekly oral erythromycin

(500 mg twice daily for 8 weeks) and azithromycin (500 mg twice weekly for 6 months) suggest that macrolide therapy can be beneficial in bronchiectasis, but these agents should not be used alone in the presence of infection because they may result in resistant nontuberculous mycobacterial organisms. Oral steroids, although sometimes used in bronchiectasis, have never been tested in a clinical trial setting.

Other Medical Treatments

Chest physiotherapy and the use of devices to aid mucociliary clearance appear to be beneficial in non–cystic fibrosis bronchiectasis. In a randomized trial, twice daily use of an oscillatory positive expiratory pressure device (Acapella) improved sputum volume and quality of life end points compared with no routine physiotherapy. Other techniques that may also have a role for airway clearance include traditional chest physical therapy with postural drainage and the use of chest wall oscillator vests. At least one clinical trial has demonstrated improvement in overall clinical status for bronchiectasis patients enrolled in a pulmonary rehabilitation program.

Inhaled therapy with nebulized hypertonic saline (7%) may enhance airway clearance and decrease exacerbations, but long-term clinical trials have not been performed in patients with non–cystic fibrosis bronchiectasis. Preliminary data suggest that inhalation of mannitol may enhance secretion clearance by improving sputum physical properties. Although recombinant human DNase is efficacious in cystic fibrosis bronchiectasis, a large clinical trial showed it had deleterious effects in patients with non–cystic fibrosis bronchiectasis when given as maintenance therapy, so it should not be used.

No randomized trials support the use of routine β-agonist or anticholinergic bronchodilators in bronchiectasis. However, a subset of patients with airway reactivity likely benefit from use of these agents (Chapter 87).

Surgery and Transplantation

Resectional surgery may have a role for patients who have focal disease or for patients who have hemoptysis that cannot be controlled by embolization of the bleeding vessels (Chapter 101). Surgical resection can also benefit some patients who have diffuse bronchiectasis unresponsive to conventional therapy and some patients infected with nontuberculous mycobacteria. Double-lung transplantation (Chapter 101) has been successfully performed in patients with end-stage lung disease due to non–cystic fibrosis bronchiectasis, and the clinical outcomes parallel those seen with transplantation for other end-stage lung diseases.

Treatment of Acute Exacerbations of Bronchiectasis

When the bronchiectasis patient experiences an acute exacerbation, antimicrobial treatments should be targeted to the known infecting organisms. Mild to moderate exacerbations can be treated with oral antibiotics, targeted to the results of the sputum culture, for 2 to 3 weeks. More severe exacerbations or exacerbations due to resistant organisms generally require intravenous antibiotics administered in hospital or at home. No benefit has yet been demonstrated by adding an inhaled antibiotic to systemic therapy for an acute exacerbation. Patients experiencing an acute exacerbation likely benefit from airway clearance modalities and the other nonantibiotic therapies discussed previously.

PROGNOSIS

Non–cystic fibrosis bronchiectasis is a heterogeneous disease with a widely variable prognosis. Patients with more severe obstructive and restrictive findings on pulmonary function tests, poor gas transfer, and chronic pseudomonal infection have the worst prognosis. Radiographic extent of disease, hypoxemia, hypercapnia, and evidence of right heart failure are also predictors of outcome. Bronchiectasis patients who are admitted to an intensive care unit for respiratory failure have been reported to have a 60% 4-year survival rate.

ATELECTASIS

DEFINITION

Atelectasis, or collapse, is due to hypoventilation of lung units. Atelectasis may involve an entire lung or a lobe, segment, or subsegment. Atelectasis can be caused by intrinsic obstruction of an airway or external compression from lymph nodes, parenchymal masses, or other entities. When lung units are atelectatic, ventilation-perfusion mismatch leads to hypoxemia. Infection may result from sustained atelectasis.

EPIDEMIOLOGY AND PATHOBIOLOGY

The lung bases and posterior segments are vulnerable to dependent atelectasis, which is caused by inadequate ventilation, particularly in the immobilized or postoperative patient. Patchy atelectasis is caused by alveolar filling processes, such as hemorrhage and edema (Chapter 91). Passive, relaxation, or compression atelectasis occurs when the lung recoils to a smaller volume because of fluid or air in the adjacent pleural space.

Obstructive or resorptive atelectasis is due to bronchial block to the entry of air, with resultant retractile consolidation. Intrinsic airway obstruction may

be caused by mucous plugs, foreign bodies, or tumors in the airway. Extrinsic airway obstruction results from compression of the airway owing to peribronchial lymph node enlargement or other masses impinging on the airway.

Rounded atelectasis is caused by pleural thickening that invaginates and traps adjacent lung. Any chronic pleural disease can cause rounded atelectasis, particularly asbestos-related pleural disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Atelectasis is typically asymptomatic and diagnosed on chest imaging, but it may cause dyspnea and tachypnea and result in hypoxemia. In postoperative patients, atelectasis may be a cause of low-grade fever. Plain chest radiography shows loss of lung volume and the displacement of the lobar fissure, mediastinum, or diaphragm toward the involved lung unit (Figs. 90-4 and 90-5). Platelike or discoid atelectasis manifests as horizontal or curvilinear lines on plain chest radiography. Rounded atelectasis is an ovoid masslike density abutting the pleura. The type and cause of atelectasis can sometimes be elucidated by CT or ultrasonography. Bronchoscopy is required to confirm intrinsic versus extrinsic compression in obstructive-resorptive atelectasis and to determine the exact pathology of the obstruction. An oxygen saturation concentration can help assess the severity of the atelectasis and overall lung dysfunction.

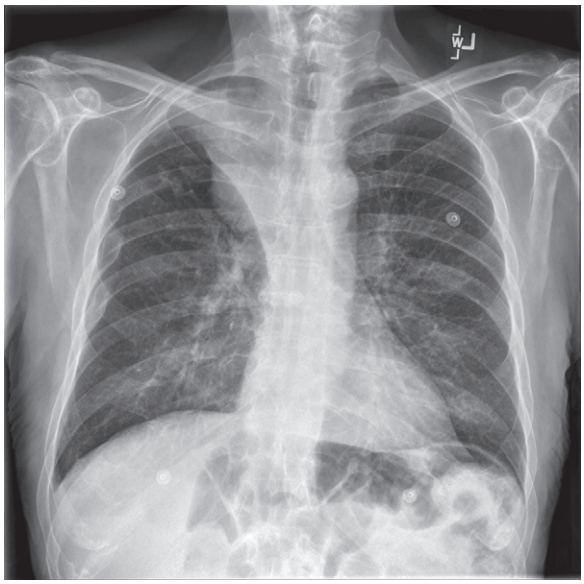

FIGURE 90-4. Plain chest radiograph demonstrating right upper lobe atelectasis (due to endobronchial tumor).

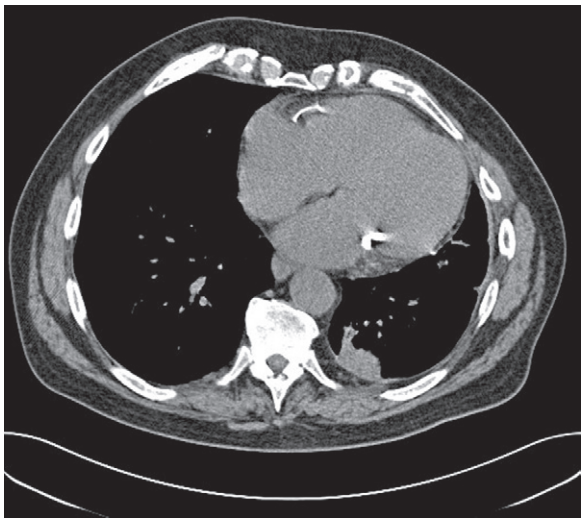

FIGURE 90-5. Computed tomographic image of rounded atelectasis.

PREVENTION AND TREATMENT

Rx

Incentive spirometry is commonly prescribed to prevent or treat atelectasis in patients with limited mobility due to recent surgery, neuromuscular weakness, or any prolonged immobilization, but there are no randomized controlled trials that prove its effectiveness. Preoperative inspiratory muscle training reduces atelectasis in patients undergoing upper abdominal surgery,[■] and prophylactic use of noninvasive ventilation may reduce pulmonary dysfunction after lung resection surgery.[■] Other modalities such as positive expiratory pressure devices and high-frequency chest wall oscillation airway clearance are of uncertain benefit.

Patchy atelectasis is treated by addressing the underlying disease process in the lung parenchyma. Compression atelectasis is treated by alleviating the pleural space process.

Obstructive or resorptive atelectasis often requires bronchoscopy for diagnosis and treatment. In patients with obstruction owing to retained secretions, multiple bronchoscopies are sometimes required, but the mucus often rapidly reaccumulates and will resolve only when the patient's overall status improves.

Rounded atelectasis does not require treatment. CT is helpful in distinguishing rounded atelectasis from parenchymal tumor.

CONGENITAL CYSTIC DISEASES OF THE THORAX

Thoracic cysts, which are exceedingly rare, develop because of abnormal development or branching of the foregut. Cysts may develop in the mediastinum at an early stage of gestation or in the lung parenchyma at a later stage. Abnormalities include bronchogenic cysts (mediastinal and parenchymal), congenital pulmonary airway malformation, and pulmonary sequestrations. The cysts are lined with airway and alveolar epithelium but do not communicate in a normal fashion with the airways or lung tissue.

Most patients with thoracic cysts present in childhood, but the cysts can remain asymptomatic and unnoticed until adulthood. In the absence of symptoms, these cystic lesions sometimes present as an incidental finding on chest imaging performed for another indication. Congenital cystic diseases can cause recurrent pneumonia, hemoptysis, or compression of normal structures.

CT scanning with CT angiography can usually detect congenital cystic lesions of the thorax, but pulmonary or bronchial angiography is sometimes necessary to define the blood flow to the lesion.

Bronchogenic cysts are usually found in the right paratracheal or subcarinal areas of the mediastinum but are occasionally seen in the lung parenchyma. These cysts are often asymptomatic, but they can cause wheezing, dyspnea, and cough when they compress adjacent structures. Secondary infection may develop in the cysts, and there are a few case reports of malignant transformation. Complete surgical resection is generally recommended, but partial excision with de-epithelization of the cysts has also been performed. Observation is also an option when the cysts are asymptomatic.

Congenital pulmonary airway malformation, previously called *congenital cystic adenomatoid malformation of the lung*, is an exceedingly rare abnormality with reported incidence of 1 in every 25,000 to 35,000 pregnancies. The abnormality is caused by arrested development of the bronchial tree. Most patients are diagnosed prenatally by ultrasound, but a few adults have first presented with complications, including pneumothorax and air embolism. Treatment is anatomic surgical resection.

Pulmonary sequestrations are areas of nonfunctioning pulmonary parenchyma with no communication to the tracheobronchial tree and abnormal arterial supply and venous drainage (Fig. 90-6). Intralobar sequestration, which accounts for about 75% of cases, does not have visceral pleura and is generally found in a lower lobe, left more frequently than right. Extralobar sequestrations have their own visceral pleura, are separate from the normal lobes, and may even be found below the diaphragms. Sequestrations usually have a feeding vessel that arises from the aorta. Patients with sequestrations may be asymptomatic but sometimes develop recurrent infections and or hemoptysis. Surgical excision with special care for the management of the feeding vessel is curative. Embolization of the feeding vessel is sometimes a successful treatment option.

Hyperlucent lungs are diagnosed by a paucity of vascular and interstitial markings noted on chest imaging. Lung parenchymal air collections can be caused by congenital parenchymal cysts, congenital lobar emphysema (almost exclusively diagnosed in infancy), giant bullous emphysema (vanishing lung syndrome), or Swyer-James syndrome. Lung parenchymal cysts may be a bullous alveolar type or may contain bronchial wall elements such as

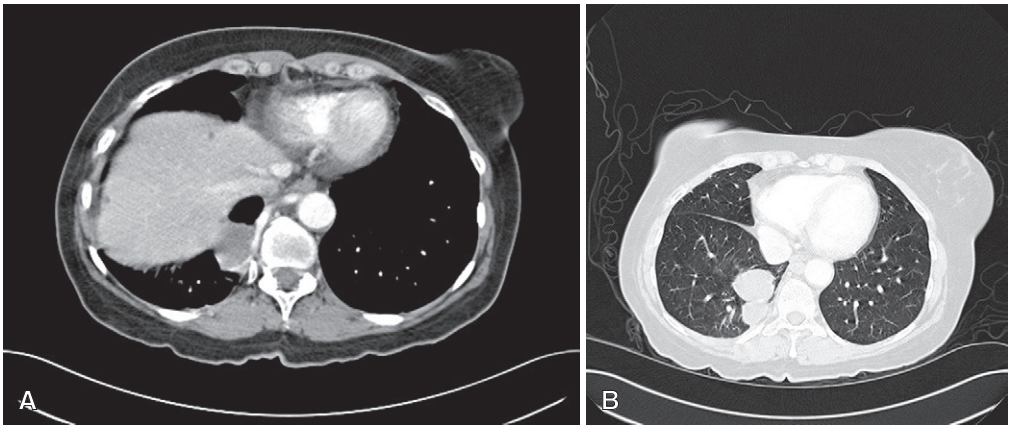

FIGURE 90-6. Pulmonary sequestration. A, Computed tomographic image of pulmonary sequestration in right lower lobe. **B,** Feeding vessel visible arising from the aorta.

cartilage, smooth muscle, and glands. They may become infected and may rupture to cause pneumothorax. Surgical resection is generally recommended unless the lesions are small. Congenital lobar emphysema, otherwise known as *congenital large hyperlucent lobe*, may cause severe respiratory distress in infants owing to compression of surrounding lung tissue. Giant bullous emphysema is a rare condition that usually affects the upper lobes of young male smokers. Compression of normal lung parenchyma from these overdistended lobes may require surgical resection.

Swyer-James-Macleod syndrome, which is characterized by unilateral lucency of an entire lung, is caused by childhood bronchiolitis obliterans owing to viral or bacterial infection or toxic inhalation. CT shows air trapping and hyperlucency of the affected lung, with a normal contralateral lung. No therapy is required.

TABLE 91-1 ALVEOLAR FILLING DISORDERS

DISEASES	PATHOPHYSIOLOGY	RADIOGRAPHIC FINDINGS
Pulmonary alveolar proteinosis	Impaired processing of surfactant by alveolar macrophages due to defects in GM-CSF signaling	Bilateral alveolar infiltrates with "crazy paving" and diffuse areas of ground-glass attenuation on CT scan
Acute interstitial pneumonia	Diffuse alveolar damage with temporal uniformity	Diffuse alveolar filling process similar to the acute respiratory distress syndrome
Diffuse alveolar hemorrhage	Bleeding from the pulmonary microcirculation, usually from the capillaries	Acute development of bilateral alveolar infiltrates
Bronchioloalveolar cell carcinoma	Cancer cells growing along the alveolar septa	Pneumonic infiltrate or nodules (either solitary or multiple)

CT = computed tomographic; GM-CSF = granulocyte-macrophage colony-stimulating factor.

91

ALVEOLAR FILLING DISORDERS

STEPHANIE M. LEVINE

DEFINITION

Alveolar filling disorders (Table 91-1) are characterized by chest radiographic findings of alveolar involvement ranging from a ground-glass appearance to consolidation; the pathologic process shows primary involvement of the alveolar air spaces distal to the terminal bronchioles. For example, in pulmonary alveolar proteinosis, the alveoli are filled by proteinaceous fluid; in bronchioloalveolar cell cancer, the alveolar walls are lined by adenocarcinoma cells. In acute interstitial pneumonia, exudative organizing fibroproliferative infiltrates fill the alveolar space; in the alveolar hemorrhage disorders, blood fills the alveolar space. Alveolar spaces filled with acute inflammatory cells, as in bacterial pneumonia (Chapter 97), or water, as in cardiogenic or hydrostatic pulmonary edema (Chapter 58), or high-protein fluid, as in noncardiogenic or increased permeability pulmonary edema (Chapter 104), are also part of the radiographic differential diagnosis of alveolar filling disorders and must be excluded.

A general approach to these suspected alveolar filling diseases (Fig. 91-1) can be stratified by time since the onset of symptoms. The typical patient may present with the onset of cough (usually dry) and dyspnea of variable duration, depending on the disease process. Hemoptysis is a frequent presenting symptom in the alveolar hemorrhagic disorders. With the exception of acute interstitial pneumonia, acute infectious symptoms such as fever, leukocytosis, and productive cough are usually absent. If the initial chest radiograph or chest computed tomographic (CT) scan is consistent with a possible alveolar filling process (Chapter 84), and acute pneumonia and pulmonary edema are excluded, bronchoscopy with bronchoalveolar lavage (Chapter 85) and transbronchial biopsy should be performed, particularly if pulmonary alveolar proteinosis, bronchioloalveolar cell cancer (Chapter 197), or alveolar hemorrhage is suspected. When these tests are nondiagnostic and in most cases of suspected acute interstitial pneumonia, a surgical lung biopsy obtained by thoracoscopy or an open surgical procedure is indicated.

PULMONARY ALVEOLAR PROTEINOSIS

EPIDEMIOLOGY

Pulmonary alveolar proteinosis is a rare alveolar filling disease caused by the accumulation of phospholipoproteinaceous material in the alveoli. The

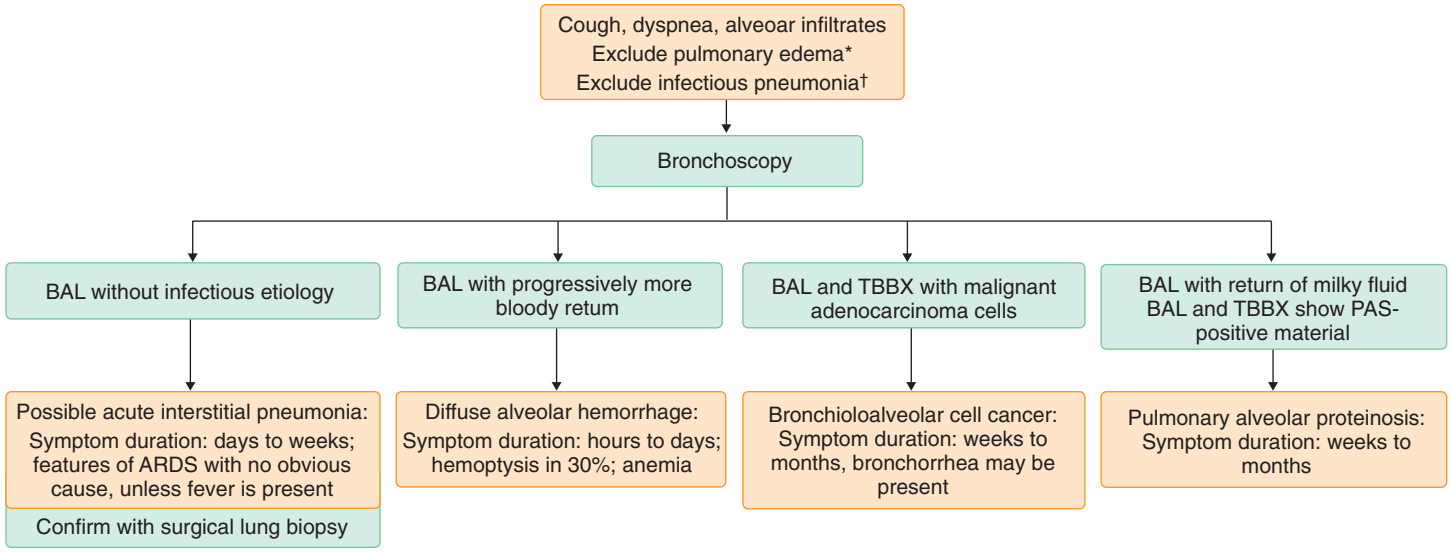

FIGURE 91-1. A general approach to the alveolar filling disorders. *See Chapter 58. †See Chapter 97. ARDS = acute respiratory distress syndrome; BAL = bronchoalveolar lavage; PAS = periodic acid–Schiff; TBBX = transbronchial biopsy.

incidence is estimated to be 3.7 cases per million people. Pulmonary alveolar proteinosis in adults is an acquired primary disorder in more than 90% of cases, but similar histopathologic features may be found with identifiable causes, such as acute silicosis (silicoproteinosis; Chapter 93), aluminum dust exposure (Chapter 93), immunodeficiency disorders (e.g., immunoglobulin G monoclonal gammopathy and severe combined immunodeficiency syndrome), hematologic malignant neoplasms (particularly myeloid leukemias; Chapters 189 and 190), and certain infections (e.g., *Pneumocystis* pneumonia). Pulmonary alveolar proteinosis has also been described after bone marrow transplantation (Chapter 181).

PATHOBIOLOGY

The pathogenesis of pulmonary alveolar proteinosis is related to impaired processing of surfactant by alveolar macrophages due to defects in granulocyte-macrophage colony-stimulating factor (GM-CSF) signaling. This impairment may be due to autoantibodies against GM-CSF or GM-CSF receptor gene mutations, but it is not thought to be due to a problem with GM-CSF production. An autosomal recessive congenital form of pulmonary alveolar proteinosis, caused by a mutation in the genes encoding surfactant protein B or C, results in abnormal surfactant function and severe respiratory distress in homozygous infants. The result of this impairment is accumulation of surfactant-rich material and progressive dysfunction in phagocytosis due to excessive production or diminished clearance of surfactant by alveolar macrophages.

Histologic examination in pulmonary alveolar proteinosis reveals alveoli filled with lipoproteinaceous material that stains pink (positive reaction) with periodic acid–Schiff stain. Classically, there is no destruction of alveolar architecture. Electron microscopy reveals lamellar (phospholipid-containing) myelin bodies.

CLINICAL MANIFESTATIONS

Pulmonary alveolar proteinosis presents in patients in the third to fourth decade with a 2:1 male predominance. Most patients (72%) are smokers. Patients present with the insidious onset of dyspnea and cough, which may be dry or occasionally productive of grayish material. The duration of symptoms before diagnosis is typically 6 weeks to 6 to 8 months. Low-grade fevers, malaise, and weight loss may also be present. Hemoptysis is unusual. On physical examination, rales are present in 50% of cases. Clubbing is an unusual finding until later stages of disease.

DIAGNOSIS

Mildly elevated leukocyte counts and mildly to moderately elevated lactate dehydrogenase levels may be found in more than 80% of patients; lactate dehydrogenase levels may correlate with the severity of disease. The chest radiograph (Fig. 91-2) and chest CT scans demonstrate a diffuse symmetrical alveolar filling process with predominance in the lower two thirds of the lung fields; the radiographic appearance may mimic pulmonary edema. The

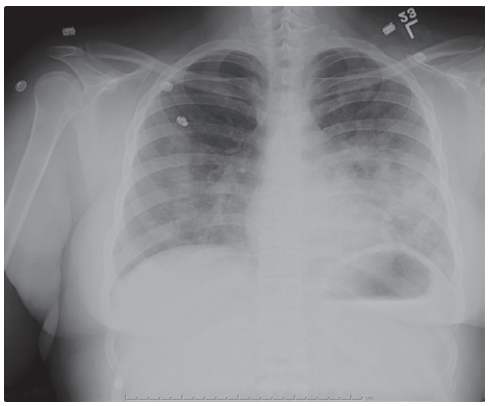

FIGURE 91-2. A chest radiograph showing bilateral alveolar infiltrates in a patient with pulmonary alveolar proteinosis.

characteristic CT pattern is often described as "crazy paving," which is due to scattered or diffuse areas of ground-glass attenuation with thickening of intralobular structures and interlobular septa in polygonal shapes (Fig. 91-3). This radiographic pattern is not specific for this disorder and can be seen with acute respiratory distress syndrome (ARDS; Chapter 104), *Pneumocystis jirovecii* pneumonia (Chapter 349), bronchioloalveolar cell carcinoma (Chapter 197), lipoid pneumonia (Chapter 94), sarcoidosis (Chapter 95), organizing pneumonia (Chapter 92), drug reactions, and pulmonary hemorrhage as well as with cardiogenic pulmonary edema (Chapter 59) and acute interstitial pneumonias. Pulmonary function tests often but not always show a restrictive pattern, with a reduced diffusing capacity. Arterial blood gas analyses reveal hypoxemia.

Bronchoscopy should be the initial procedure when pulmonary alveolar proteinosis is suspected. The diagnosis of pulmonary alveolar proteinosis can be established in most cases by the recovery of milky white to sandy-colored or light brown fluid on bronchoalveolar lavage. When it is subjected to microscopic analysis, the bronchoalveolar lavage fluid has a positive reaction on periodic acid–Schiff staining. Transbronchial biopsy or thoracoscopic biopsy can confirm the diagnosis by providing tissue that has similar staining characteristics.

TREATMENT

Rx

About 8 to 30% of cases of pulmonary alveolar proteinosis resolve spontaneously, and smoking cessation may contribute to spontaneous resolution. A second group of patients will progress to respiratory failure. The remainder will have stable disease. Superinfection with *Nocardia* species, atypical

mycobacteria, and other opportunistic organisms can occur in more than 15% of patients as a result of macrocyte phagocytic dysfunction.

Therapy begins with multistage or sequential whole lung lavage performed under general anesthesia with a double-lumen endotracheal tube. This procedure may have to be repeated at variable intervals. A small open-label trial using GM-CSF resulted in improved quality of life, oxygenation, pulmonary function, and exercise capacity in 48% of patients studied. Lung transplantation can be performed, but recurrent pulmonary alveolar proteinosis has been reported.

Survival rates at 5 years approach 75%.

TREATMENT Rx

Treatment includes supportive intensive care unit management. In small case series, corticosteroids at doses of 1 g of methylprednisolone intravenously per day for three consecutive days followed by prednisone or equivalent at 1 mg/kg/day with a taper during several weeks to months, with or without cyclophosphamide, may be of benefit, but mortality remains higher than 60% during the subsequent 6 months. Patients also can have recurrences in months to years. Some cases of acute interstitial pneumonia may resolve without sequelae, but in some series, more than 50% of survivors may be left with residual fibrosis.

ACUTE INTERSTITIAL PNEUMONIA

DEFINITION

Acute interstitial pneumonia, also referred to as the *Hamman-Rich syndrome*, is a rare and often fatal disease that mimics ARDS (Chapter 104). The etiology is unknown, and acute interstitial pneumonia is sometimes defined as the development of ARDS in the absence of known triggers. A similar acute presentation may be seen in patients with idiopathic pulmonary fibrosis (Chapter 92), but most investigators believe that acute interstitial pneumonia is a separate disease process.

PATHOBIOLOGY

The pathogenesis of acute interstitial pneumonia is damage to the epithelium of the alveolar membranes by a neutrophil-mediated mechanism; the result is pouring of exudate into the air space in the initial exudative phase of disease. Histologic examination reveals diffuse alveolar damage with intra-alveolar hyaline membrane formation, interstitial and intra-alveolar edema, acute inflammation, and epithelial cell necrosis with a nonspecific distribution and temporal uniformity. This process progresses to the organizing phase, characterized by alveolar septal thickening, type II pneumocyte hyperplasia, and fibroblast proliferation along the interstitium and alveolar spaces. In situ thrombi of small pulmonary arteries may be present. Finally comes a fibrotic phase with alveolar septal thickening from organizing fibrosis. One of the key pathologic findings in acute interstitial pneumonia is the temporal uniformity of the diffuse alveolar damage and of organizing and proliferating connective tissue. This uniformity supports a single acute injury at a particular point in time. Long-standing fibrosis is not a typical pathologic finding in acute interstitial pneumonia.

CLINICAL MANIFESTATIONS

Acute interstitial pneumonia manifests with equal frequency in men and women, typically in previously healthy individuals in the 50- to 55-year age range. It develops acutely to subacutely during a few days to a few weeks. The mean duration of symptoms is 15 days. Dry cough, shortness of breath, malaise, and fever (in 50% of patients) are typical clinical findings. A virus-like prodrome period has been described. Pulmonary rales are heard on physical examination, and hypoxemia is characteristic. Acute interstitial pneumonia often progresses to hypoxemic ventilatory failure, and intensive care unit admission with mechanical ventilation is usually required. Early mortality is high. Radiographic features of acute interstitial pneumonia are diffuse alveolar infiltrates and air space consolidation similar to the appearance of ARDS; CT scans reveal bilateral air space consolidation with areas of ground-glass opacities with little honeycombing. Septal thickening and a subpleural distribution of the opacities may also be present.

DIAGNOSIS

The diagnosis of acute interstitial pneumonia is made in the appropriate clinical setting in a patient who has a clinical presentation compatible with ARDS but without a clear etiology. The differential diagnosis histologically and clinically includes other causes of ARDS (Chapter 104), such as severe infection, trauma, and sepsis, and other causes of acute lung injury (Chapter 94), such as drug toxicity, inhalation injury, and collagen vascular diseases. The presentation is clinically and radiographically similar to that of diffuse alveolar hemorrhage, acute hypersensitivity pneumonitis, acute exacerbation of pulmonary fibrosis, acute eosinophilic pneumonia, and cryptogenic organizing pneumonia. Bronchoscopy with bronchoalveolar lavage is often performed to exclude alveolar hemorrhage, eosinophilic pneumonias, and infectious causes of lung injury. In a small number of cases, transbronchial biopsy may yield the diagnosis, but definitive diagnosis in most cases of acute interstitial pneumonia requires a surgical lung biopsy.

DIFFUSE ALVEOLAR HEMORRHAGE

DEFINITION

The alveolar hemorrhage syndromes cause alveolar filling disease, usually with an acute onset and often with life-threatening severity. They can be associated with vasculitides, such as microscopic polyangiitis (Chapter 278) and c-ANCA-associated (Wegener's) vasculitis (Chapter 278); immunologic diseases, such as Goodpasture's syndrome (anti–glomerular basement membrane antibody disease; Chapter 123); collagen vascular diseases, such as systemic lupus erythematosus (Chapter 274); cocaine inhalation (Chapter 33); drugs (including penicillamine, mitomycin C, trimellitic anhydride, all-*trans* retinoic acid, propylthiouracil, and isocyanates); bone marrow transplantation (Chapter 181); coagulopathy (Chapter 177); and mitral stenosis (Chapter 75). A small percentage of idiopathic and recurrent cases are termed *idiopathic pulmonary hemosiderosis*. In Goodpasture's syndrome, there is a strong association with tobacco use and a male predominance, with young men most frequently affected. A viral syndrome and exposure to hydrocarbons may simulate Goodpasture's disease. Idiopathic pulmonary hemosiderosis most often occurs in children and young adults.

PATHOBIOLOGY

Alveolar hemorrhage is caused by bleeding from the pulmonary microcirculation, including the capillaries, arterioles, and venules. It may be associated with injury or neutrophilic inflammation of the capillaries or a capillaritis, usually when it is associated with collagen vascular or vasculitic processes. In Goodpasture's syndrome, for example, the circulating anti–glomerular basement membrane antibodies are directed against the α_3 chain of type IV collagen in the glomerular basement membrane, where they cause glomerulonephritis; these core antibodies can cross-react with the alveolar capillary basement membranes, resulting in alveolar hemorrhage. Alternatively, alveolar hemorrhage may be associated with relatively bland pathologic changes with red blood cells in the alveolar spaces. Idiopathic pulmonary hemosiderosis is an example of bland hemorrhage.

CLINICAL MANIFESTATIONS

Patients present acutely (usually in hours to a week) with dyspnea, shortness of breath, hemoptysis (which may not be present in all patients), and cough. Some patients also have low-grade fever. Lung examination reveals rales.

Laboratory examination may reveal anemia. In Goodpasture's syndrome and the ANCA-associated vasculitides, hematuria and renal insufficiency due to glomerulonephritis are typically present.

Radiographic features include the acute development of bilateral alveolar filling disease similar to pulmonary edema but without cardiomegaly or pleural effusions. Rapid remission and recurrences are seen with repeated episodes of bleeding, which also may result in chronic interstitial changes on the chest radiograph. Pulmonary function testing may reveal an increase in the diffusion capacity for carbon monoxide because of the presence of hemoglobin in the alveolar spaces.

DIAGNOSIS

The diagnosis of alveolar hemorrhage is usually made in the appropriate clinical setting by the triad of diffuse alveolar infiltrates (see Fig. 91-3), hemoptysis (in two thirds of patients), and anemia. Bronchoalveolar lavage typically demonstrates the return of progressively more bloody aliquots of fluid, and cytologic analysis reveals that more than 20% of the macrophages are hemosiderin laden. Goodpasture's syndrome is diagnosed by circulating anti–glomerular basement membrane antibodies, which are present in more than 90% of patients, or by the demonstration of linear deposition

FIGURE 91-3. A chest computed tomographic scan showing the "crazy paving" pattern characteristic of pulmonary alveolar proteinosis.

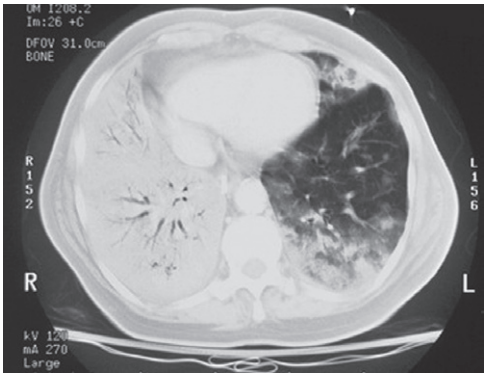

FIGURE 91-4. A chest computed tomographic scan in a patient with bronchioloalveolar cell cancer revealing the pneumonic form of the disease.

of immunoglobulin G antibodies along the alveolar or renal capillary basement membrane tissue when it is viewed by direct immunofluorescence. c-ANCA-associated vasculitis causes a focal, segmental, necrotizing glomerulonephritis and is associated with the presence of proteinase 3 antineutrophilic cytoplasmic antibodies in 90% of active cases (Chapter 278). Necrotizing granulomatous inflammation is often found in the upper airway in addition to the lungs and kidneys. A perinuclear myeloperoxidase antineutrophilic antibody is often present in association with microscopic polyarteritis (Chapter 278). Patients with systemic lupus erythematosus usually have antinuclear antibodies (Chapter 274). Idiopathic pulmonary hemosiderosis is a diagnosis of exclusion after other causes of diffuse alveolar hemorrhage have been eliminated.

TREATMENT

Rx

Treatment of alveolar hemorrhage varies according to its underlying cause. Massive hemoptysis from any cause of alveolar hemorrhage should be managed as needed. In the case of drug- or toxin-related alveolar hemorrhage, the offending agent should be withdrawn, and supportive care is indicated. In Goodpasture's syndrome, the ANCA-associated vasculitides, and other vasculitides (Chapter 278), treatment typically includes immunosuppressant agents such as corticosteroids (methylprednisolone, 500 to 2000 mg/day in divided doses for 3 to 5 days followed by a prednisone taper beginning at 1 mg/kg/day during the next 6 to 9 months) and cyclophosphamide (2 mg/kg/day orally or 0.75 g/m^2 intravenously for one dose). In Goodpasture's syndrome, plasmapheresis is also a mainstay of therapy to remove the offending circulating antibody. Plasmapheresis (3 to 14 exchanges) may also be used in some cases of alveolar hemorrhage from ANCA-associated vasculitis and systemic lupus erythematosus.

PROGNOSIS

Recurrent alveolar hemorrhage from any cause, such as idiopathic pulmonary hemosiderosis, can be associated with the development of pulmonary fibrosis. Alveolar hemorrhage related to collagen vascular disease, vasculitides, and idiopathic pulmonary hemosiderosis can have mortality rates ranging from 25 to 50%. With Goodpasture's syndrome, renal failure is common, and the degree of renal impairment may correlate with outcome.

BRONCHIOLOALVEOLAR CELL CARCINOMA

DEFINITION

Bronchioloalveolar cell carcinoma, which is a subtype of bronchogenic adenocarcinoma, is characterized by well-differentiated, malignant cells lining the alveolar cell wall (Chapter 197). Of bronchogenic carcinomas, bronchioloalveolar cell carcinoma is the least strongly associated with tobacco use, and patients are more likely to be nonsmokers. Unlike other non–small cell lung cancers, the female-to-male ratio approaches 1:1, and younger patients may be affected. Using the strict pathologic definition described later, the prevalence of bronchioloalveolar carcinoma among the non–small cell carcinomas is less than 5%.

PATHOBIOLOGY

Bronchioloalveolar cell carcinoma usually arises in the periphery of the lung and is characterized by pure lepidic growth, which means contiguous growth along the intact alveolar septa, without stromal, pleural, vascular, or lymphatic invasion and without a known primary adenocarcinoma elsewhere. Bronchioloalveolar cell carcinoma can be categorized into mucinous and nonmucinous forms histologically; the mucinous type is thought to derive from respiratory goblet cells, and the nonmucinous type from type II pneumocytes or Clara cells.

CLINICAL MANIFESTATIONS

Patients present with the gradual onset of shortness of breath and cough. The duration of symptoms is usually several months. Constitutional symptoms such as malaise and weight loss may be present. An unusual but unique clinical finding is bronchorrhea, with patients reporting the production of copious amounts of clear sputum daily. This finding is more common in the pneumonic form of disease. Nodal involvement and extrathoracic metastases are less frequent than in other forms of non–small cell lung cancer.

DIAGNOSIS

Radiographic patterns vary and can include localized disease with peripheral solitary or multiple nodules or masses in 60% of cases or a persistent pneumonic pattern in 40% of cases (Fig. 91-4). The radiographic findings are often thought to be consistent with pneumonia, and a typical clinical presentation is that of a nonresolving peripheral density on chest radiograph. In addition, computed tomography may show areas of ground-glass attenuation. Positron emission tomography may be normal because of the low glucose uptake of this lesion. The diagnosis of bronchioloalveolar cell carcinoma is most often made by bronchoscopy with transbronchial biopsy.

TREATMENT

Rx

For staging and treatment, bronchioloalveolar cell carcinoma is approached like other types of non–small cell lung cancers (Chapter 197), although bronchioloalveolar carcinoma may respond to epidermal growth factor receptor (EGFR) agents. Bilateral lung transplantation has been performed, but recurrence in the transplanted lungs has been reported.

PROGNOSIS

Prognosis correlates with disease stage and probably with the histologic and radiographic patterns. Patients with a single focus of disease (i.e., a solitary nodule) who undergo surgical resection have a prognosis better than that of patients with nonbronchioloalveolar adenocarcinomas of like stage. Multinodular, pneumonic, and diffuse forms of disease have a worse prognosis, as does the mucinous histologic subtype.

INTERSTITIAL LUNG DISEASE

GANESH RAGHU

DEFINITION

In an apparently immunocompetent host, interstitial lung disease (ILD) is a clinical term for a heterogenous group of lower respiratory tract disorders with many potential causes. However, clinical and physiologic features common to all ILDs include exertional dyspnea, a restrictive pattern on pulmonary function testing (Chapter 85), coexistent airflow obstruction, decreased diffusing capacity (D_{LCO}), increased alveolar-arterial oxygen difference (P_{AO_2}-P_{aO_2}) (Chapter 103) at rest or during exertion, and absence of pulmonary infection or neoplasm. ILDs comprise several acute and chronic lung disorders with variable degrees of pulmonary fibrosis (Table 92-1). The term *interstitial* is a misnomer because the pathologic processes are not restricted to the interstitium, which is the microscopic space bounded by the basement membranes of epithelial and endothelial cells. Rather, all of the several cellular and soluble constituents that make up the gas exchange units (alveolar wall, capillaries, alveolar space, and acini) and the bronchiolar lumen, terminal bronchioles, and pulmonary parenchyma beyond the gas exchange units (as well as the pleura, lymphatics, and sometimes the lymph nodes) are involved in the pathogenesis and manifestations of ILD.

EPIDEMIOLOGY

Among persons 18 years or older, the prevalence of all ILDs in the United States is about 81 per 100,000 men and 67 per 100,000 women. The overall incidence is also higher in men (31.5 per 100,000 per year) than in women (26.1 per 100,000 per year). Moreover, the prevalence of undiagnosed or early ILD is estimated to be 10 times that of clinically recognized disease; as physicians' awareness of these entities increases, it is expected that the frequency of the diagnosis of ILD will rise. Among the ILDs, the most common is idiopathic pulmonary fibrosis, which represents at least 30% of incident cases; in the United States, its annual incidence is estimated to be 6.8 to 16.3 per 100,000, with a prevalence of 14.0 to 42.7 per 100,000.

PATHOBIOLOGY

ILDs are thought to result from an unknown tissue injury and attempted repair in the lung of a genetically predisposed person. Genetic variants within the *hTERT* or *hTR* components of the telomerase gene and surfactant protein gene have been associated in a subset of familial pulmonary fibrosis and in some sporadic cases. An *MUC5B* promotor polymorphism is associated with familial interstitial pneumonia and idiopathic pulmonary fibrosis.

In *idiopathic pulmonary fibrosis,* varying degrees of acute, subacute, and chronic fibroproliferation are present in the lungs at the time of diagnosis. Ultimately, progressive fibrosis results in honeycombing, an end-stage finding that is often associated with increased pulmonary vascular resistance and secondary pulmonary hypertension. As a reflection of these dynamic processes, histopathologic examination of lung tissue often reveals highly heterogeneous findings; for example, a single biopsy specimen may show normal alveoli adjacent to abnormal areas of inflammation and fibrosis, with or without granulomas, vasculitis, or secondary vascular changes within the pulmonary parenchyma.

CLINICAL MANIFESTATIONS

ILDs are typically characterized by progressive dyspnea. Nonproductive cough and fatigue are also common complaints. Pleuritic chest pain may occur with certain collagen vascular or drug-induced ILDs, whereas acute pleuritic chest pain with dyspnea may represent a spontaneous pneumothorax (Chapter 99) in association with lymphangioleiomyomatosis, tuberous sclerosis (Chapter 426), neurofibromatosis, or Langerhans cell histiocytosis. Hemoptysis suggests a diffuse alveolar hemorrhagic syndrome, systemic lupus erythematosus (Chapter 274), lymphangioleiomyomatosis, Wegener's granulomatosis (Chapter 283), or Goodpasture's syndrome (Chapter 123); it is rare in other ILDs. In patients with existing ILD, new hemoptysis should prompt consideration of a superimposed malignancy, pulmonary embolus, or infection such as aspergillosis.

In some patients, the first and the only clue to the presence of an ILD may be the finding of coarse rales (crackles) on auscultation of the lungs. These coarse crackles must be distinguished from the finer rales typical of heart failure (Chapter 58) or noncardiogenic pulmonary edema (Chapter 104). Unlike patients with obstructive lung disease, wheezes are not common. A history of wheezing suggests the coexistence of occult hyperactive airways and airflow obstruction and raises the possibility of allergic bronchopulmonary aspergillosis (Chapter 347), Churg-Strauss syndrome (Chapter 278), chronic eosinophilic pneumonia (see later), or parasitic infection (Chapter 352). In some patients, the initial presentation may be with peripheral

cyanosis, clubbing, or the signs and symptoms of an underlying systemic disease (see later).

DIAGNOSIS

The first key in patients with an ILD is to establish the syndromic diagnosis and then pursue the differential diagnosis of its specific cause (Fig. 92-1). However, a conclusive cause often may not be identified despite an exhaustive medical history and invasive diagnostic interventions, including sufficiently large and multiple lung biopsy specimens. Thus, the cause of several of the ILDs, even when diagnosed as specific entities, remains unknown.

History

The patient's age, sex, and cigarette smoking history may provide useful clues to the diagnosis. Idiopathic pulmonary fibrosis is an adult disorder that usually occurs in patients older than 50 years. Pulmonary sarcoidosis (Chapter 95), in contrast, is more common in young adults and middle-aged persons. Pulmonary Langerhans cell histiocytosis (previously known as pulmonary histiocytosis X or eosinophilic granuloma) characteristically occurs in young cigarette-smoking men, whereas lymphangioleiomyomatosis occurs exclusively in women of childbearing age. Respiratory bronchiolitis-associated interstitial lung disease is seen almost exclusively in cigarette smokers but occurs in both men and women of all ages.

The medical history also should focus on environmental factors, especially changes in environmental exposure (domestic, recreational, hot tub, whirlpool baths, indoor swimming pool, ventilation system at home, automobiles, and workplace), occupational exposure, medications, and drug use (Chapters 93 and 94). A family medical history should address possible familial ILD. Environmental risk factors that may suggest the diagnosis of hypersensitivity pneumonitis include farming or exposure to avian antigens ("bird fancier's lung" or "pigeon breeder's lung"), visible molds, water leaks, or humidifiers in the domestic environment (hypersensitivity to thermophilic actinomycetes). Other at-risk occupations include mining (pneumoconioses), machine tool grinding, sandblasting and working with granite (silicosis), welding and working in a shipyard (asbestosis), and working in the aerospace or electronic industries (berylliosis) (Chapters 93 and 94). Because of the long interval between the exposure and the onset of symptoms in many occupations associated with ILD, it is important to take a lifelong occupational history (Chapter 18) as well as to establish the interval between exposure and the onset of symptoms. Because the list of medications known to cause ILD is long and continues to grow (Table 92-2), a careful history regarding recent use of prescription and over-the-counter products is essential. Risk factors for immunosuppression, including infection with human immunodeficiency virus, raise the possibility of opportunistic lung infections (Chapter 398), neoplasm (Chapter 197), and transplant-related pulmonary complications.

Particular attention should be paid to the onset and duration of symptoms, the rate of disease progression, and association with hemoptysis, fever, or extrathoracic symptoms. Symptoms that persist 4 weeks or less and the presence of fever suggest cryptogenic organizing pneumonia, drug-induced pulmonary injury, or acute hypersensitivity pneumonitis, whereas idiopathic pulmonary fibrosis, ILD associated with connective tissue diseases, and Langerhans cell histiocytosis tend to have a more subacute onset. Extrapulmonary symptoms suggests that the ILD may be associated with systemic disorders (e.g., sarcoidosis; Chapter 95), and symptoms such as dysphagia, dry eyes or mouth, skin rashes, or arthritis may suggest a collagen vascular disorder (Chapters 274 and 278). Proximal muscle aches or weakness suggests the possibility of polymyositis or dermatomyositis (Chapter 277), and recurrent sinusitis suggests Wegener's granulomatosis (Chapter 278). Extrathoracic manifestations present in tuberous sclerosis (Chapter 426) include hematuria, epilepsy, and mental retardation.

Physical Examination

Physical examination of the respiratory system is rarely helpful in the diagnostic evaluation of ILD because findings such rhonchi and rales on auscultation and digital clubbing are nonspecific. Findings on cardiac examination, such as an accentuated P_2, a right ventricular heave, or tricuspid insufficiency, are suggestive of pulmonary hypertension (Chapter 68) and cor pulmonale in patients with advanced lung disease. However, extrathoracic findings such as skin abnormalities, peripheral lymphadenopathy, and hepatosplenomegaly may be more specifically associated with underlying sarcoidosis (Chapter 95); muscle tenderness and proximal muscle weakness may point to coexisting polymyositis (Chapter 277); and signs of arthritis may indicate collagen vascular disease (Chapters 272, 274, and 278) or sarcoidosis (Chapter 95).

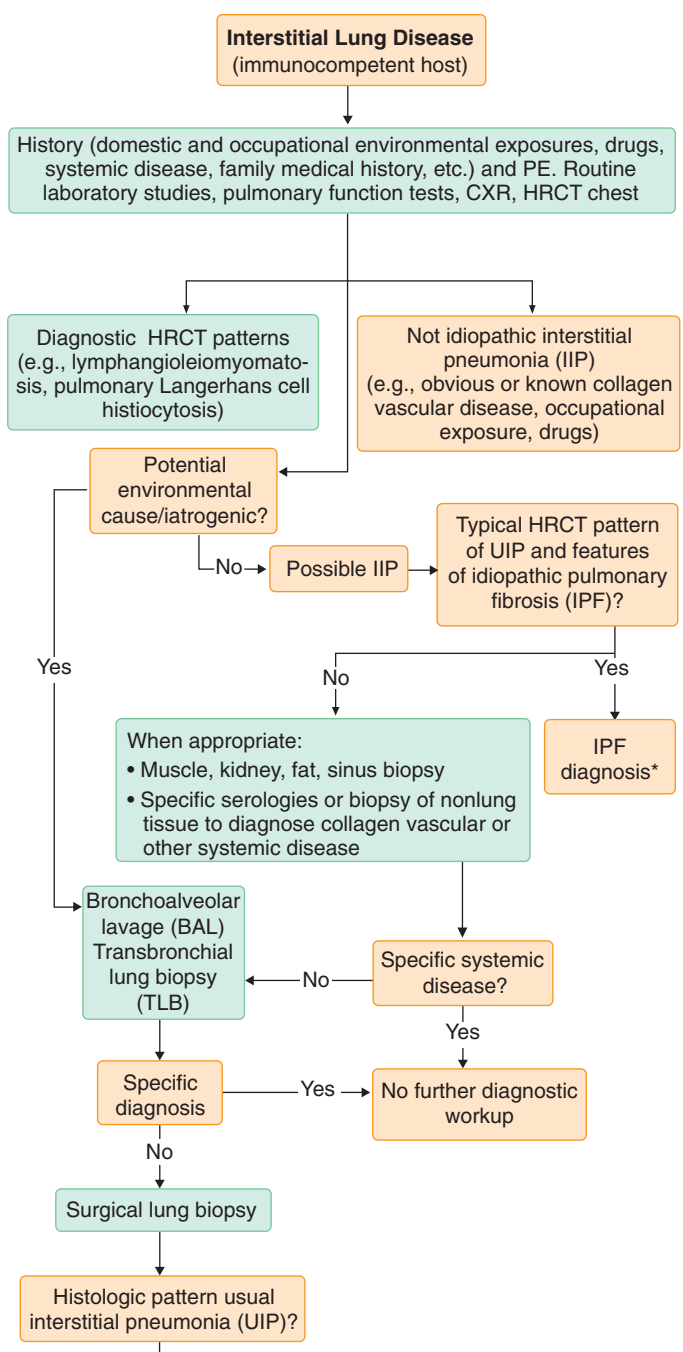

FIGURE 92-1. An approach to interstitial lung disease. DAD = diffuse alveolar damage; DIP = desquamative interstitial pneumonia; HRCT = high-resolution computed tomography; LIP = lymphoid interstitial pneumonia; NSIP = nonspecific interstitial pneumonia; OP = organizing pneumonia; PE = physical examination; RB-ILD = respiratory bronchiolitis–associated interstitial lung disease; UIP = usual interstitial pneumonia. *Adapted from American Thoracic Society/European Respiratory Society: International multidisciplinary consensus classification of idiopathic interstitial pneumonias. *Am J Respir Crit Care Med.* 2002;165:277-304 and Raghu G, Collard HR, Egan JJ, et al. An official ATS/ERS/JRS/ALAT statement: idiopathic pulmonary fibrosis: evidence-based guidelines for diagnosis and management. *Am J Respir Crit Care Med.* 2011;183:788-824.

Characteristic rashes occur in several collagen vascular diseases, disseminated Langerhans cell histiocytosis, tuberous sclerosis, and neurofibromatosis. Ophthalmologic findings (Chapter 431) such as iridocyclitis, uveitis, or conjunctivitis may be a clue to the diagnosis of sarcoidosis or a collagen vascular disease, whereas central nervous system abnormalities may be present in sarcoidosis, systemic lupus erythematosus, Langerhans cell histiocytosis, or tuberous sclerosis.

Laboratory Testing

Routine laboratory testing should include a complete blood count, leukocyte differential, erythrocyte sedimentation rate, chemistry panel (calcium, liver enzymes, electrolytes, creatinine), and urinalysis. Although these data rarely yield a specific diagnosis, they may provide helpful clues. When appropriate, patients should be screened for systemic lupus erythematosus (e.g., antinuclear antibodies), rheumatoid arthritis (rheumatoid factor, anticitrullinated peptide antibody), scleroderma (ScL 70), dermatomyositis or polymyositis (creatine kinase, aldolase, and anti-Jo-1 antibody), Wegener's granulomatosis (antineutrophil cytoplasmic antibodies), and Goodpasture's syndrome (anti–basement membrane antibodies).

Mild hypoxemia is typically present on arterial blood gas analysis because of abnormal ventilation-perfusion ratios, especially in moderate to severe cases of ILD. However, carbon dioxide retention is rare and suggests possible coexisting emphysema (Chapter 88) or a hypoventilatory disorder (Chapter 86).

Noninvasive Evaluation

Chest Radiograph

The distribution and appearance of radiographic abnormalities (Chapter 84) may prove useful in differentiating the clinicopathologic syndromes in patients with ILD (Table 92-3). Comparison of previous chest radiographs with the current one is important in establishing the rate of progression of the patient's disease. A diffuse ground-glass pattern is often observed early in the course of ILD, followed by progression to reticular (linear) infiltrates with nodules (reticulonodular infiltrates) or, in the case of alveolar filling disorders, ill-defined nodules (acinar rosettes) with air bronchograms. Most ILDs cause infiltrates in the lower lung zones, but upper lobe predominance is typically present in sarcoidosis, berylliosis, Langerhans cell histiocytosis, silicosis, chronic hypersensitivity pneumonitis, cystic fibrosis, and ankylosing spondylitis, whereas the middle and lower lung zones show the most prominent abnormalities in lymphangitic carcinomatosis, idiopathic pulmonary fibrosis, subacute eosinophilic pneumonia, asbestosis, and pulmonary fibrosis caused by rheumatoid arthritis or progressive systemic sclerosis. Hilar adenopathy and mediastinal adenopathy are not common in ILDs; their presence should suggest sarcoidosis, berylliosis, silicosis, lymphocytic interstitial pneumonia, amyloidosis, or Gaucher's disease. A pattern of peripherally located pulmonary infiltrates in the upper and middle lung zones with relatively clear perihilar and central zones is a clue to chronic eosinophilic pneumonia. Recurrent infiltrates raise the possibility of cryptogenic organizing pneumonia, chronic eosinophilic pneumonia, or drug- or radiation-induced pneumonitis, whereas fleeting or migratory infiltrates may occur in Churg-Strauss syndrome (allergic angiitis), allergic bronchopulmonary aspergillosis, tropical eosinophilic pneumonia, or Löffler's syndrome. Localized pleural plaques may indicate asbestosis, whereas diffuse pleural thickening can result from asbestosis, rheumatoid arthritis, progressive systemic sclerosis, radiation pneumonitis, nitrofurantoin, or malignancy. In the absence of left ventricular failure, the presence of a pleural effusion (Chapter 99) raises the possibility of rheumatoid arthritis, systemic lupus erythematosus, acute hypersensitivity pneumonitis, sarcoidosis, asbestosis, amyloidosis, lymphangioleiomyomatosis, or lymphangitic carcinomatosis. Reduction of lung volumes is typical in most ILDs; the presence of preserved lung volumes or hyperinflation should raise suspicion for chronic hypersensitivity pneumonitis, Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, sarcoidosis, or tuberous sclerosis. However, plain chest radiographs may be normal in about 10% of patients with ILD.

High-Resolution Computed Tomography

Because of its increased sensitivity and ability to distinguish ground-glass changes, which are generally considered to be reversible areas of lung disease, from irreversible fibrotic and honeycomb changes, high-resolution computed tomography (HRCT) is essential in both the diagnosis and staging of ILD. Although microscopic ILD cannot be excluded by a normal HRCT, HRCT allows recognition of abnormalities not apparent in plain chest radiographs and may lead to an earlier diagnosis, help narrow the differential diagnosis patterns (Table 92-4), aid in selecting the site or sites for bronchoalveolar lavage and lung biopsy, and assist in choosing among therapeutic options and in estimating the response to treatment. The presence of patchy subpleural reticular and basilar septal fibrosis, traction bronchiectasis, and honeycombing increases the level of diagnostic confidence for the pattern of usual interstitial pattern, which is characteristic of idiopathic pulmonary fibrosis. The finding of bilateral cysts, including their size, configuration, distribution, and appearance, helps differentiate among lymphangioleiomyomatosis, tuberous sclerosis, and pulmonary Langerhans cell histiocytosis. HRCT can detect ILD despite normal chest radiographs in patients with asbestosis, silicosis, sarcoidosis, and scleroderma. Patients with respiratory bronchiolitis-associated interstitial lung disease typically have patchy ground-glass

TABLE 92-3 CHARACTERISTIC CHEST RADIOGRAPHIC PATTERNS IN PATIENTS WITH INTERSTITIAL LUNG DISEASE

PATTERN	SUGGESTED DIAGNOSES*
Decreased lung volumes	Idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia, desquamative interstitial pneumonia, collagen vascular disease, chronic eosinophilic pneumonia, asbestosis, chronic hypersensitivity pneumonitis, or drug-induced interstitial lung disease (ILD)
Increased or preserved lung volumes	Idiopathic pulmonary fibrosis with emphysema, respiratory bronchiolitis-associated ILD, cryptogenic organizing pneumonia, hypersensitivity pneumonitis, lymphangioleiomyomatosis, Langerhans cell histiocytosis, sarcoidosis, neurofibromatosis, tuberous sclerosis
Micronodules	Infection, hypersensitivity pneumonitis, sarcoidosis, respiratory bronchiolitis-associated ILD
Septal thickening	Malignancy, infection, chronic congestive heart failure, pulmonary veno-occlusive disease
Honeycombing	Idiopathic pulmonary fibrosis, fibrotic nonspecific interstitial pneumonia, collagen vascular disease, asbestosis, chronic hypersensitivity pneumonitis, sarcoidosis
Recurrent infiltrates	Cryptogenic organizing pneumonia, chronic eosinophilic pneumonia, drug- or radiation-induced ILD
Migratory or fleeting infiltrates	Cryptogenic organizing pneumonia, hypersensitivity pneumonitis, Churg-Strauss syndrome, Löffler's syndrome, allergic bronchopulmonary aspergillosis
Pleural disease	Collagen vascular disease, asbestosis, malignancy, radiation-induced ILD, amyloidosis, sarcoidosis, lymphangioleiomyomatosis, nitrofurantoin-induced ILD
Pneumothorax	Langerhans cell histiocytosis, lymphangioleiomyomatosis, tuberous sclerosis, neurofibromatosis
Mediastinal and/or hilar adenopathy	Lymphocytic interstitial pneumonia, collagen vascular disease, silicosis, chronic berylliosis, malignancy, infection, sarcoidosis, amyloidosis, Gaucher's disease
Normal (rare)	Cellular nonspecific interstitial pneumonia, respiratory bronchiolitis–associated interstitial lung disease, collagen vascular disease, hypersensitivity pneumonitis, sarcoidosis
LOCATION OF RADIOGRAPHIC ABNORMALITY	**SUGGESTED DIAGNOSES***
Mid to upper lung zone	Hypersensitivity pneumonitis, chronic berylliosis, ankylosing spondylitis, silicosis, Langerhans cell histiocytosis, sarcoidosis, cystic fibrosis
Lower lung zone	Idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia (fibrotic), collagen vascular disease, asbestosis, chronic hypersensitivity pneumonitis
Peripheral	Idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia (fibrotic), cryptogenic organizing pneumonia, chronic eosinophilic pneumonia

TABLE 92-4 RADIOGRAPHIC FEATURES OF IDIOPATHIC INTERSTITIAL PNEUMONIAS

CLINICAL DIAGNOSIS	USUAL RADIOGRAPHIC FEATURES	TYPICAL FINDINGS ON HRCT
Idiopathic pulmonary fibrosis	Basal-predominant reticulation abnormality with volume loss	Peripheral, basal, subpleural reticulation with honeycombing, traction bronchiectasis, and focal ground-glass attenuation
Nonspecific interstitial pneumonia	Ground-glass and reticular opacification	Peripheral, basal, subpleural, symmetrical ground-glass attenuation with irregular lines and consolidation
Cryptogenic organizing pneumonia	Patchy bilateral consolidation	Subpleural or peribronchial patchy consolidation and/or nodules
Acute interstitial pneumonia	Diffuse ground-glass density/consolidation	Diffuse consolidation and ground-glass opacification, often with lobular sparing and late traction bronchiectasis
Desquamative interstitial pneumonia	Ground-glass opacity	Peripheral, lower lung zone ground-glass attenuation with reticulation and/or small cysts
Respiratory bronchiolitis-associated interstitial lung disease	Bronchial wall thickening, ground-glass opacification	Diffuse bronchial wall thickening with poorly defined centrilobular nodules and patchy ground-glass opacification
Lymphocytic interstitial pneumonia	Reticular opacities and nodules	Diffuse centrilobular nodules, ground-glass attenuation, septal and bronchovascular wall thickening, and thin-walled cysts

HRCT = high-resolution computed tomography.

attenuation on HRCT in concert with bilateral interstitial prominence, fine nodular radiographic infiltrates, and normal lung volumes. Images obtained in the supine and prone positions and on deep inspiration and exhalation sometimes help to differentiate fibrosis from atelectasis.

Pulmonary Function Tests

The most characteristic physiologic abnormalities in patients with ILD, regardless of etiology, are a restrictive lung defect and decreased D_{LCO} (Chapter 85). Forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) are decreased proportionally such that the ratio of the two remains normal or may even be increased. Both total lung capacity and lung volumes measured by body plethysmography are reduced. Pulmonary function tests (PFTs) may be useful in monitoring the progression of disease and prognosis; significant changes in FVC, D_{LCO} (corrected to hemoglobin), and physiologic measurements (FVC, D_{LCO}) at 1 year portend a worse survival in patients with idiopathic pulmonary fibrosis.

Certain PFT findings may also aid in the differential diagnosis. A mixed obstructive-restrictive pattern occurs in patients with Churg-Strauss syndrome, allergic bronchopulmonary aspergillosis, endobronchial sarcoidosis, hypersensitivity pneumonitis, cryptogenic organizing pneumonia, tropical pulmonary interstitial eosinophilia, coexisting chronic obstructive pulmonary disease or asthma, or secondary bronchiectasis. Diseases associated with respiratory muscle weakness, such as polymyositis, progressive systemic sclerosis, and systemic lupus erythematosus, may exhibit a decrease in maximal voluntary ventilation and increased residual volume out of proportion to the decrease in FEV_1.

Exercise Testing

The magnitude of the increase in P_{AO_2}-P_{aO_2} on exercise correlates well with the severity of disease and the degree of pulmonary fibrosis in patients with idiopathic pulmonary fibrosis. Other exercise-induced physiologic abnormalities in ILD include a decrease in work rate and maximal oxygen consumption, abnormally high minute ventilation at submaximal work rates, decreased peak minute ventilation, and failure of tidal volumes to increase at submaximal levels of work while the respiratory rate increases disproportionately. The 6-minute walk test, performed on a flat surface, can provide quantitative data on exercise capacity and oxygen desaturation with exercise.

Invasive Evaluation

A collegial interaction and multidisciplinary discussions among the pulmonary clinician, chest radiologist, thoracic surgeon, and pathologist can help determine the best diagnostic approach for an individual patient (see Fig. 92-1).

Findings on bronchoalveolar lavage (BAL) can be diagnostic in some patients with ILD and can narrow the differential diagnosis in others (see Table 85-3 in Chapter 85). For example, a lymphocyte-predominant cellular pattern raises the possibility of sarcoidosis or hypersensitivity pneumonitis in the appropriate clinical setting. Eosinophils are seen in pulmonary Langerhans cell granulomatosis, an asbestos body count greater than 1 fiber per milliliter of BAL fluid is seen in asbestosis, and specially staining surfactant material is seen in pulmonary alveolar proteinosis. A transbronchial lung biopsy may reveal noncaseating granulomas in sarcoidosis, "loose" noncaseating granulomas in hypersensitivity pneumonitis, giant cell granulomas in hard metal pneumoconiosis, or smooth muscle proliferation in lymphangioleiomyomatosis. However, failure to establish a diagnosis on BAL and transbronchial lung biopsy does not exclude these entities.

Video-assisted thoracoscopic biopsy (Chapter 101) or open lung biopsy may be required to obtain an adequate sample for histologic evaluation of a patient with unexplained signs and symptoms when other studies have failed to establish a diagnosis, but most patients with idiopathic pulmonary fibrosis do not need to have a biopsy to confirm the diagnosis. The mortality rate for the procedure is generally less than 1%, and the morbidity is less than 3%.

TREATMENT

Rx

When the cause of the ILD is clearly known (e.g., acute or subacute hypersensitivity pneumonitis, occupational ILD, iatrogenic), further avoidance of the inciting agent or agents is essential (Chapter 93). Although systemic corticosteroids are generally indicated and are associated with a favorable response in some ILDs, the dosage and duration are unclear and essentially based on anecdotal experience (Table 92-5).

Supportive oxygen supplementation is dictated by clinical needs. For selected patients with end-stage ILDs, such as those associated with significant pulmonary fibrosis and pulmonary hypertension, lung transplantation (Chapter 101) may be a feasible and viable option. Treatments for pulmonary hypertension (Chapter 68) are generally recommended, although their utility for ILD patients is unproved.

TABLE 92-5 INTERSTITIAL LUNG DISEASE: CLINICAL RESPONSE TO SYSTEMIC CORTICOSTEROIDS ALONE*

GENERALLY RESPONSIVE	UNRESPONSIVE†
Sarcoidosis	Idiopathic interstitial pneumonia
Acute hypersensitivity pneumonitis	Idiopathic pulmonary fibrosis (usual interstitial pneumonia)
Drug induced	Desquamative interstitial pneumonia (subset)
Environmental causes (some)	Chronic secondary and advanced pulmonary fibrosis
Idiopathic interstitial pneumonia	Chronic hypersensitivity pneumonitis (subset)
Cryptogenic organizing pneumonia	Chronic radiation fibrosis
Nonspecific interstitial pneumonia (cellular)	Cryptogenic organizing pneumonia (subset)
Respiratory bronchiolitis-associated ILD	Acute interstitial pneumonia (?)
Lymphocytic interstitial pneumonia	Chronic pulmonary hemorrhage syndromes
Desquamative interstitial pneumonia (subset)	Pulmonary veno-occlusive disease
Acute interstitial pneumonia (?)	Environmental (e.g., asbestosis, pneumoconiosis)
Acute pulmonary capillaritis	End-stage ILDs, pulmonary fibrosis coexisting or associated with pulmonary hypertension
Eosinophilic pneumonia (acute and chronic)	Pulmonary Langerhans cell granulomatosis
Acute radiation pneumonitis‡	Lymphangioleiomyomatosis
Organizing pneumonia associated with collagen vascular diseases	ILD in inherited disorders (?)

*The dosage plus duration of corticosteroids used is variable and based on anecdotal experience, individual expert opinion, clinical judgment, and response as judged by objective measurements (clinical, radiologic, and/or physiologic). Oral prednisone/prednisolone is the most common corticosteroid used. Most patients who respond during the first few weeks of 20 to 60 mg of prednisone per day require maintenance low-dose oral prednisone at 5 to 10 mg/day beyond 6 months. Some patients who require maintenance of oral prednisone doses higher than 20 mg/day beyond 4 to 6 months may tolerate lower doses of prednisone if other immune-modulating agents (e.g., azathioprine, mycophenolate) are used in combination. There is no evidence to recommend a specific regimen. Patients should be monitored carefully and regularly for known side effects of corticosteroid use (e.g., osteoporosis, glucose intolerance), and preventive and therapeutic measures must be undertaken appropriately.

†Some patients unresponsive to oral corticosteroids alone may respond to combined treatment with corticosteroids and other immune-modulating drugs (e.g., azathioprine, mycophenolate).

‡Although most patients respond to modest doses of oral prednisone (initially, 40 to 60 mg/day), it is important to taper the prednisone very slowly to reach a maintenance dose of 5 to 10 mg/day beyond 6 months; rapid taper of oral prednisone has been associated with "rebound"—an exaggerated lung injury beyond the irradiated segment of the lung and in the contralateral lung.

ILD = interstitial lung disease.

SPECIFIC TYPES OF INTERSTITIAL LUNG DISEASE

Idiopathic Interstitial Pneumonias

Idiopathic interstitial pneumonias, which are a subset of acute or chronic ILDs of unknown etiology, are characterized by the presence of varying degrees of interstitial and alveolar inflammation and fibrosis. Distinct clinicopathologic forms of idiopathic interstitial pneumonia include idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia, respiratory bronchiolitis-associated ILD, desquamative interstitial pneumonia, acute interstitial pneumonia, cryptogenic organizing pneumonia, and lymphocytic interstitial pneumonia.

Although clinical severity may vary, the idiopathic interstitial pneumonias tend to manifest as an insidious onset of exertional dyspnea and a nonproductive cough. Chest pain and systemic symptoms such as weight loss and fatigue may be present. Bibasilar end-inspiratory crackles are often heard on auscultation. Clubbing, although not specific, is found in 25 to 50% of patients with idiopathic pulmonary fibrosis. Findings on the chest radiograph are most often nonspecific, and the presence of normal lung markings on the chest radiograph does not exclude ILD. On HRCT, many pathologic entities have characteristic image patterns that have greatly aided diagnosis (see Table 92-4).

IDIOPATHIC PULMONARY FIBROSIS

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Idiopathic pulmonary fibrosis accounts for 50 to 60% of all idiopathic interstitial pneumonias. Idiopathic pulmonary fibrosis occurs in adult men and women with a mean age at onset of 62 years. It is a distinct entity limited to the lungs in adults, usually older than 50 years, and generally occurs in men with a history of cigarette smoking. Typical manifestations include a gradual onset and progression of exertional dyspnea, restrictive abnormalities on PFTs (Chapter 85), and a distinct pattern of bilateral pulmonary fibrosis on HRCT. Most often patients have otherwise been in good health and have no known collagen vascular disease or exposure to drugs or environmental factors known to cause pulmonary fibrosis, although patients with significant cigarette smoking history may have coexisting emphysema.

The natural course of idiopathic pulmonary fibrosis in most patients is a slow and steady decline with a median survival of 3 to 5 years after the diagnosis. A small subset of patients decline at a rapid rate over several months. Another subset of patients remain stable over several years before declining. About 5 to 10% of patients experience acute exacerbation that requires hospitalization and intensive care. There are no known risk factors or biomarkers that accurately identify which patients will have various clinical courses.

DIAGNOSIS

Chest radiographs typically show basal-predominant reticular abnormalities with low lung volumes. The diagnostic features on HRCT are peripheral, predominantly basilar patchy intralobular reticulation, often with subpleural honeycomb cysts, traction bronchiectasis, and traction bronchiolectasis as the disease becomes more advanced (Fig. 92-2A). Reticulation may progress to honeycombing, although neither alveolar consolidation nor parenchymal nodules are present. When compared with the other idiopathic interstitial pneumonias, the HRCT appearance of idiopathic pulmonary fibrosis is distinguished by a greater extent of fibrotic abnormality, by its hallmark honeycombing, and by a notable absence of extensive ground-glass opacification, micronodules, cysts, consolidation, and extensive mediastinal adenopathy, all of which are typical of *usual interstitial pneumonia.*

PFTs usually show a progressive restrictive pattern. However, patients with milder disease may have normal lung volumes and a small decrease in DLCO; rarely, PFTs may be normal.

The cellular pattern in BAL fluid, which is nonspecific, is marked by an excess of neutrophils in proportion to the extent of reticular change on HRCT; the percentage of eosinophils may be mildly increased. The histopathologic pattern of usual interstitial pneumonia consists of patchy interstitial changes alternating with zones of honeycombing, fibrosis, minimal inflammatory cells, collagen deposition, and normal lung (see Fig. 92-2B). Subepithelial fibroblastic foci, small aggregates of myofibroblasts, and fibroblasts within myxoid matrix are invariably present and represent areas of active fibrosis. The presence of temporal heterogeneity, or areas at different stages of fibrosis transitioning with normal areas and honeycomb cysts, along with fibrotic foci within the lung, is an essential feature of usual interstitial pneumonia that distinguishes it from other processes such as nonspecific interstitial pneumonia. Interstitial cellular inflammation is minimal in usual interstitial pneumonia. Although usual interstitial pneumonia characterizes the microscopic abnormality in idiopathic pulmonary fibrosis, the same histologic and radiologic pattern can also be seen in patients with rheumatologic lung diseases and asbestosis (Chapter 93).

In the appropriate clinical setting (and after exclusion of other known clinical conditions associated with ILD) (see later), a definitive diagnosis of idiopathic pulmonary fibrosis is based on the presence of a pattern of usual interstitial pneumonia on HRCT and/or surgical lung biopsy (Table 92-6).

TABLE 92-6 DIAGNOSIS OF IDIOPATHIC PULMONARY FIBROSIS: CRITERIA

The diagnosis of idiopathic pulmonary fibrosis requires the presence of usual interstitial pneumonia (UIP) in the absence of other causes of interstitial lung disease (e.g., domestic, occupational, and environmental exposures, connective tissue disease, and drug toxicity) AND

a. The presence of a UIP pattern on HRCT of the chest in the absence of a lung biopsy or
b. Specific combinations* of patterns on HRCT of the chest (UIP, possible UIP, inconsistent with UIP) and histopathologic features (UIP, probable UIP, possible UIP, not UIP) on surgical lung biopsy

HRCT FEATURES OF UIP	HISTOPATHOLOGIC FEATURES OF UIP
• Subpleural, basal predominance • Reticular abnormality • Honeycombing with or without traction bronchiectasis • Absence of peribronchovascular predominance, extensive ground-glass abnormality, diffuse micronodules, discrete cysts, diffuse mosaic attenuation, or consolidation	• Evidence of marked fibrosis/architectural distortion, +/− honeycombing in a predominantly subpleural/paraseptal distribution • Presence of patchy involvement of lung parenchyma by fibrosis • Presence of fibroblast foci • Absence of features against a diagnosis of UIP suggesting an alternate diagnosis*

*From Raghu G, Collard HR, Egan JJ, et al. An official ATS/ERS/JRS/ALAT statement: idiopathic pulmonary fibrosis: evidence-based guidelines for diagnosis and management. *Am J Respir Crit Care Med.* 2011;183:788-824.
HRCT = high-resolution computed tomography.

TREATMENT

Because no treatment to date has been proved to improve survival or other clinically relevant outcomes, all treatments for idiopathic pulmonary fibrosis should be considered experimental. Physicians are urged to enroll their patients with idiopathic pulmonary fibrosis into one of the many ongoing clinical trials. The physician must spend adequate time to tailor treatment to individual patients' preferences and values.

A recent clinical trial demonstrated better preservation of PFT results after 1 year of treatment with combined oral prednisone (initiated at 0.5 mg/kg ideal body weight per day during the first month and tapered to a maintenance dose of 0.1 to 0.2 mg/kg of ideal body weight per day, or about 10 mg/day, over the subsequent 3 to 4 months), azathioprine (maintenance dose of 2 mg/kg of ideal body weight per day, or 100 to 150 mg/day), and *N*-acetylcysteine (600 mg three times daily) than with prednisone and azathioprine.[1] However, no randomized trials have compared the results of a triple-drug regimen with no treatment at all.

Pirfenidone (1800 mg daily for 1 year), a novel antifibrotic agent, reduced the loss of lung function and improved progression-free survival in one randomized trial in Japan, where it is approved for the treatment of idiopathic pulmonary fibrosis.[2] Interferon-γ1b,[3] cyclophosphamide, colchicine, D-penicillamine, and oral corticosteroids as monotherapy or in combination with immunosuppressive agents are not beneficial.

Despite the absence of data, patients who require hospitalization and intensive care for an acute exacerbation with loss of respiratory function in the absence of infection or other complications are usually treated with empirical intravenous corticosteroids (e.g., methylprednisolone 1.0 g intravenously as a pulse dose once a day for 3 days and followed by hydrocortisone, 125 mg every 6 hours for another 3 to 5 days), with further dosing dependent on the clinical response. Ancillary treatment measures, including supplemental oxygen (based on clinical and physiologic needs), prompt detection and treatment of respiratory tract infections and pulmonary embolism (Chapter 98), pulmonary rehabilitation, and immunization for influenza, herpes zoster, and pneumococcus, are all appropriate. Pulmonary hypertension, if present, may be treated (Chapter 68). Lung transplantation (Chapter 101) is indicated in selected patients, but about two thirds of patients with idiopathic pulmonary fibrosis are older than 60 to 65 years, which is a relative contraindication to lung transplantation. Gastroesophageal reflux, which is more common in patients with idiopathic pulmonary fibrosis, should receive appropriate treatment (Chapter 140). It is important to initiate discussion of palliative care measures before patients reach the terminal stages of the disease.

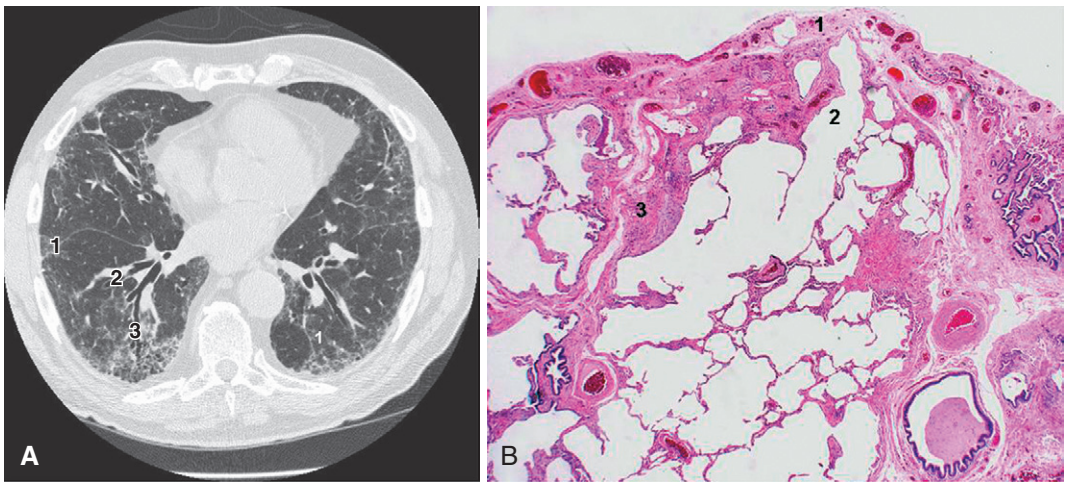

FIGURE 92-2. Diagnosis of idiopathic pulmonary fibrosis. A, The usual interstitial pneumonia pattern of idiopathic pulmonary fibrosis in the lower lobes on high-resolution computed tomography consists of (1) subpleural fibrotic changes with (2) traction bronchiectasis and (3) honeycomb cysts in the lower lobes. **B,** Usual interstitial pneumonia pattern of idiopathic pulmonary fibrosis. Note the presence of (1) subpleural fibrosis with (2) traction emphysema, (3) fibroblastic foci, and temporal heterogeneity of microscopic abnormalities at low magnification. (Courtesy of Dr. Kevin Leslie.)

PROGNOSIS

The usual clinical course is progressive impairment of lung function and gas exchange with a fatal outcome, unless the patient undergoes lung transplantation. Median survival is 3 to 5 years after diagnosis. Patients who survive longer generally have less fibrosis on HRCT, less functional impairment, no evidence of pulmonary hypertension, and no significant oxygen desaturation during a modified version of the 6-minute walk test. Patients with coexisting emphysema, pulmonary hypertension, or episodes of acute exacerbation have even shorter survival times.

NONSPECIFIC INTERSTITIAL PNEUMONIA

Nonspecific interstitial pneumonia is an ILD that is often associated with collagen vascular diseases or hypersensitivity pneumonitis; it may also occur as an idiopathic entity. Two subgroups have been described: cellular and fibrotic. Because the average age at onset is about 10 years earlier in nonspecific interstitial pneumonia than in idiopathic pulmonary fibrosis, and because the clinical features of idiopathic fibrotic nonspecific interstitial pneumonia are very similar to early cases of idiopathic pulmonary fibrosis, questions persist as to whether idiopathic fibrotic nonspecific interstitial pneumonia is a separate clinical entity or represents an early form of idiopathic pulmonary fibrosis.

DIAGNOSIS

Chest radiographs show bilateral patchy pulmonary infiltrates with a lower lung zone predominance in all forms of nonspecific interstitial pneumonia. HRCT reveals a predominant ground-glass pattern of attenuation, usually bilateral and often associated with subpleural reticulation and loss of volume in the lower lobe. In cellular nonspecific interstitial pneumonia, HRCT shows ground-glass opacification, consolidation or both, whereas the biopsy shows mild to moderate lymphoplasmacytic interstitial chronic inflammation. The major differential diagnosis to consider as an alternative to cellular nonspecific interstitial pneumonia is acute or subacute hypersensitivity pneumonitis, so a thorough history regarding environmental exposures is crucial. In contrast, fibrotic nonspecific interstitial pneumonia has a bilateral lower lobe distribution with architectural derangement on HRCT; histopathologically, it has uniformly dense interstitial fibrosis and may sometimes be difficult to distinguish from idiopathic pulmonary fibrosis and usual interstitial pneumonia in the early clinical stages. In these circumstances, the diagnosis of fibrotic nonspecific interstitial pneumonia can be ascertained only by the histologic features in a surgical lung biopsy specimen.

TREATMENT AND PROGNOSIS Rx

Patients with cellular nonspecific interstitial pneumonia usually respond to treatment with corticosteroids (see Table 92-5), and their prognosis is generally better than that of patients with idiopathic pulmonary fibrosis. Given its similarities with idiopathic pulmonary fibrosis, treatment approaches to fibrotic nonspecific interstitial pneumonia have been extrapolated from studies in idiopathic pulmonary fibrosis. However, no clinical trials document this approach.

RESPIRATORY BRONCHIOLITIS–ASSOCIATED INTERSTITIAL LUNG DISEASE

This ILD is almost invariably associated with chronic and current cigarette smoking, and it usually manifests clinically during the fourth or fifth decade of life. However, it may also be detected incidentally on radiographs in relatively younger and asymptomatic persons with a previous history of cigarette smoking or in people passively exposed to chronic cigarette smoke.

DIAGNOSIS

PFTs show varying degrees of airway obstruction, mildly decreased or preserved total lung capacity, and decreased D_{LCO}. The chest radiograph typically reveals bronchial wall thickening and areas of ground-glass attenuation. HRCT reveals centrilobular nodules with an upper lobe predominance, patchy ground-glass attenuation, and peribronchial alveolar septal thickening (Fig. 92-3A). Areas of hypoattenuation (mosaic attenuation) represent air trapping as a result of small airways disease. The characteristic finding on BAL is numerous brown-pigmented alveolar macrophages, often with a modest increase in neutrophils. The hallmark histopathologic feature on biopsy is the accumulation of pigmented alveolar macrophages with glassy eosinophilic cytoplasm and granular pigmentation within respiratory bronchioles, typically with a chronic inflammatory cell infiltrate in the bronchioles and surrounding alveolar walls (see Fig. 92-3B). Fibroblastic foci and honeycomb change are not present, but centrilobular emphysema is frequent.

TREATMENT AND PROGNOSIS Rx

Progression to honeycomb lung and end-stage fibrosis seldom occurs, and the prognosis is good with cessation of smoking. Discontinuation of cigarette smoking is essential, and patients may benefit from low-dose corticosteroids (e.g., prednisone, 10 to 20 mg/day) for a few months.

DESQUAMATIVE INTERSTITIAL PNEUMONIA

Desquamative interstitial pneumonia is a rare entity (<3% of all ILDs) that may represent a more extensive form of respiratory bronchiolitis-associated ILD. Although most affected individuals are cigarette smokers, the histologic pattern of desquamative interstitial pneumonia may also occur in pneumoconiosis, rheumatologic disease, and drug-associated ILD. Patients are often initially seen with advanced disease and striking hypoxemia.

DIAGNOSIS

PFTs reveal a restrictive lung defect and decreased D_{LCO} with or without coexisting airway obstruction. The chest radiograph shows patchy basal consolidation with a lower lobe and peripheral predominance. HRCT shows bilateral symmetrical ground-glass opacities with a predominantly basal and peripheral distribution as well as diffuse alveolar septal thickening (Fig. 92-4A). Irregular linear opacities, typically associated with traction bronchiectasis, may be noted. The finding of small discrete cysts, believed to represent trapped air in dilated bronchioles, within areas of ground-glass

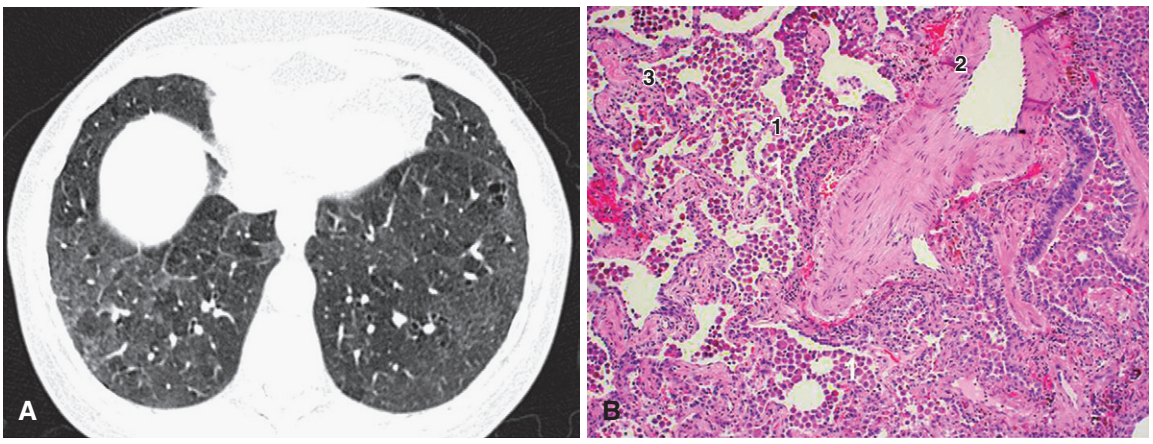

FIGURE 92-3. Respiratory bronchiolitis–associated interstitial lung disease. A, Ground-glass attenuation with a mosaic pattern on high-resolution computed tomography. **B,** Note the dense aggregates of (1) pigmented macrophages present in the air spaces around the terminal airways with (2) variable bronchiolar metaplasia and (3) interstitial fibrosis.

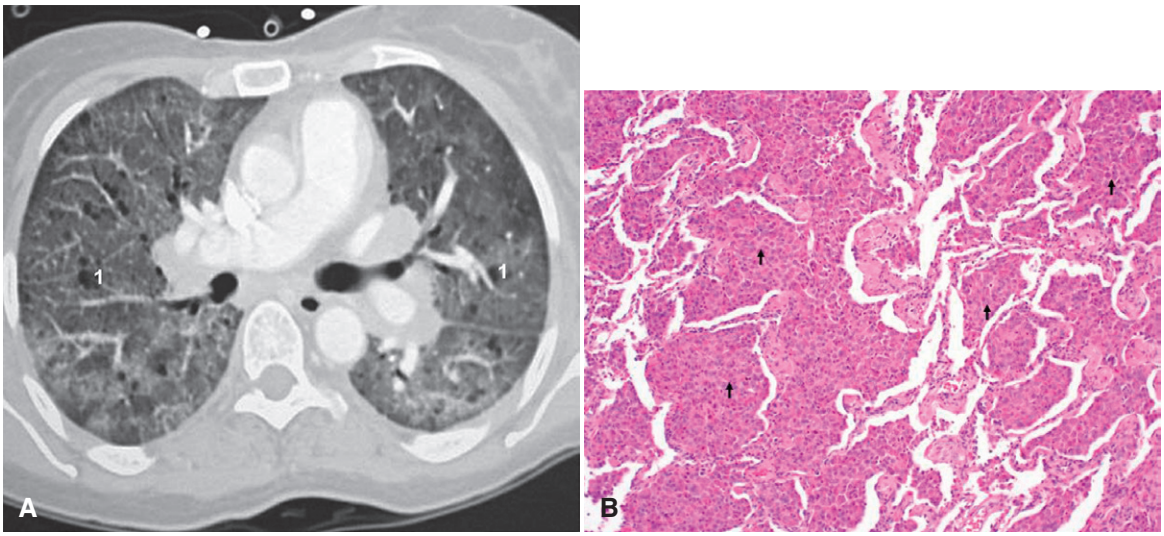

FIGURE 92-4. Desquamative interstitial pneumonia. A, Ground-glass attenuation with (1) cystic spaces on high-resolution computed tomography. **B,** Note that the alveolar spaces are densely filled with macrophages *(arrowheads)*.

changes and intervening normal lung parenchyma is highly suggestive of desquamative interstitial pneumonia. Fluid recovered from BAL quite often shows increased numbers of pigmented alveolar macrophages, frequently with increased neutrophils. Histopathologic findings on biopsy include diffuse alveolar septal thickening, hyperplasia of type II pneumocytes, and intense accumulation of intra-alveolar granular pigmented macrophages in a uniform manner (see Fig. 92-4B); fibrosis is minimal.

TREATMENT AND PROGNOSIS

Rx

Therapeutic outcomes are generally good, particularly with cessation of smoking and administration of oral corticosteroid therapy (see Table 92-5); the estimated overall survival rate is 70% at 10 years. However, a subset of patients may progress despite cessation of cigarette smoking, and a trial of corticosteroid therapy and lung transplantation is an appropriate consideration for selected patients.

ACUTE INTERSTITIAL PNEUMONIA

Acute interstitial pneumonia is seen in otherwise healthy persons immediately after an apparent viral upper respiratory infection (Fig. 92-5). The syndrome, historically known as Hamman-Rich syndrome (Chapter 91), mimics the acute respiratory distress syndrome.

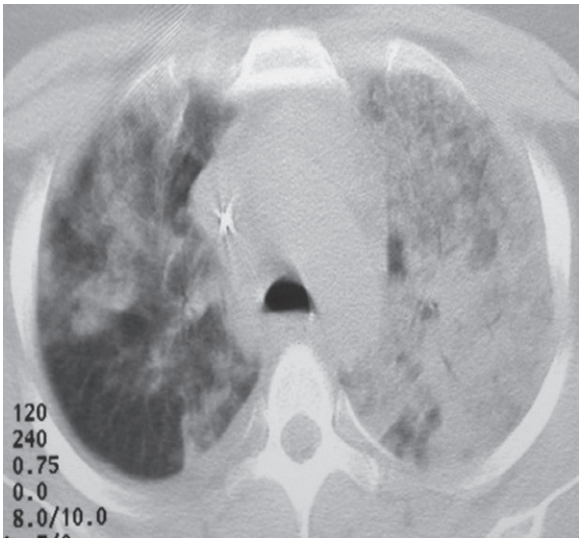

FIGURE 92-5. Acute interstitial pneumonia with diffuse alveolar damage histologically. Note the dense air space consolidation.

CRYPTOGENIC ORGANIZING PNEUMONIA

Cryptogenic organizing pneumonia, previously referred to as bronchiolitis obliterans organizing pneumonia of unknown cause (BOOP), is an idiopathic pneumonia that most commonly manifests as a flulike illness with a nonproductive cough, followed by exertional dyspnea.

DIAGNOSIS

PFTs show a restrictive defect, but 20% of patients, most of whom are current or past smokers, also have an obstructive defect. Chest radiography reveals patchy unilateral or bilateral alveolar opacities that may be peripheral or migratory; small nodular opacities are seen in 10 to 50% of cases. In about 90% of patients, HRCT shows areas of air space consolidation with lower lung zone predominance, frequently in a subpleural or peribronchial distribution; other features include small nodules along bronchovascular bundles and ground-glass attenuation. BAL is nonspecific; increased lymphocytes, neutrophils, and eosinophils may be seen. On biopsy, key histologic features are excessive proliferation of granulation tissue within the small airways and alveolar ducts as well as chronic inflammation in the surrounding alveoli.

TREATMENT AND PROGNOSIS

Rx

Most patients recover rapidly and completely when treated with oral corticosteroids (see Table 92-5) for 6 months but may relapse after discontinuation and require oral corticosteroids indefinitely, often with adjunct immunosuppressive agents such as azathioprine. A small subset of patients in whom pulmonary fibrosis develops despite corticosteroids and azathioprine behave similarly to patients with idiopathic pulmonary fibrosis. Spontaneous remissions are known to occur.

LYMPHOID AND LYMPHOCYTIC INTERSTITIAL PNEUMONIA

This condition is more common in women, especially in the fifth decade of life, but it may occur at any age. Concurrent collagen vascular disease or an autoimmune disorder (especially Sjögren's syndrome) should be sought because idiopathic lymphocytic interstitial pneumonia is very rare. Symptoms are nonspecific and include a gradual onset of cough and exertional dyspnea.

DIAGNOSIS

Chest radiographs show a reticular or reticulonodular pattern predominantly involving the lower lung zones. HRCT reveals bilateral ground-glass

attenuation, small or large nodules, and scattered cysts; perivascular honeycombing and reticular abnormalities may also be seen. Increased numbers of lymphocytes are found on BAL, and biopsy reveals a dense interstitial lymphocytic infiltrate.

TREATMENT AND PROGNOSIS

Rx

Some patients respond to or stabilize with oral corticosteroids (see Table 92-5). The prognosis is variable, with more than one third of patients progressing to diffuse pulmonary fibrosis.

Interstitial Lung Disease Associated with Collagen Vascular Disease

Many of the collagen vascular diseases, including progressive systemic sclerosis (Chapter 275), rheumatoid arthritis (Chapter 272), systemic lupus erythematosus (Chapter 274), dermatomyositis and polymyositis (Chapter 277), Sjögren's syndrome (Chapter 276), and mixed connective tissue disorder (Chapter 275), may have ILD as one of their manifestations. In fact, up to 20% of patients with collagen vascular disease may initially be thought to have an ILD alone. Therefore, these diagnoses must be considered in patients with ILD, even in the absence of extrathoracic findings. Conversely, because pulmonary involvement is a major cause of death in patients with collagen vascular disease, the presence of ILD should be carefully sought in affected patients. All forms of idiopathic interstitial pneumonia can occur in patients with collagen vascular disease. The natural history of ILD complicating collagen vascular diseases is variable, especially because coexisting pulmonary vascular disease or nonparenchymal pulmonary involvement may be present.

PROGRESSIVE SYSTEMIC SCLEROSIS

Of the collagen vascular diseases, progressive systemic sclerosis is most frequently associated with ILD. Pulmonary symptoms may antedate cutaneous or digital manifestations of the disease by several years. Most patients affected have nonspecific interstitial pneumonia, with a minority having a usual interstitial pneumonia pattern, and D_{LCO} levels correlate with mortality. Pulmonary hypertension, which can occur in the absence of pulmonary fibrosis, may result in cor pulmonale. The chronic pulmonary fibrosis also increases the risk for bronchogenic carcinoma, usually either bronchoalveolar cell carcinoma or adenocarcinoma. In a controlled trial, treatment with cyclophosphamide (50 to 100 mg/day orally) for 1 year stabilized the PFT findings and improved health-related quality of life in patients with scleroderma-related interstitial lung disease.

RHEUMATOID ARTHRITIS

Although rheumatoid arthritis is more common in women (2:1 to 4:1 ratio), ILD associated with rheumatoid arthritis is more common in men (3:1 ratio). Most cases occur at 50 to 60 years of age, and pulmonary symptoms follow the onset of arthritis in about 75% of cases. Lung involvement in rheumatoid arthritis may take many forms, but bronchiectasis, bronchiolitis, idiopathic interstitial pneumonias, and pleural effusions or pleural thickening are some of the most common. Early in the course, the histologic changes are similar to those of idiopathic interstitial pneumonias, including pulmonary fibrosis, but are distinguished by a prominent lymphocytic infiltrate that may contain germinal follicles adjacent to vessels and airways. As the disease progresses, the infiltration becomes less pronounced and is replaced by fibrous tissue, honeycomb changes, or both. Other pulmonary manifestations include pulmonary nodules, vasculitis, pulmonary hypertension, and Caplan's syndrome (progressive upper lobe nodular pulmonary fibrosis in a coal miner with rheumatoid arthritis) but are relatively rare. Treatment is directed at the underlying rheumatoid arthritis (Chapter 272).

SYSTEMIC LUPUS ERYTHEMATOSUS

Pulmonary abnormalities complicating systemic lupus erythematosus (Chapter 274) may vary greatly. Pleural disease or pleural effusions (or both) are commonly present in lung disease that complicates systemic lupus erythematosus. Acute lupus pneumonitis may mimic acute interstitial pneumonia, with widespread ground-glass attenuation admixed with consolidation, or it may manifest as diffuse alveolar hemorrhage. Chronic ILD may also occur. Infection must always be considered in acutely ill patients who have received steroids or other immunosuppressive therapy. Rarely, the restrictive lung defect, which may be predominantly a result of diaphragmatic weakness, leads to a chest radiographic pattern of small-appearing lungs that may look progressively smaller over time. This so-called shrinking lung is generally resistant to corticosteroids or other immunosuppressive agents used to treat systemic lupus erythematosus. Otherwise, treatment of the ILD is similar to treatment of the underlying systemic lupus erythematosus.

DERMATOMYOSITIS AND POLYMYOSITIS

In contrast to progressive systemic sclerosis, the pattern of lung involvement in dermatomyositis and polymyositis is more heterogeneous. Usual interstitial pneumonia, nonspecific interstitial pneumonia, and organizing pneumonia have all been reported. Most patients have anti-Jo-1 antibody, and the disease is typically progressive over time. An acute interstitial pneumonia–like syndrome occurs in a subset of patients and is associated with high mortality rate despite aggressive immunosuppressive agents and high-dose corticosteroids. ILD may precede the muscular manifestations by months to years or be superimposed on established muscle disease. The severity of the muscular disease does not correlate with that of the ILD. Treatment is directed at the underlying disease (Chapter 277).

SJÖGREN'S SYNDROME

ILD is seen in patients with Sjögren's syndrome, particularly those with the primary form of the disease. Lymphocytic interstitial pneumonia is the most frequent subtype, but cryptogenic organizing pneumonia may also be present. Respiratory infections and bronchiectasis are common in advanced stages, perhaps because of inspissated mucus. Response to corticosteroid or immunosuppressive therapy is usually good (Chapter 275).

MIXED CONNECTIVE TISSUE DISEASE

This overlap syndrome (Chapter 275) combines features of progressive systemic sclerosis, systemic lupus erythematosus, rheumatoid arthritis, and polymyositis or dermatomyositis. Pulmonary disease is common, but it is most often subclinical and identified only radiographically. Treatment includes corticosteroids and other immune-modulating agents for the underlying disease.

ANKYLOSING SPONDYLITIS

The most common pulmonary manifestation of ankylosing spondylitis (Chapter 273) is upper lobe, bilateral reticulonodular infiltrates with cyst formation as a result of parenchymal destruction. There is no known effective therapy for this apical fibrobullous disease.

Hypersensitivity Pneumonitis

EPIDEMIOLOGY AND PATHOBIOLOGY

Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, is a syndrome caused by repeated inhalation of specific antigens from occupational or environmental exposure (Chapters 93 and 94) in sensitized individuals. Within a short period after inhalation of an inciting agent, patients develop a nonspecific diffuse pneumonitis with inflammatory cell infiltration of the bronchioles, alveoli, and interstitium. In the subacute and chronic stages, loosely formed, noncaseating, epithelioid cell granulomas may be dispersed in the interstitium. Hypersensitivity pneumonitis can occur with exposure to a wide range of inhaled antigens (Chapters 93 and 94). Some of the more common exposures are farmer's lung, bird fancier's lung, parakeet keeper's lung, and pigeon breeder's lung. Hobbies (woodworker's lung) and recreational activities (sauna taker's lung) may be implicated as well as occupations (Chapter 93).

CLINICAL MANIFESTATIONS

The clinical features and severity of symptoms vary according to the frequency and intensity of exposure. A history of exposure to potential agents or changes in the domestic and other environments (or both) is essential to diagnosis and treatment (Chapters 18 and 93). The interval between exposure to the antigen and the clinical manifestations of lung disease is unknown, although symptoms can occur as soon as 4 to 12 hours after exposure. In such cases, fever and chills are common symptoms, are often temporally related to the workplace or to hobbies, and may actually disappear on vacations or during absence from the site of exposure, only to recur when exposure is resumed. In more chronic and low-level exposures, however, the onset is insidious.

DIAGNOSIS

Findings on chest radiography are diverse, with focal patchy consolidation or a diffuse ground-glass appearance in acute hypersensitivity pneumonitis, micronodular and reticular shadowing in subacute forms, and diffuse, predominantly upper lung zone reticulation with honeycombing in the chronic form. Chest radiographs may be normal in up to 30% of patients with significant physiologic abnormalities.

On HRCT, small centrilobular ill-defined nodules of ground-glass densities are seen, along with evidence of mosaic attenuation (trapped air) as a result of concomitant bronchiolitis. Chronically, findings of lung fibrosis may be indistinguishable from the patterns seen in usual interstitial pneumonia and idiopathic pulmonary fibrosis.

BAL may be quite helpful by showing the most marked increase in lymphocytes of any of the ILDs as well as increased numbers of plasma cells. The characteristic histologic triad in hypersensitivity pneumonitis is cellular nonspecific interstitial pneumonia, cellular bronchiolitis, and granulomatous inflammation; however, this triad is seen in no more than 75% of affected patients. Differentiation from cellular nonspecific interstitial pneumonia may be challenging.

Precipitating serum antibodies for potential causes of hypersensitivity pneumonitis confirm exposure but not cause and effect, and the absence of antibodies does not exclude hypersensitivity pneumonitis. In some cases, a thorough investigation of the patient's home and workplace by an industrial hygienist may reveal molds, spores, thermoactinomycetes species, and other precipitating causes.

TREATMENT AND PROGNOSIS

Rx

Further avoidance of exposure to the antigen or antigens and treatment with corticosteroids (see Table 92-5) are important if improvement is to be obtained. Continued exposure to the unidentifiable antigens or prolonged exposure to antigens, or both, can lead to chronic hypersensitivity pneumonitis and irreversible fibrosis that may not respond to any treatment regimen. In the fibrotic stages, the prognosis may be similar to that for idiopathic pulmonary fibrosis.

Occupational Interstitial Lung Diseases

ILDs associated with specific occupations generally involve the inhalation and deposition of dust in the lungs, followed by a tissue reaction that ultimately results in fibrosis. Examples include silicosis (inhalation of silica in crystalline form or silicon dioxide as quartz, cristobalite, or tridymite; at-risk occupations include sandblasting and working with granite), coal workers' pneumoconiosis (inhalation of coal dust), asbestosis (deposition of fibers during mining, milling, or other handling of asbestos; welding and working in a shipyard are two at-risk occupations), berylliosis (seen in aerospace workers and in electronic industries), and hard metal disease (Chapter 93). Radiographic features vary depending on the inciting inhalant. Cessation of the exposure is important, but the fibrosis is generally irreversible.

Drug-Induced Interstitial Lung Disease

More than 300 drugs, biomolecules, or homeopathic remedies (see Table 92-2) can cause acute, subacute, or chronic ILD, and the list continues to increase as new medications are introduced. The clinical and radiographic manifestations are quite varied. Examples of known syndromes include chronic nitrofurantoin-induced ILD that mimics idiopathic pulmonary fibrosis (and is fatal in approximately 8% of cases), granulomatous pneumonitis secondary to methotrexate (<5%), sarcoid-like granulomatous ILD induced by interferon-α and tumor necrosis factor modulating agents, nonspecific bilateral alveolar and interstitial inflammatory and fibrotic abnormalities caused by bleomycin and other chemotherapeutic agents, and alveolar and interstitial abnormalities and nodular densities in acute and chronic amiodarone pulmonary toxicity. Most drug-induced ILD is reversible if recognized early and if use of the responsible drug is discontinued. In addition to discontinuing the implicated drug, treatment with corticosteroids (see Table 92-5) is indicated in patients with moderate to severe functional impairment.

Alveolar Filling Disorders

In alveolar filling disorders (Chapter 91), air spaces distal to the terminal bronchioles are filled with blood, lipid, protein, water, or inflammatory cells. The radiographic appearance is that of an alveolar infiltrate with small nodular densities and ill-defined margins; hence, the radiographic picture is similar to an ILD, and virtually all the alveolar filling disorders may result in ILD, including Goodpasture's syndrome, pulmonary alveolar proteinosis (primary and secondary), alveolar hemorrhage syndromes (Chapter 91), acute interstitial pneumonia, and bronchoalveolar cell carcinoma (Chapter 197).

IDIOPATHIC PULMONARY HEMOSIDEROSIS

This rare disorder of children and young adults is characterized by intermittent, diffuse alveolar hemorrhage without evidence of vasculitis, inflammation, granulomas, or necrosis. The etiology is poorly understood. Anemia and hepatosplenomegaly may be present. Hemosiderin-laden macrophages in BAL fluid and lung tissue are part of the diagnostic picture. The chest radiograph reveals diffuse, bilateral alveolar infiltrates. A chronic interstitial infiltrate may develop after repeated episodes, infrequently with hilar and mediastinal adenopathy. Systemic corticosteroids (see Table 92-5) may be beneficial in treating acute disease.

CHRONIC EOSINOPHILIC PNEUMONIA

The clinical manifestation of chronic eosinophilic pneumonia varies over a wide spectrum, from asymptomatic to respiratory failure. The disease often occurs in women in the second to fourth decades of life; such women often manifest constitutional symptoms of fevers, sweats, weight loss, fatigue, dyspnea, and cough. Peripheral blood eosinophilia (Chapter 173), usually at levels of 10 to 40%, is common but may be absent in up to one third of affected patients at initial evaluation. On chest radiography and HRCT, the cardinal feature is peripheral multifocal consolidation, predominantly in the upper and mid lung zones. These dense peripheral infiltrates, which have sometimes been called the "photographic negative of pulmonary edema," often resolve dramatically after treatment with corticosteroids. Ground-glass attenuation commonly accompanies the consolidation. BAL fluid may show greater than 40% eosinophils during exacerbations. Treatment with corticosteroids (see Table 92-5) results in rapid response, frequently within hours; in fact, such a dramatic resolution of symptoms with radiographic clearance of infiltrates shortly after initiation of corticosteroid therapy is considered "diagnostic." However, the rate of relapse is high, so most patients require prolonged treatment with low-dose corticosteroids (prednisone, 5 to 10 mg/day) to stay in remission.

Interstitial Lung Disease Associated with Pulmonary Vasculitides

Wegener's Granulomatosis

Wegener's granulomatosis (Chapter 278) is the most common form of vasculitis that involves the lung. The systemic necrotizing granulomatous inflammation and small-vessel vasculitis are often manifested first in the upper respiratory tract as chronic rhinitis or sinusitis (or both), epistaxis, oropharyngeal ulcerations, gingival hyperplasia with clefting, or serous otitis media. Destruction of the nasal cartilage may lead to septal perforation or a saddle nose deformity. Ulcerative lesions of the tracheobronchial tree, cavitating nodules within the lung parenchyma, and diffuse alveolar hemorrhage caused by pulmonary capillaritis are lower respiratory tract manifestations. Focal segmental necrotizing glomerulonephritis is the most common extrathoracic manifestation, although pulmonary involvement may occur without renal disease. Chest radiography usually reveals multiple nodular or cavitating infiltrates, but single nodules may be found as well. The diagnosis is most commonly made serologically, with demonstration of antineutrophil cytoplasmic antibodies, although a negative test does not exclude the disease. Treatment is usually with cyclophosphamide (50 to 100 mg/day or 2 mg/kg of ideal body weight per day, but not more than 150 mg/day) in conjunction with oral corticosteroids (prednisone, 10 to 40 mg/day). Initial remission occurs in more than 90% of patients, but most patients require treatment for several years. Relapses may occur in up to 30% of patients, especially when treatment is tapered; such patients may need treatment indefinitely. Rituximab is an alternative if cyclophosphamide is unsuccessful or not tolerated (Chapter 278). Prophylaxis for *Pneumocystis carinii* infection is indicated in patients receiving chronic treatment.

CHURG-STRAUSS SYNDROME (ALLERGIC ANGIITIS)

This systemic necrotizing vasculitis (Chapter 291) affects both the upper and lower respiratory tracts and is almost invariably preceded by allergic disorders such as asthma, allergic rhinitis, sinusitis, or a drug reaction. Peripheral and lung eosinophilia, bronchospasm, increased immunoglobulin E levels, and

rashes are common manifestations. The pulmonary radiographic findings are bilateral patchy, fleeting infiltrates, diffuse nodular infiltrates, or diffuse reticulonodular disease. Histopathologic examination of lung tissue is generally diagnostic with features of granulomatous angiitis or vasculitis. Although treatment with corticosteroids is indicated, the dosage and duration are unclear (see Table 92-5).

IDIOPATHIC PULMONARY CAPILLARITIS

Idiopathic pulmonary capillaritis may involve the pulmonary vasculature within the alveolar walls and be manifested as ILD. Patients may also have subclinical alveolar hemorrhage, often associated with the presence of perinuclear antineutrophilic cytoplasmic antibodies. Corticosteroids are the mainstay of treatment, but the doses and duration of treatment are unclear. Frequently, patients need adjunctive treatment with cyclophosphamide or rituximab, similar to patients with vasculitis and Wegener's granulomatosis (Chapter 278).

Other Forms of Interstitial Lung Disease

Sarcoidosis

See Chapter 95.

PULMONARY LANGERHANS CELL HISTIOCYTOSIS

This condition, previously known as pulmonary histiocytosis X or eosinophilic granuloma of the lung, is an idiopathic, granulomatous ILD that typically occurs in the second or third decade of life; there is a male preponderance. The currently accepted term is *Langerhans cell histiocytosis*. Pulmonary Langerhans cell histiocytosis is rare, with an estimated incidence of two to five cases per million population. The large majority (~90%) of affected individuals are smokers, and current evidence suggests that the disorder results from an abnormal immune response to a component or derivative of cigarette smoke.

CLINICAL MANIFESTATIONS

The clinical findings are variable and range from an abnormal chest radiograph in an asymptomatic patient to progressive dyspnea with a nonproductive cough. Systemic symptoms of malaise, fever, and weight loss may be present. Hemoptysis is rare. Spontaneous pneumothorax, which occurs in approximately 25% of patients and is due to rupture of subpleural cysts, may be an initial finding. Langerhans cell histiocytosis may be confined to the lung or may be a component of a multisystem disease that includes painful cystic bone lesions and diabetes insipidus (Chapter 232).

DIAGNOSIS

The chest radiograph shows diffuse symmetrical reticulonodular opacities superimposed on multiple small cysts in the upper and mid lung zones. HRCT reveals subpleural nodules, scattered ground-glass densities, and irregular cysts of varying number, size, and configuration in both lungs, with sparing of the lung bases; in the appropriate clinical setting, this pattern may be pathognomonic. As the disease progresses, the increase in fibrosis and cysts may lead to honeycombing of the lung. PFTs are characterized by a mixed restrictive and obstructive pattern, including a reduction in diffusing capacity. Vital capacity is disproportionately reduced compared with total lung capacity because of air trapping within the cysts; the result is an increased residual volume. BAL reveals Langerhans cells (atypical histiocytes) that have the characteristic "x body" (i.e., Birbeck granule) on electron microscopy; immunostaining shows CD1 antigen on the cell surface and S-100 protein in the cytoplasm. However, the absence of these findings does not exclude the diagnosis. The diagnosis is usually made by transbronchial biopsy or open lung biopsy, which reveals interstitial and peribronchiolar collections of histiocytes, eosinophils, and lymphocytes; peribronchiolar nodules; and cysts with areas of central stellate fibrosis.

TREATMENT AND PROGNOSIS

Rx

Although definitive regression after discontinuation of smoking has not been proved, small series report improvement, so patients should be encouraged to discontinue smoking. The prognosis in pulmonary Langerhans cell histiocytosis is usually favorable, with approximately 75% of patients improving or stabilizing, especially with cessation of smoking; some patients, however, may progress to end-stage lung disease. In patients with progressive disease, corticosteroids (see Table 92-5) with or without vincristine, cyclosporine, cyclophosphamide, and azathioprine have been used with some anecdotal reports of success. Lung transplantation has been performed, but recurrent disease has been reported in the allograft.

LYMPHANGIOLEIOMYOMATOSIS

This rare interstitial lung disease is limited to women, primarily of childbearing age. Proliferation of abnormal smooth muscle around bronchioles leads to bilateral small cysts, which give an appearance of ILD on chest radiographs, and progressive impairment of lung function. Hemoptysis, pneumothorax (from rupture of subpleural cysts), and chylothorax (from lymphatic obstruction) may be initial symptoms that distinguish this disorder from other diffuse lung diseases. Although lymphangioleiomyomatosis is usually limited to the lungs, an association with angiomyolipomas of the mediastinal and retroperitoneal lymph nodes and kidney has been described, so the disease may mimic the manifestations of tuberous sclerosis (Chapter 426). Coarse reticulonodular infiltrates, often with cysts or bullae, are typically seen on chest radiographs. In contrast to most other ILDs, increased lung volumes may be present and should prompt consideration of this diagnosis in a nonsmoking woman of reproductive age. HRCT shows characteristic diffuse thin-walled cysts, generally less than 2 cm in diameter. BAL may show occult alveolar hemorrhage. Lung biopsy reveals abnormal smooth muscle cells lining the airways, lymphatics, and blood vessels, with concurrent airflow obstruction and replacement of the lung parenchyma with cysts.

TREATMENT AND PROGNOSIS

Rx

In a randomized trial, sirolimus, an inhibitor of rapamycin signaling, initially at 2 mg per day and titrated to maintain trough levels between 5 and 15 ng/mL, was safe and stabilized lung function. Treatment with progesterone or tamoxifen has been tried, but no randomized trials support the use of interventions to alter the estrogen-progesterone balance. Although lung transplantation is indicated as the patient reaches severe functional impairment, the disease may recur in the transplanted lung. Most patients currently die of respiratory failure about 10 years after the onset of symptoms.

Inherited Disorders

Several rare genetic disorders are associated with ILD and pulmonary fibrosis. Inheritance is autosomal dominant with variable penetrance for most cases of familial idiopathic pulmonary fibrosis and idiopathic interstitial pneumonia and for tuberous sclerosis (Chapter 426), neurofibromatosis (Chapter 426), and familial hypocalciuric hypercalcemia (Chapter 253). Inheritance is autosomal recessive for Gaucher's disease (Chapter 215), Niemann-Pick disease (Chapter 215), and Hermansky-Pudlak syndrome (Chapter 215). The congenital form of the alveolar filling disorder pulmonary alveolar proteinosis also is inherited in an autosomal recessive manner.

Tuberous sclerosis (Chapter 426), an autosomal dominant disease of variable penetrance, is characterized pathologically by the presence of hamartomas in multiple organs. The most well-known clinical manifestations include epilepsy, mental retardation, adenoma sebaceum, and renal angiomyolipomas. ILD occurs in only 1% of patients with tuberous sclerosis, usually in women older than 30 years with little or no mental retardation. The pulmonary involvement, which is indistinguishable from lymphangioleiomyomatosis both radiographically and histopathologically, may be manifested as exertional dyspnea, recurrent pneumothorax, and hemoptysis. HRCT reveals thin-walled cysts and a diffuse reticulonodular infiltrate. Recurrent parenchymal hemorrhage may lead to hemosiderin deposition and interstitial pulmonary fibrosis. There is no cure, and treatment is supportive.

Neurofibromatosis (Chapter 426) may affect all age groups and both sexes. Type 1 (von Recklinghausen's disease) is characterized by cafe au lait spots, neurofibromas, optic glioma, and bony lesions; the more rare type 2 is associated with bilateral acoustic neuromas. Diffuse ILD is manifested as bilateral lower lobe fibrosis as well as bullae or cystic changes. Interstitial fibrosis and alveolitis with thickening of the alveolar septa, accompanied by a cellular infiltrate, are seen on lung biopsy. Management is as for idiopathic pulmonary fibrosis.

Gaucher's disease (Chapter 215), a lysosomal glycolipid storage disorder, has a predilection for the Ashkenazi Jewish population. Pulmonary manifestations, which occur most frequently in type 2 disease, may be a result of interstitial infiltration by Gaucher cells with fibrosis, alveolar consolidation, and filling of alveolar spaces; capillary plugging by Gaucher cells may cause secondary pulmonary hypertension. Treatment is as for the systemic disease, and the general approaches for idiopathic interstitial pneumonias and pulmonary arterial hypertension may be followed for these patients.

Niemann-Pick disease (Chapter 215) is a rare lipid storage disease that may cause infiltration of the characteristic "foam cell" throughout the pulmonary lymphatics, the pulmonary arteries, and the pulmonary alveoli. Patients with type B may survive into adulthood. Treatment is as for the systemic disease.

Hermansky-Pudlak syndrome (Chapter 215) is characterized by oculocutaneous albinism, a bleeding diathesis, and ceroid inclusions in macrophages. Most patients are of Puerto Rican ancestry, and women are affected more frequently than men. Pulmonary fibrosis, with onset in the third or fourth decade, is slowly progressive. Treatment principles and interventions are largely supportive and extrapolated from other related conditions, especially idiopathic pulmonary fibrosis.

OCCUPATIONAL LUNG DISEASE

SUSAN M. TARLO

Occupational lung diseases include a wide spectrum of respiratory disorders with symptoms, signs, and diagnostic test results that often present with features similar to nonoccupational diseases (Table 93-1). For example, adult-onset asthma (Chapter 87) may be occupational asthma, presumed sarcoidosis (Chapter 95) may actually be chronic beryllium disease, apparent idiopathic pulmonary fibrosis may be asbestosis, or a suspected viral pneumonia (Chapter 97) may be hypersensitivity pneumonitis from an occupational cause such as contaminated metal-working fluid.

When evaluating any respiratory disease, the clinician should consider the possibility of an occupational cause or contribution (see E-Fig. 18-1 in Chapter 18; see Table 93-1). The onset of disease after an occupational exposure may occur with a short latency period, as for an acute toxic inhalation injury, or over a period of months to years, as for occupational asthma or hypersensitivity pneumonitis. Latency can be 20 years or more in chronic beryllium disease or lung cancer from chromium, asbestos, or other carcinogens. The most relevant job and occupational exposure history will therefore depend in part on the type of lung disease: for acute syndromes, the recent job exposure is most relevant; for asthma or hypersensitivity pneumonitis, the exposures at the onset of symptoms and ongoing exposures are most relevant; but for chronic diseases or diseases that may result from a long latency exposure, a full working history is essential. Consideration also should be given to potentially relevant exposures that may be related to a patient's hobbies or avocations (e.g., woodworking, model building, or insect collecting).

The clinical relevance of a correct occupational attribution is most apparent for diseases with a close temporal relationship between exposure and the onset of symptoms because intervention to reduce or remove exposure may reverse the disease or prevent progression. In addition, interventions in the workplace may reduce or prevent disease in other workers. However, even for diseases with a potential long latency, such as chronic beryllium disease, identification of disease in one worker should be regarded as a sentinel event that can lead to investigation of the workplace exposures and introduction of preventive measures. With the assistance of their physicians, workers with occupational lung diseases also often can qualify for workers' compensation.

EPIDEMIOLOGY

No reliable figures exist for the total incidence or prevalence of occupational lung diseases, and regional variation in occupations and exposures is substantial. Work-related asthma has become the most common chronic occupational lung disease in developed countries, where occupational asthma (asthma caused by work) accounts for about 15% of all adult-onset asthma, and work-exacerbated asthma occurs in 25 to 52% of asthmatic workers. The occupational contribution of workplace dusts, fumes, and gases to chronic obstructive pulmonary disease (COPD) is estimated at 15%.

In contrast, pneumoconiosis from silica or coal dust, although still important in developing countries, is declining in incidence in developed countries (E-Fig. 93-1) as a result of occupational hygiene measures. For example, approximately 100,000 Americans received benefits from the Federal Black Lung Program in 2005, compared with about 500,000 in 1980, and the percentage of coal miners with pneumoconiosis has fallen from 11% in the mid-1970s down to 3%. However, newer exposures that lead to silicosis include the textile industry's use of jet silica blasting of denim jeans, reported from Turkey. Newly recognized asbestos-related diseases continue to occur, owing to the long latency period between exposure and clinical disease, despite the declining exposure to asbestos in developed countries. Although annual deaths from asbestosis have now reached a plateau in North America and will likely decline, new cases of mesothelioma, which has a latency of up to 35 years or more, are not estimated to plateau until 2020.

Chronic beryllium disease declined in frequency and severity after the elimination of beryllium from fluorescent lightbulbs in the 1950s, but then increased because of the increasing use of beryllium in nuclear facilities, aerospace, electronics, dental ceramics, metal alloys, recycling of metals, and products such as golf clubs and bicycles. The beryllium lymphocyte proliferation test can identify beryllium sensitization, which can be found in up to 10% of exposed workers and facilitates earlier diagnosis of chronic beryllium disease.

SPECIFIC OCCUPATIONAL LUNG DISORDERS

Occupational lung diseases are often misdiagnosed as other common nonoccupational diseases, but a careful history and appropriate investigations can lead to a correct diagnosis. For many occupational lung diseases, the diagnosis can significantly improve prognosis and lead to measures to prevent illness in other workers.

Work-Related Asthma

Work-related asthma includes both occupational asthma that is caused by work and asthma that is not caused by work but is exacerbated by work exposures.

SENSITIZER-INDUCED OCCUPATIONAL ASTHMA

EPIDEMIOLOGY

Occupational asthma is most commonly associated with a specific immune response to a high- or low-molecular-weight sensitizer (Table 93-2). Sensitizer-induced occupational asthma usually affects no more than 5 to 10% of workers exposed to the sensitizing agent, but exposure to complex platinum salts or detergent enzymes may result in symptoms in about 50% of highly exposed workers. In most studies, higher levels of exposure are associated with higher rates of sensitization in the exposed populations, but there is no clear threshold exposure below which all workers are protected from the risk of sensitization.

PATHOBIOLOGY

Genetic factors increase the risk of sensitization, but the risks appear to be polygenic and may differ for different allergens and sensitizers. Underlying atopy, as exemplified by a history of allergy or positive skin tests to common environmental allergens (Chapter 257), carries an increased risk of

TABLE 93-1 EXAMPLES OF OCCUPATIONAL RESPIRATORY DISEASES THAT COULD BE MISDIAGNOSED AS COMMON NONOCCUPATIONAL RESPIRATORY DISEASE

DISEASE THAT IS MIMICKED	POSSIBLE OCCUPATIONAL DISEASE	EXAMPLES OF SUGGESTIVE FEATURES LEADING TO A CORRECT DIAGNOSIS
Asthma	Occupational asthma from a work sensitizer	Asthma symptoms begin and are worse during a working period, with some improvement on days or weeks off work. Exposure to a high- or low-molecular-weight workplace sensitizer
	Occupational asthma—irritant-induced, including reactive airways dysfunction syndrome	Asthma begins within days after a high-level (accidental) workplace exposure
	Work-exacerbated asthma	Asthma usually began before starting the job or exposure, but severity is worse on days of work, or work exposures to expected asthma triggers or common allergens at work
COPD	Occupational COPD	Prolonged exposure at work to dusts, fumes, or gases
Pneumonia	Acute hypersensitivity pneumonitis	Symptoms typically resolve within days and recur on re-exposure to the same work trigger (e.g., metal-working fluid, moldy hay, humidifiers)
Acute viral respiratory illness or pneumonia	Humidifier fever, organic dust toxic syndrome, metal fume fever, polymer fume fever, cotton dust fever	Exposure triggers the episodes
Sarcoidosis	Chronic beryllium disease	History of exposure to beryllium dust or fumes up to 30 years or more before onset of disease
	Silicosis	History of exposure; typical radiographic findings of rounded opacities with upper lobe predominance and progressive massive fibrosis, biopsy
Idiopathic pulmonary fibrosis	Asbestosis	History of moderate or high previous asbestos exposure and appropriate latency period, often with other markers of asbestos exposure, such as radiographic evidence of pleural plaques
	Chronic hypersensitivity pneumonitis	± Work exposure to a known trigger, ± improvement during periods away from exposure
	Flock-worker's lung	Lymphocytic bronchiolitis and interstitial lung disease from nylon/synthetic textile microfibers
Idiopathic pulmonary fibrosis or hypersensitivity pneumonitis	Hard metal disease	History of exposure to hard metal (tungsten, cobalt), and histologic findings of giant cell pneumonitis on lung biopsy
Chest infections	Occupational causes of chest infections, e.g., SARS or TB in health care workers, histoplasmosis in construction workers, anthrax in wool workers or farmers	History of occupation and exposures
Pleural effusion	Asbestos-related benign pleural effusion	Previous asbestos exposure with appropriate latency; pleural plaques commonly present
Incidental pulmonary nodule	Rounded atelectasis from asbestos	Previous asbestos exposure with appropriate latency; pleural plaques commonly present
Multiple nodules	Silicosis or pneumoconiosis	History of exposure, distribution of nodules, presence of progressive massive fibrosis
Lung cancer	Occupational lung cancer	History of exposure to carcinogens at work, with an appropriate latency period (e.g., asbestos, radon, chromium)
Bronchiolitis obliterans	Popcorn lung	History of working with microwave popcorn or flavorings

COPD = chronic obstructive pulmonary disease; SARS = severe acute respiratory syndrome; TB = tuberculosis.

sensitization to the high-molecular-weight allergens, and smoking (Chapter 31) has been reported as a risk factor for sensitization to complex platinum salts. Currently, no host factors are sufficiently specific to justify exclusion of workers from settings with exposure to potential sensitizers.

Occupational asthma from a high-molecular-weight allergen is associated with specific immunoglobulin E (IgE) antibody production. Low-molecular-weight sensitizers may act as haptens or may induce neoantigens by reacting with proteins in vivo, but specific IgE antibodies have been demonstrated with only a few low-molecular-weight sensitizers, such as complex platinum salts and acid anhydrides used in epoxy compounds.

CLINICAL MANIFESTATIONS

Sensitizer-induced occupational asthma has a latency period ranging from weeks to several years before it develops, but most patients develop symptoms within the first few years of exposure. Once a patient has become sensitized and has developed asthma, even very small subsequent exposures can trigger asthma, sometimes including exposures that may be below the limit of measurable detection. Pulmonary function and histologic changes are similar to those in nonoccupational asthma (Chapter 87). Sensitizer-induced occupational asthma from a high-molecular-weight agent sensitizer typically causes a prompt asthmatic response within minutes after exposure with or without a late asthmatic response starting 4 to 6 hours after exposure. By comparison, responses to low-molecular-weight sensitizers typically start 4 to 6 hours after exposure.

DIAGNOSIS

The diagnosis of sensitizer-induced occupation asthma is clinically suspected by history and should be considered in all cases of new-onset asthma in patients who work. Supportive features include symptomatic improvement when away from work, such as weekends off work or holidays, but not necessarily in the evenings after a work shift, when symptoms from a late asthmatic response may occur. In patients who are exposed to high-molecular-weight sensitizers, allergic rhinitis or conjunctivitis associated with work frequently appears before the development of asthma. A detailed occupational history (Chapter 18) or review of material safety data sheets or occupational hygiene reports may reveal a known occupational sensitizer. However, more than 300 occupational respiratory sensitizers are currently known, and new agents or exposures are reported each year; as a result, the absence of a recognized sensitizer does not exclude occupational asthma.

Although the history can be very helpful, the evaluation should always include objective pulmonary function testing (Chapter 85) to confirm asthma, either when the patient has symptoms or within 24 hours of the typical suspected work exposure (Fig. 93-1). Allergy skin-prick tests, blood samples, or both should be obtained to test for specific IgE antibodies to any relevant sensitizer if feasible. Serial monitoring of peak expiratory flow rates, symptom diaries, or use of rescue inhalers can provide supportive information. The results of a methacholine challenge test (Chapter 87) toward the

TABLE 93-2 COMMON CAUSES OF SENSITIZER-INDUCED OCCUPATIONAL ASTHMA

OCCUPATION	ALLERGEN BY SETTING
Bakers	Wheat, rye, fungal amylase in flour
Laboratory workers	Animal allergens, e.g., proteins in rat urine, mouse or rabbit dander
Detergent-making, medical instrument cleaning, pharmaceuticals or laboratory workers	Enzymes: e.g., *Bacillus subtilis*, pancreatic enzymes
Farmers	Grains, plant, and animal allergens; mites
Greenhouse workers and florists	Pollen, fungi, mites
Food workers	Airborne food allergens, e.g., powdered milk or eggs and vegetables
Some office workers	Fungal allergens in moldy or "sick" buildings
Health care workers	Latex allergens from gloves, glutaraldehyde, orthophthaldehyde, aerosolized medications
Factory or other industrial workers	Chemicals in spray paints, glues, polyurethane, coatings and spray insulation, adhesives
Electronic workers	Soldering flux with colophony

end of a typical work week can help when compared with results after 10 days or more without exposure. A comparison of eosinophil counts in induced sputum at work and after a period away from exposure, showing higher levels when exposed, provides supportive diagnostic information. If the diagnosis is still in doubt, a carefully controlled specific inhalation challenge with the suspected workplace sensitizer can be performed. Each investigation can be falsely positive or negative, so a combination of investigations is advised while the patient continues to work until the diagnosis is confirmed. Given the specialized nature of many of these studies, consultation with a specialist is recommended. The main differential diagnosis for patients with confirmed asthma is the coincidental onset of asthma with subsequent work-exacerbated asthma. Other conditions, such as vocal cord dysfunction, may explain symptoms or may coexist with asthma and confound the diagnosis.

TREATMENT AND PREVENTION

Rx

The optimal management of patients with sensitizer-induced occupational asthma includes complete removal from further exposure to the sensitizer and cross-reacting agents combined with the usual pharmacologic approach to the treatment of asthma (Chapter 87) and advocacy for appropriate workers' compensation. Consideration of the other exposed workers typically includes communication with the workplace or public health officials, in the hope that measures may be instituted to protect other workers from similar exposures and symptoms. Recommendations for primary prevention have been to reduce exposures to occupational sensitizers as far as possible, removing unnecessary sensitizing agents (e.g., removing high-powdered and high-protein latex gloves) and limiting exposures to sensitizers with occupational hygiene measures. Ongoing medical surveillance measures in the workplace may also be of value.

PROGNOSIS

Outcome is best if an early diagnosis results in removal from further exposure while asthma is relatively mild. Improvement may continue to occur up to 10 years after removal from exposure, but asthma does not completely resolve in most patients. For patients with occupational asthma from natural rubber latex, use of powder-free, low-protein latex gloves by coworkers and direct avoidance of natural rubber products by the sensitized worker results in improvement that is similar to the improvement in patients who are completely removed from work.

Work-Exacerbated Asthma

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Work-exacerbated asthma is defined as asthma that is not caused by work but is aggravated or exacerbated by work conditions. Asthma may have been present before starting employment or may begin coincidentally during employment, but it is not caused by work. Work exposures that commonly exacerbate asthma include extreme temperature or humidity, exertion, dusts, fumes, and gases. Patients may be exposed at work to common environmental allergens (e.g., fungal allergens in an office setting or dust mites or animals in domestic settings) that exacerbate asthma in patients who are sensitized to these allergens. Symptoms of work-exacerbated asthma may occur transiently with an unusual work exposure (e.g., during renovation in a work building) or may occur on a daily basis (e.g., daily exposure to fumes while performing physical exertion in an industrial setting).

DIAGNOSIS AND TREATMENT

Rx

Transient work-exacerbated asthma is commonly diagnosed on the basis of the history of work exposures and the associated increase in asthmatic symptoms, medication requirements, or unscheduled physician visits. The recommended evaluation of patients with daily or frequent work exacerbations of asthma is similar to that for patients with suspected occupational asthma. Work-related changes in serial peak flow recordings mimic those seen in occupational asthma, but sputum eosinophil counts typically show less of a work-related increase than is observed with occupational asthma. If the workplace exposure includes a potential work sensitizer, immunologic testing or a controlled challenge exposure may confirm whether respiratory sensitization has occurred.

Management includes the same pharmacologic measures as for non-work-related exacerbations, including the optimization of pharmacologic asthma management (Chapter 87) and, when needed, adjusting the work exposures to avoid ongoing exacerbations. Occupational hygiene measures can reduce exposures, but some patients require a change in job description or work area. Workers' compensation may be available for some patients who miss work owing to work-exacerbation of asthma.

IRRITANT EXPOSURE AND REACTIVE AIRWAYS DYSFUNCTION SYNDROME

A high level of usually accidental exposure to an irritant agent can cause asthma. Although the clinical manifestations can be dramatic, irritant-induced occupational asthma represents a relatively small proportion of all occupational asthma. The most definitive criteria for this condition are those applied to the term *reactive airways dysfunction syndrome*: the onset of asthma symptoms within 24 hours of the exposure, generally severe enough to lead to an unscheduled physician visit; exposure to a single high-level irritant; asthma symptoms that persist for at least 3 months; pulmonary function testing that confirms asthma with a significant beneficial response to bronchodilators or a bronchoconstrictor response to a methacholine challenge; and the lack of preexisting lung disease or other conditions to explain the symptoms. When these criteria are not completely met (e.g., symptoms start later than 24 hours after exposure or resolve within weeks after exposure), the term *irritant-induced asthma* is commonly applied, recognizing that this diagnosis is less certain than reactive airways dysfunction syndrome.

Irritant-induced asthma and reactive airways dysfunction syndrome may clear after weeks or months. Management is the same as for other causes of asthma (Chapter 87), although these patients are often less responsive to the usual pharmacologic treatment.

Occupational hygiene measures at the workplace should be improved to prevent similar future exposures. Affected patients may need a modified work environment to prevent subsequent exacerbations of asthma.

OCCUPATIONAL CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic exposure to dusts, fumes, and gases can cause occupationally induced COPD, with pathophysiologic changes essentially identical to those seen in COPD that is related to smoking (Chapter 88). Symptoms of chronic bronchitis, including chronic cough and sputum production, may occur with or without changes on pulmonary function testing. Causes include mineral dusts such as silica and organic dust exposures such as those of farmers and woodworkers; particulate matter in diesel exhaust fumes; and nitrogen oxides, ozone, and ultrafine particles in welding fumes.

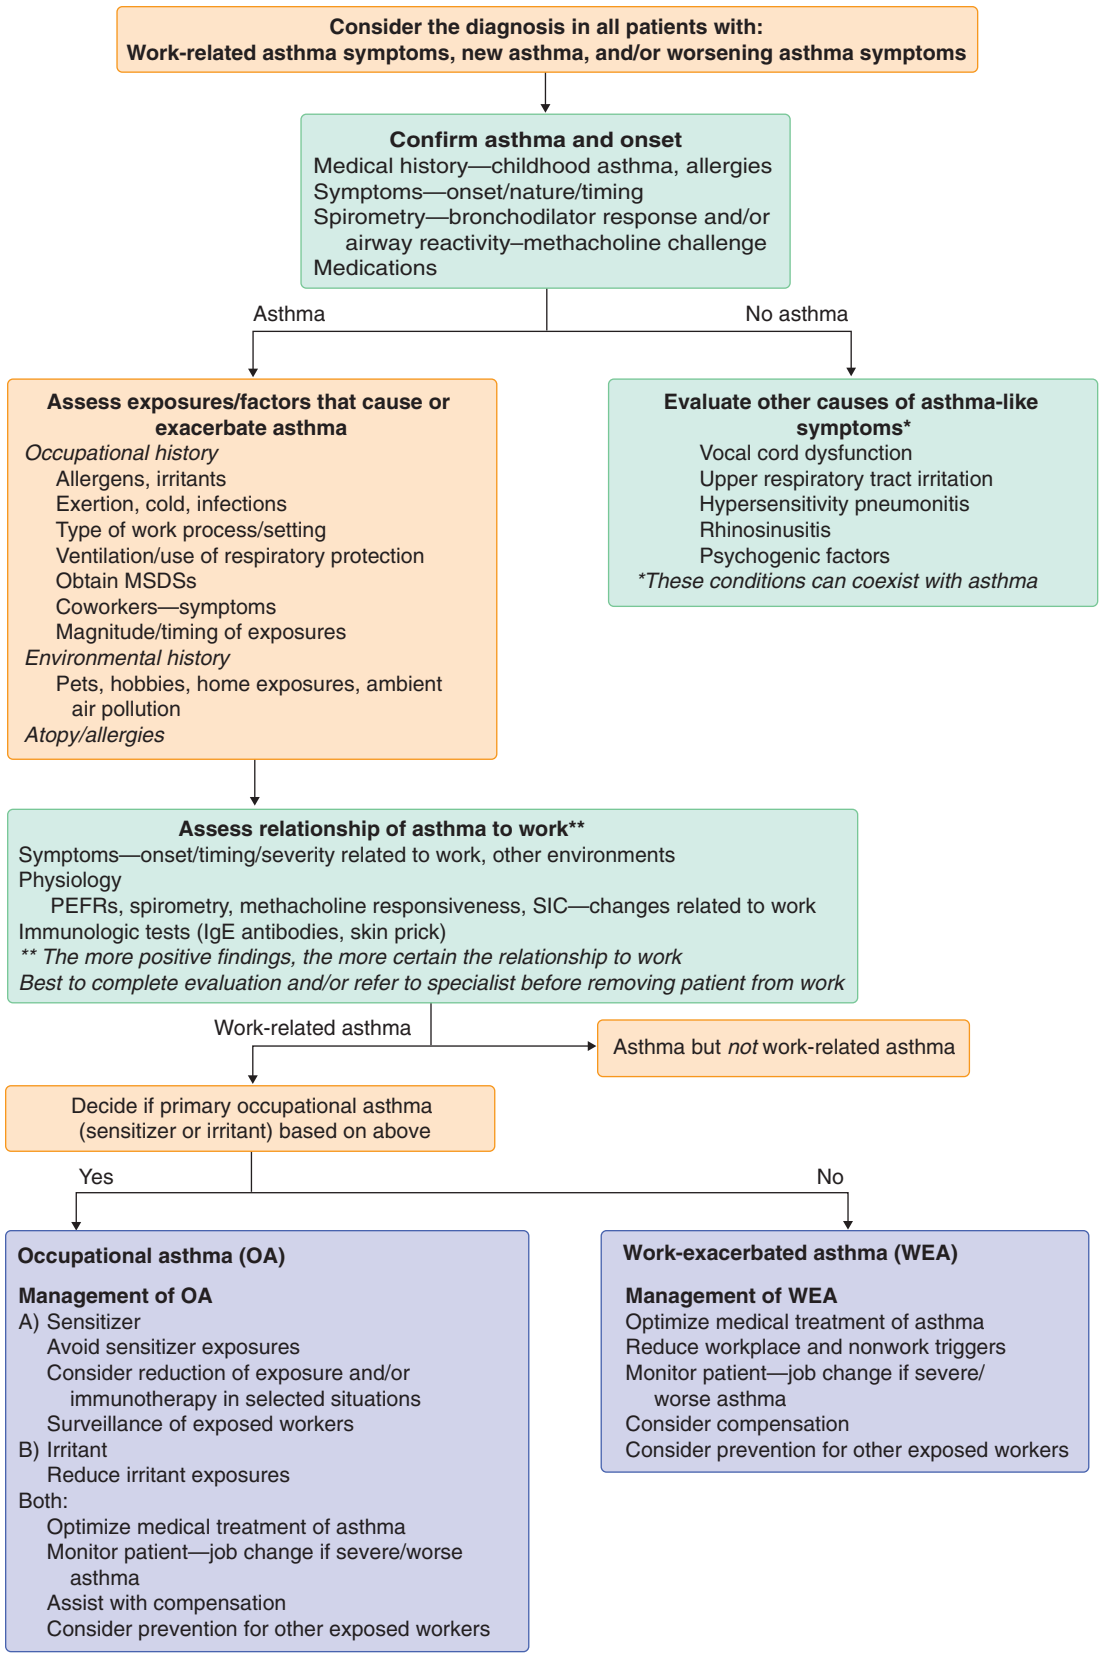

FIGURE 93-1. Clinical evaluation and management of work-related asthma. IgE = immunoglobulin E; MSDS = Material Safety Data Sheets; PEFR = peak expiratory flow rates; SIC = specific inhalation challenge. (From American College of Chest Physicians. Consensus statement: diagnosis and management of work-related asthma. *Chest.* 2008;134:1S-41S.)

No specific diagnostic tests distinguish an occupational from a nonoccupational cause of COPD. The history of exposure, with objective documentation, is helpful. Confirmation of the absence of a smoking history can assist in determining probability of an occupational cause, but a positive smoking history does not exclude an occupational contribution.

Management is the same as for patients with nonoccupational COPD (Chapter 88). In addition, however, further exposure to dusts, fumes, and gases that are likely to worsen disease should be minimized.

HYPERSENSITIVITY PNEUMONITIS

Many exposures that lead to hypersensitivity pneumonitis (Chapter 92) occur in the workplace, and several bear the name of the occupation or job associated with them: farmer's lung; maple bark stripper's lung; cheese washer's lung; thatcher's lung; mushroom worker's lung, and metal-working fluid hypersensitivity pneumonitis (Table 93-3). Occupational causes also include exposure to contaminated humidifiers (with protozoa or fungi) in factories

TABLE 93-3 EXAMPLES OF OCCUPATIONAL CAUSES OF HYPERSENSITIVITY PNEUMONITIS

OCCUPATION	CAUSE
Farmer	Thermophilic actinomycetes in moldy hay
Metal worker	Contamination of metal-working fluids with microorganisms such as *Mycobacteria immunogens* or fungi
Worker exposed to humidifiers	Contamination with microorganisms such as protozoa or fungi
Sugarcane worker	Moldy sugarcane (bagassosis)
Maple bark stripper	Fungi
Chicken or turkey worker	Avian proteins
Pharmaceutical worker	Penicillin
Food handler	Soybeans
Office worker	Microorganisms contaminating air conditioners or humidifiers
Swimming pool attendant	Fungal contamination in sprays around pool area
Animal worker	Rat proteins
Mushroom worker	Fungi
Wheat farmer or handler	Weevil-infested flour
Greenhouse worker	Fungi
Workers spraying urethane paint or adhesives/sealants (or less often, other workers using diisocyanate)	Methylene diphenyl diisocyanate, hexamethylene diisocyanate, toluene diisocyanates
Chemical worker using plastics, resins, paints	Trimellitic anhydride

or office buildings (humidifier lung), as well as lifeguards exposed to sprays of water from pool fountains contaminated with microorganisms. Metal workers or machinists can develop hypersensitivity pneumonitis from recirculated coolants that can become contaminated with gram-negative bacteria or atypical mycobacteria, which then are aerosolized in the coolant mist and inhaled.

PATHOBIOLOGY

Most antigenic exposures that lead to hypersensitivity pneumonitis are organic, especially thermophilic actinomycetes (Chapter 337), fungi, atypical mycobacteria (Chapter 333), and protozoa. Other common antigens include avian and rat proteins. Less commonly, hypersensitivity pneumonitis can be induced by low-molecular-weight chemical antigens, such as penicillin or methylene diphenyl diisocyanate (MDI), which is used as a sealant or binder. Small particles, commonly 3 to 5 μm in mass median aerodynamic diameter, reach the small airways and alveoli, where the immune response leads to hypersensitivity pneumonitis. This immune response is associated with specific IgG antibodies and T lymphocytes, and it recurs with repeated exposures.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The acute form of disease manifests as cough, dyspnea, chills, and malaise, typically 4 to 8 hours after exposure and clearing by 12 to 24 hours. On examination, patients typically are febrile and tachypneic, with reduced chest expansion and basal crackles. Neutrophilia is common, and the chest radiograph shows acute infiltrates. Pulmonary function testing may show a restrictive pattern, with a reduced diffusing capacity, and arterial blood gases may show hypoxemia owing to ventilation-perfusion mismatch.

Chronic hypersensitivity pneumonitis may follow repeat acute episodes or start de novo. It causes a chronic dry cough, progressive dyspnea, and often significant weight loss. The physical examination typically reveals reduced chest expansion and basal crackles. Results on pulmonary function testing and radiographic findings may be similar to nonspecific idiopathic pulmonary fibrosis (Chapter 92), and ground-glass opacities are often seen on a computed tomography (CT) scan of the chest. Bronchoalveolar fluid typically shows an increase in the lymphocyte count, and there may be a predominance of CD8 T lymphocytes (Chapter 85).

The specific occupational cause for hypersensitivity pneumonitis may be suspected from a temporal relationship to work exposures. The differential diagnosis in the chronic form includes idiopathic pulmonary fibrosis, although clubbing is less common in hypersensitivity pneumonitis. Radiographic and pulmonary function test findings may also mimic idiopathic pulmonary fibrosis, but a distinguishing finding is often a bronchoalveolar lavage that shows lymphocytes as high as 60 to 80% of the cells, usually with a predominance of $CD8^+$ T lymphocytes, but sometimes with $CD4^+$ cells in chronic forms of disease.

Laboratory investigations include determining the presence of serum IgG antibodies to the suspected antigen. However, IgG antibodies may also be present in exposed individuals who do not have disease and are therefore not specific to the diagnosis. Conversely, failure to demonstrate specific antibodies is not uncommon in hypersensitivity pneumonitis because the limited number of antigens used for testing may not include the relevant occupational antigen. Specific challenge with the suspected antigen in a laboratory setting is occasionally needed if the diagnosis is in doubt.

Some patients can safely undergo "work challenge" that monitors changes in symptoms, fever, blood neutrophil count, radiographic findings, and pulmonary function with and without exposure to the suspected agent. Lung biopsy, if performed, may show granulomas and foreign body giant cells. If other findings are supportive of hypersensitivity pneumonitis, however, open biopsy and challenges usually are not needed.

TREATMENT AND PROGNOSIS

Rx

Treatment principles are the same as for nonoccupational hypersensitivity pneumonitis (Chapter 94). Removal from exposure to the causative agent is the primary treatment measure. As with occupational asthma from a sensitizer, the removal must be complete and often requires a change in work if the causative agent cannot be removed. Reduction of exposure by use of respiratory protective devices is generally not practical and not effective, with the exception of air-supplied helmet respirators for occasional short-term exposures. Patients with acute hypersensitivity pneumonitis may not require any medications in addition to removal from antigen exposure, but if acute episodes are severe, they may need supportive measures, including corticosteroids (e.g., 20 to 60 mg of prednisone orally per day), supplemental oxygen, and intensive care (Chapter 94). Chronic hypersensitivity pneumonitis may require additional oral corticosteroid treatment (e.g., 5 to 10 mg of prednisone orally per day) as for nonoccupational chronic hypersensitivity pneumonitis, and severe end-stage fibrosis may lead to need for lung transplantation. Prognosis is better with early diagnosis and complete removal from exposure to the causative agent. Preventive measures include occupational hygiene measures to avoid contamination of aerosolized fluid or dusts with bio-organisms and use of appropriate respiratory protective devices.

CHRONIC BERYLLIUM DISEASE

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute toxic pneumonitis was described in workers who had high exposure to beryllium in the manufacture of fluorescent lightbulbs in the 1940s, and a hypersensitivity response causing chronic beryllium disease was described in the 1950s. Acute toxic effects are now rare, but chronic beryllium disease remains a problem because of the expanded use of beryllium (Table 93-4) and better recognition of sensitization by development of an immunologic blood test.

Chronic beryllium disease is a hypersensitivity disease with a strong genetic association with HLA-DPB1 gene variants that code for Glu69 and that have been identified in 83 to 97% of patients with disease. However, this gene variant occurs in 30 to 48% of the general population and, as a result, is not useful as a screening test.

CLINICAL MANIFESTATIONS

The pulmonary clinical features of chronic beryllium disease are similar to those of sarcoidosis (Chapter 95), ranging from asymptomatic histologic or radiographic findings, to potential progression, to severe granulomatous restrictive lung disease. Onset can occur up to 20 years or more after exposure to beryllium, even if the patient no longer is exposed. The clinical history in all patients with apparent sarcoidosis must include inquiry about possible beryllium exposure, even many years ago.

DIAGNOSIS AND TREATMENT

Rx

The chest radiograph shows changes that appear identical to sarcoidosis with enlarged hilar or mediastinal lymph nodes or multiple lung nodules, or both (Fig. 93-2). Sensitization to beryllium can be detected by a beryllium lymphocyte proliferation test that demonstrates the presence of sensitized lymphocytes in blood or bronchoalveolar lavage fluid. This test also can detect sensitization to beryllium among asymptomatic exposed workers, who can then be evaluated to assess possible chronic beryllium disease and provided with advice for reducing or eliminating further work exposures.

After disease develops, removal from exposure is advised, but the disease may still worsen. Progressive deterioration in lung function is treated similarly to sarcoidosis (Chapter 95), with oral corticosteroids and supportive measures.

ASBESTOS-RELATED DISEASES

Although the use of asbestos has declined, and better protective equipment has been mandated, asbestos-related disease has continued to occur owing to the long latency between exposure and disease. Chrysotile asbestos has less effect on the lungs than other forms of asbestos, that is, amphiboles. Effects of exposure include benign and malignant disease.

Benign asbestos disease is often asymptomatic and identified on chest imaging. Pleural thickening and pleural plaques, commonly with calcification, can occur 20 to 30 years after first exposure and may initially appear on the chest radiograph as calcified linear opacities over the hemidiaphragms and cardiac border (see Fig. 84-10 in Chapter 84). If extensive, it may be difficult to exclude intrapulmonary opacities except by CT scan. Pleural plaques are a marker of asbestos exposure but do not occur in all workers with significant asbestos exposure. They generally do not cause significant changes in lung function, except diffuse pleural thickening may result in exertional dyspnea and extrapulmonary restrictive lung disease. Pleural thickening may cause rounded atelectasis (Chapter 90) when encasement of a portion of the peripheral lung tissue by thickened pleura causes an apparent lung nodule, typically with a "comet sign" showing the thickened pleura. Benign pleural effusion can develop, typically about 10 to 15 years after asbestos exposure. It requires further investigation because the differential diagnosis includes malignant pleural effusion (Chapter 99).

Asbestosis is the term for interstitial lung disease caused by asbestos. The clinical presentation is usually with dry cough and dyspnea on exertion. Physical examination usually reveals digital clubbing and basal crackles on lung auscultation. Chest imaging shows basal interstitial lung disease, with or without additional pleural changes as described earlier. Pulmonary function testing shows restrictive lung disease (Chapter 85), and histologic findings are the same as in usual interstitial pneumonia (Chapter 92). Findings supporting the diagnosis of asbestosis rather than usual interstitial pneumonia include a significant duration and level of exposure to asbestos, an appropriate latency of usually 20 to 40 years after first exposure, and the finding of ferruginous asbestos bodies in sputum or lung tissue (Fig. 93-3). Unfortunately, pharmacologic treatment is not effective, and the lung disease may progress to end-stage fibrosis. Management is supportive, including supplemental oxygen and consideration for lung transplantation (Chapter 101). As with the other diseases of long latency, preventing exposure is paramount.

Mesothelioma (Chapter 197), a malignant tumor of the pleura, peritoneum, or both, is the one complication of asbestos exposure that can occur after even relatively minor exposure, such as second-hand exposure from dust on clothing in the families of those working with exposure. It typically occurs 30 to 40 years after exposure to asbestos and may present incidentally on chest imaging or with chest pain or weight loss. Radiographs show pleural thickening, and a pleural effusion may be present. Mesothelioma often is difficult to distinguish from benign pleural thickening without a biopsy. No treatment has proved effective (Chapter 197), so routine screening to detect mesothelioma in exposed persons is not currently recommended. The risk of lung cancer (Chapter 197) increases after significant exposure to asbestos, with a usual latency period of 20 to 30 years. Smoking and asbestos exposure have multiplicative effects on the risk of lung cancer.

TABLE 93-4 POTENTIAL EXPOSURES TO BERYLLIUM

OCCUPATIONAL EXPOSURES
Metal and alloy production (alloys of aluminum, copper, and nickel; recently includes golf clubs and metal pen clips)
Ceramic manufacturing
Metal casting, including dental technicians (crowns, bridges)
Electronics, including computer components, transistors, microwave and x-ray windows, heat sinks, telecommunications
Aerospace and atomic engineering (rocket fuels, heat shields, nose cones, and metal parts)
Aircraft manufacture and repair
Nuclear reactors, nuclear weapons and defense industry
Coating of cathode ray tubes for radar and similar installations
Laboratories
Extraction from ore
Metal reclamation and recycling
NONOCCUPATIONAL EXPOSURES
Family members exposed to dust from workers' clothing
Breakage of old fluorescent lamps (made before 1950 in North America)
Downwind exposure from industrial accidents (e.g., from a nuclear processing plant in Kazakhstan, in the former Soviet Union in 1990)

From Tarlo SM, Rhee K, Powell E, et al. Marked tachypnoea in siblings with chronic beryllium disease due to copper-beryllium alloy. *Chest.* 2001;119:647-650.

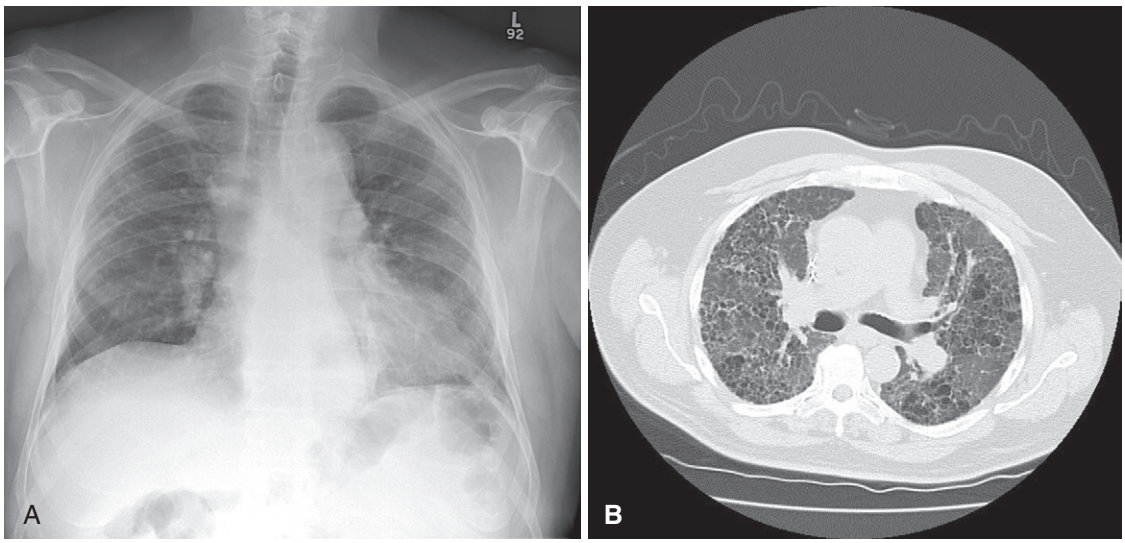

FIGURE 93-2. Posteroanterior chest radiograph (A) and high-resolution computed tomography scan (B) from patients with chronic beryllium disease. The chest radiograph demonstrates hilar adenopathy and infiltrates, and the scan shows air space destruction and infiltrates.

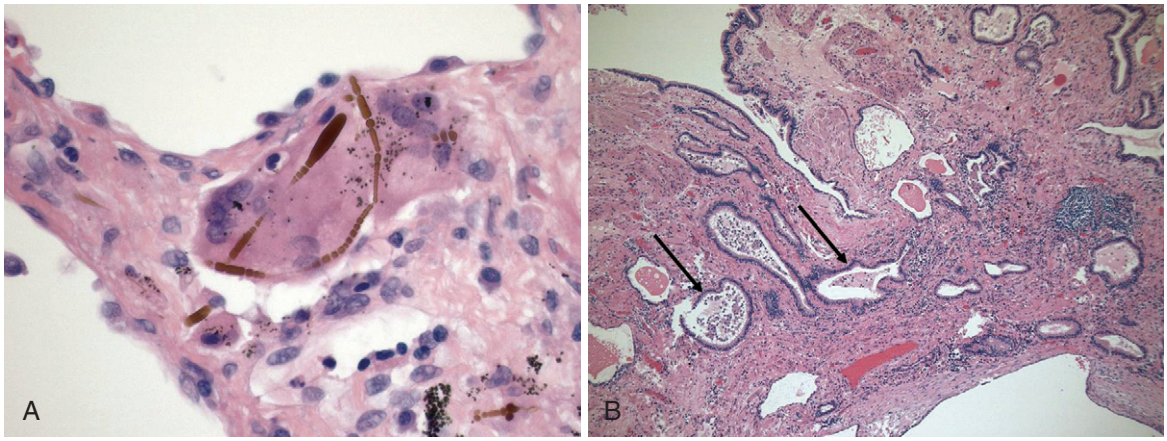

FIGURE 93-3. Histology from a lung biopsy showing asbestos bodies. Ferruginous bodies consisting of asbestos fibers coated by iron-protein-mucopolysaccharide material with typical golden-brown, beaded appearance. The two longest asbestos bodies at the centre of the figure are present within a multinucleated giant cell. (Hematoxylin and eosin stain, × 400). (Courtesy of Dr. David Hwang, Toronto General Hospital.)

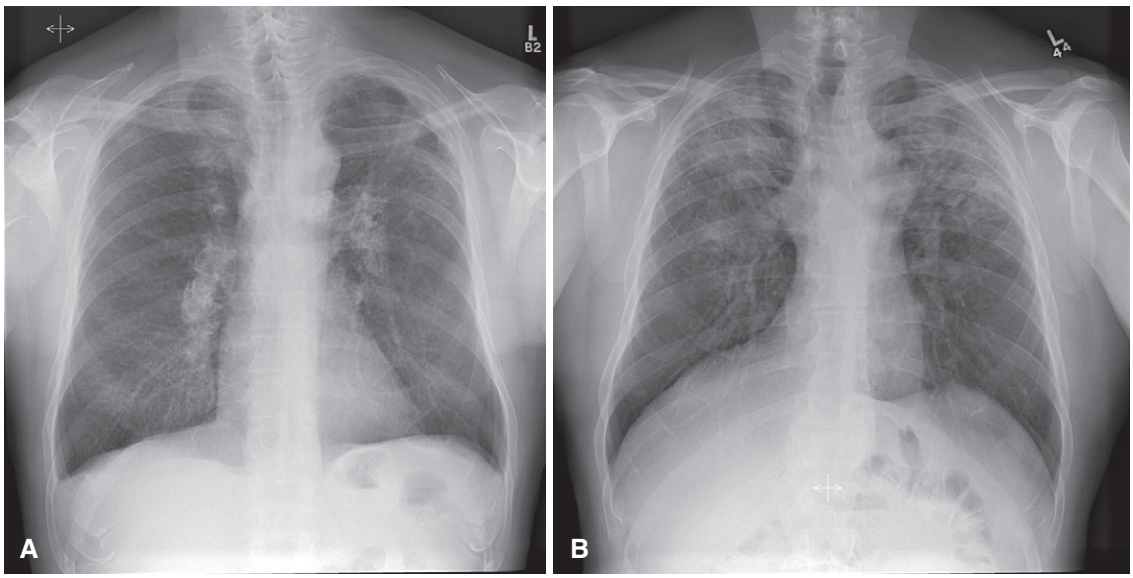

FIGURE 93-4. Posteroanterior chest radiographs from two patients with silicosis. A, Small nodules and eggshell calcification of hilar lymph nodes. **B**, Progressive massive fibrosis of the upper lung zones with compensatory emphysema.

SILICOSIS AND OTHER PNEUMOCONIOSES

The incidences of silicosis and other inorganic dust diseases of the lungs (Table 93-5) have declined substantially in recent decades owing to better worksite protection in mines, sandblasting, and other settings. There is an association between silicosis and the development of collagen-vascular disease, especially rheumatoid arthritis. Patients with pneumoconiosis and rheumatoid arthritis may be at higher risk of developing rheumatoid nodules in the lung, so-called Caplan's syndrome, and mycobacterial infections.

Patients may initially be identified incidentally during a medical surveillance program or by a chest radiograph that shows multiple small lung nodules, often with enlarged mediastinal lymph nodes that can mimic sarcoidosis (Fig. 93-4). Nodules can coalesce and lead to progressive massive fibrosis, especially in the upper lungs, with compensatory emphysema in the lower lung fields. On chest imaging, mediastinal lymph nodes may have a characteristic "eggshell" calcification in silicosis. Treatment is supportive. Patients with exposure to silica or coal dust may develop COPD from the dust exposure. Patients who develop end-stage lung disease may be considered for lung transplantation.

TABLE 93-5 JOBS THAT CAN LEAD TO SILICOSIS

Mining: surface or underground mining (tunneling)
Milling: ground silica for abrasives and filler
Quarrying
Sandblasting: e.g., of buildings, preparing steel for painting
Pottery; ceramic or clay work
Grinding, polishing using silica wheels
Stone work
Foundry work: grinding, molding, chipping
Refractory brick work
Glass making: to polish and as an abrasive
Boiler work: cleaning boilers
Manufacture of abrasives

ACUTE FEBRILE SYNDROMES

A variety of occupational exposures can cause acute febrile respiratory syndromes that may mimic acute viral respiratory illnesses (Table 93-6). The mechanism of these syndromes is incompletely understood, but they are associated with systemic neutrophilia and cytokine activation, often with increased interleukin-6 (IL-6) and IL-8.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Typically, chills, fever, malaise, dry cough, and chest tightness start about 6 to 8 hours after onset of an exposure at work and generally resolve by the next day. Occasionally, shortness of breath and other respiratory symptoms are

TABLE 93-6 OCCUPATIONAL CAUSES OF AN ACUTE FEBRILE SYNDROME

SYNDROME	CAUSE
Polymer fume fever or Teflon fever	Polytetrafluoroethylene and other fluorocarbon polymer fumes
Metal fume fever	Zinc fumes from welding of galvanized steel, less commonly other metal fumes
Cotton mill fever	Dust and endotoxins from bacterial contamination of unprocessed cotton, flax, and hemp
Humidifier fever	Microorganisms found in reservoirs, e.g., humidifiers, air conditioners, aquariums
Organic dust toxic syndrome	Grain dust, moldy wood chips

severe enough for patients to seek emergency medical attention. Infiltrates on the chest radiograph can occur with neutrophilia and hypoxemia that can mimic acute pneumonia or acute hypersensitivity pneumonitis. Symptoms and signs generally resolve in 24 to 48 hours without antibiotics and recur with further exposures, although the clinical manifestations generally become milder with repeated daily exposures (e.g., Monday morning fever in cotton mill workers). Workers are often familiar with the syndrome because it commonly affects up to 30% of exposed workers. If the diagnosis is not provided by the patient, however, careful elicitation of potential work exposures is needed.

TREATMENT

Rx

Treatment is supportive. If the causative exposure can be removed (e.g., cleaning a contaminated humidifier), symptoms can be prevented. If the cause cannot be removed and symptoms are severe, the patient may need reduction or change of the work exposure.

OCCUPATIONAL LUNG CANCER

A significant duration and level of exposure to a recognized carcinogen such as asbestos, hexavalent chromium (as in chromate production and the pigment industry), soluble radon compounds or radon gas, polycyclic aromatic hydrocarbons, chloromethyl ethers, arsenic, or silica can increase the risk of lung cancer (Chapter 197). Such a history should be elicited in all patients. The International Agency for Research on Cancer provides a listing of occupational lung carcinogens and the likelihood of their association with cancer (*http://monographs.iarc.fr/ENG/Monographs/PDFs/index.php*).

PHYSICAL AND CHEMICAL INJURIES OF THE LUNG

DAVID C. CHRISTIANI

SUBMERSION INCIDENTS: DROWNING

DEFINITION

Drowning is defined as "the process of experiencing respiratory impairment from submersion/immersion in liquid." The term *near-drowning* was previously used to describe individuals who survived a submersion incident, at least temporarily, but it has been abandoned on the basis of recommendations of the First World Congress of Drowning in Amsterdam in 2002.

EPIDEMIOLOGY

The estimated annual number of deaths worldwide due to drowning is 500,000. About 4200 persons are treated per year for nonfatal drowning in U.S. emergency departments, and about another 3400 suffer fatal drowning. Alcohol use, age younger than 4 years, and male gender are associated with increased rates of both nonfatal and fatal drowning.

PATHOBIOLOGY

The initial response to submersion/immersion is apnea, followed almost invariably by aspiration. Laryngospasm may result in aspiration of a variable quantity of liquid medium into the lungs. Hypoxemia, hypercapnia, and acidemia develop acutely. Aspiration of either fresh or salt water results in occlusion of the airway, reduced surfactant activity, direct alveolar injury, and bronchospasm. Acute lung injury or the acute respiratory distress syndrome (ARDS), associated with noncardiogenic pulmonary edema and severe hypoxemia, may develop hours or days after the incident. Mortality is primarily due to cardiovascular effects as a result of severe early or late hypoxia. The most serious secondary consequence of hypoxia is anoxic brain injury. Acute renal failure may also occur. Alcohol consumption also increases the risk for hypothermia. Changes to serum electrolytes with drowning in either fresh water or salt water are not clinically significant.

CLINICAL MANIFESTATIONS

The initial presentation of a drowning victim varies widely. Hypothermia, which is common in drowning victims, may be associated with bradycardia or cardiac arrest due to asystole or ventricular fibrillation. Tachypnea, tachycardia, and low-grade fever are typical in nonhypothermic patients. Cyanosis may be present, and a coughing patient may produce pink frothy sputum. Neurologic evaluation may reveal agitation with or without intoxication or coma. The patient should be examined carefully for signs of associated trauma.

Expected laboratory findings include mild electrolyte abnormalities independent of whether submersion occurs in salt water or fresh water, moderate leukocytosis, slight decrease in hematocrit in the first 24 hours or slight increase in free hemoglobin with a stable hematocrit in fresh water submersion due to hemolysis, severe hypoxemia, and metabolic acidosis. Evidence of disseminated intravascular coagulation may occur. Initial electrocardiographic changes include sinus tachycardia and nonspecific ST segment and T wave changes, which revert to normal within hours. Life-threatening ventricular arrhythmias, complete heart block, or evidence of myocardial infarction can occur early or late in the course. Chest radiographs may initially be normal, despite severe respiratory impairment. Bilateral patchy alveolar infiltrates indicating progression to acute lung injury or ARDS may develop.

DIAGNOSIS

The diagnosis of drowning is made on clinical history of submersion in liquid medium with resulting respiratory impairment. Patients with unusual presenting circumstances should be carefully examined for evidence of trauma or assault.

PREVENTION

Drowning incidents are largely preventable, particularly in children. Pool fencing is a proven, effective strategy to prevent drowning. The primary cause of drowning of infants and toddlers is lack of adult supervision, and supervision of all young children near any form of water is strongly recommended. The role of alcohol in teenage and adult drowning incidents is substantial, and all individuals participating in water-based activities should restrict alcohol intake. The use of personal flotation devices is recommended for children and adults.

TREATMENT

Rx

Once the victim has been recovered from submersion, treatment should focus on basic life support algorithms, including notification of emergency response personnel and establishment of an adequate airway and cardiopulmonary resuscitation, if necessary (Chapter 63). If the victim is apneic, rescue breathing should occur immediately, even before removal from the water. Cervical spine stabilization is needed if there is a history of diving, use of a water slide, signs of injury, or signs of alcohol intoxication. Spinal cord injury

(Chapter 406) is otherwise unlikely, and cervical spine stabilization techniques and equipment may impede timely and effective treatment. Attempts to remove water from the airway are unnecessary. Cardiac arrhythmias should be treated with Advanced Cardiac Life Support (ACLS) protocols, including the use of automated external defibrillators when appropriate (Chapter 63). Most drowning victims who receive cardiopulmonary resuscitation or rescue breathing will vomit; if vomiting occurs, the head should be turned to the side and the vomitus removed with a finger. When vomiting occurs in patients who may have spinal cord injury, log rolling techniques are recommended for turning the patient to the side.

All victims of a submersion incident should be transported to a hospital for further evaluation, treatment of potential respiratory failure (Chapter 104), and monitoring for up to 24 hours. Bronchoscopy may be required to evaluate localized wheezing or persistent atelectasis. Prophylactic antibiotics are not useful, but evidence of pneumonia (Chapter 97) should be treated with appropriate antibiotics. Because unusual microorganisms may be isolated from the lower airways, efforts should be made to identify specific microbial flora pertinent to the locus of the drowning incident.

Treatment of neurologic injury is focused on supportive care while the extent of cerebral edema is minimized. To decrease cerebral edema and intracranial pressure, intravenous 23% hypertonic saline (30 mL initially then 75 to 100 mL/hour; goal serum sodium level of 155 mM/L) through a central line may be preferred to mannitol (1 g/kg bolus of 20% solution initially, with repeated doses of 0.25 to 0.5 g/kg every 6 to 8 hours). Hyperventilation to a $Paco_2$ of 34 to 36 mm Hg may be helpful. Intracranial pressure may increase in response to shivering or purposeless movements, which should be reduced. Induced therapeutic hypothermia improves neurologic outcome after cardiac arrest (Chapter 109), and current recommendations for drowning victims who remain comatose after rescue are to avoid rewarming to core or tympanic temperatures above 34° C and to maintain temperature of 32° to 34° C for 24 to 48 hours. Hyperthermia should be avoided at all times.

PROGNOSIS

The mortality rate for drowning victims who present alive to an emergency department is about 25%. Long-term neurologic deficits persist in approximately 6% of nonfatal drowning victims. Although prolonged duration of submersion is associated with a worse prognosis, young children who are hypothermic when they are rescued after submersion times of up to 60 minutes have recovered without neurologic damage. Other factors associated with poor prognosis include hypotension, persistent apnea, coma, more than a 10-minute delay in receiving basic life support, and duration of resuscitation of more than 25 minutes.

DISEASES OF HIGH ALTITUDE

DEFINITION

Neurologic and pulmonary disturbances, primarily due to direct tissue effects of hypoxia, occur in individuals who either ascend to or reside at altitudes of 7000 feet (2133 meters) or more (Table 94-1).

EPIDEMIOLOGY

Acute mountain sickness is the most common high-altitude syndrome. It occurs in approximately 20% of individuals who ascend to altitudes of 7000 to 9000 feet, 40% at 10,000 to 14,000 feet, and more than 50% above 14,000 feet. The incidence of chronic mountain sickness, also known as Monge's disease, is thought to be between 5 and 18%. More severe neurologic disturbances due to high-altitude cerebral edema are rare, occurring in approximately 1 to 2% of individuals who ascend to altitudes above 15,000 feet. High-altitude pulmonary edema occurs in approximately 2 to 6% of otherwise healthy individuals who ascend to altitudes of 8000 to 15,000 feet. However, the incidence in individuals with a prior history of high-altitude pulmonary edema may be as high as 60%, or higher during rapid ascents. The occurrence of high-altitude retinal hemorrhage is approximately 33% among individuals who ascend to very high altitudes (up to 19,000 feet) and is thought to be common at lower altitudes as well. High-altitude retinal hemorrhage is not associated with high-altitude cerebral edema or long-term visual consequences.

TABLE 94-1 HIGH-ALTITUDE SYNDROMES

SYNDROME	CLINICAL DESCRIPTION
Acute mountain sickness	Recent ascent to altitudes above 7000 feet; headache, anorexia, and malaise; common
Chronic mountain sickness	Dwelling above 10,000 feet; headache, fatigue, dyspnea, and digestive disturbances; incidence: 5-18%
High-altitude cerebral edema	Above 15,000 feet; confusion, ataxia, hallucinations, coma, or death; rare
High-altitude pulmonary edema	Above 9500 feet; dyspnea, cough, and tachycardia; incidence: 2-6%
High-altitude retinal hemorrhage	Above 15,000 feet; asymptomatic or reversible vision changes; common

PATHOBIOLOGY

Clinically significant hypoxemia is the underlying factor in all high-altitude diseases. The decrease in barometric pressure during an ascent to altitude causes a decrease in the alveolar pressure of oxygen (PAO_2). For example, PAO_2 drops from 105 mm Hg at sea level to 60 mm Hg at 10,000 feet and to 40 mm Hg at 18,000 feet. Below 60 mm Hg, oxygen dissociates from hemoglobin more readily (see Fig. 161-2 in Chapter 161), thereby decreasing oxygen saturation and oxygen delivery to tissues. The effect is even more noticeable in individuals with impaired diffusion capacity, for example, emphysema, interstitial lung diseases, or heart failure. Furthermore, increased ventilatory drive induces an acute respiratory alkalosis. In the brain, hypoxia causes cerebral vasodilation, whereas hypobaria causes cerebral vasoconstriction. In severe hypoxia, vasodilation is the likely cause of cerebral edema in susceptible individuals. The response to hypoxia in the lungs is primarily increased pulmonary arterial pressures due to hypoxic pulmonary vasoconstriction, which results in reversible injury to pulmonary capillaries, increased capillary permeability, and eventually pulmonary edema. Reduced oxygen consumption also occurs, perhaps from impaired mitochondrial function in the presence of hypoxia. Periodic breathing during sleep is also noted but has minimal if any clinical significance.

CLINICAL MANIFESTATIONS

Symptoms of acute mountain sickness begin 2 to 3 hours after ascent and include breathlessness, lightheadedness, fatigue, nausea, anorexia, headache, and insomnia. Most symptoms resolve within 2 to 3 days, although insomnia may persist. Chronic symptoms of headache, fatigue, sleep disturbances, dyspnea, and digestive complaints are seen with chronic mountain sickness in individuals residing at higher elevations. Chronic mountain sickness may be associated with polycythemia (hemoglobin concentrations above 21 g/dL). Severe neurologic symptoms with high-altitude cerebral edema include ataxia and confusion that may progress to coma or death. Symptoms of high-altitude pulmonary edema that usually begin 2 to 4 days after ascent to higher altitudes include dyspnea, cough, and tachycardia. Funduscopic changes of flame-shaped hemorrhages are seen with high-altitude retinal hemorrhage.

DIAGNOSIS

Diagnosis of most high-altitude disease is made on the basis of clinical manifestations at high altitude. Diagnosis of chronic mountain sickness, and a milder form often called subacute mountain sickness, is more challenging because it may mimic other cardiopulmonary, neurologic, or psychiatric disease. Individuals with chronic mountain sickness typically have higher hemoglobin concentrations, higher serum erythropoietin levels, higher nocturnal heart rates, lower nocturnal oxygen saturation, and higher systolic and diastolic arterial pressure than normal individuals living at similar altitude.

PREVENTION

Prevention of high-altitude disease can be achieved by avoidance in high-risk individuals, such as young children and persons with a history of high-altitude disease. Gradual ascent and acclimatization are crucial to prevention of high-altitude illness, particularly at extreme altitudes. At altitudes up to 10,000 feet, 2 to 3 days or more may be needed for adjustment to the effects of hypoxia. For mountaineers, current recommendations are to ascend no more than approximately 984 feet (300 m) per day at altitudes higher than 9843 feet (3000 m).

When rapid ascent is unavoidable, such as flights to high-altitude locales, the carbonic anhydrase inhibitor acetazolamide (250 mg orally once or twice daily) provides effective prophylaxis of acute mountain sickness, and 125 mg at night may improve sleep. Dexamethasone (given in doses of 4 mg twice daily) and prednisolone (20 mg daily) have been shown to decrease the

severity of acute mountain sickness. The long-acting β-adrenergic agonist salmeterol (125 μg inhaled twice daily) also reduces the risk for high-altitude pulmonary edema.■ Sumatriptan, 50 mg, after ascent is useful for reducing symptoms.■ The calcium-channel blocker nifedipine (20 mg of slow-release formulation) is useful for preventing recurrent high-altitude pulmonary edema in individuals with previous episodes.

TREATMENT

Rx

For acute, life-threatening symptoms such as high-altitude pulmonary edema and high-altitude cerebral edema, the best treatment is immediate descent, if possible, combined with supplemental oxygen therapy and, if needed, use of a portable hyperbaric chamber. For individuals who develop less severe symptoms, sildenafil (50 mg) can increase exercise capacity at altitude by 10 to 35%.■ Increasing inspired oxygen concentrations in high-altitude working facilities also improves productivity and quality of sleep. Sustained-release theophylline (375 mg twice daily) significantly reduces the symptoms of acute mountain sickness compared with placebo.■ Acetazolamide (250 mg or 500 mg once daily) is also useful in treating symptoms of chronic mountain sickness.■ Milder forms of acute mountain sickness, such as headache, can be treated with typical doses of nonsteroidal anti-inflammatory medications, including aspirin and acetaminophen.

PROGNOSIS

Symptoms of high-altitude disease respond rapidly to immediate descent. However, high-altitude cerebral edema and high-altitude pulmonary edema can be fatal, particularly at extreme altitudes and weather when descent may be impossible.

DECOMPRESSION ILLNESS: DECOMPRESSION SICKNESS, BAROTRAUMA, AND ARTERIAL GAS EMBOLISM

DEFINITION

Exposures to changes in ambient pressure cause a spectrum of illness, either (1) by increasing or decreasing the volume of gas in air-filled body cavities, or (2) by causing the release of inert gas bubbles from solution in tissues or blood vessels. Symptoms associated with decreasing ambient pressure, which occur most commonly with ascent from depth during recreational or occupational diving, are known as decompression illness. The most common form of decompression illness is decompression sickness, which is classified as either type I (mild symptoms, such as general fatigue or joint pain) or type II (more severe neurologic or cardiopulmonary disturbances). Life-threatening forms of decompression illness include pulmonary barotrauma and arterial gas embolism syndromes. During the descent of a dive, increasing ambient pressure may cause mild symptoms of facial or sinus pain, often called "the squeezes."

EPIDEMIOLOGY

In addition to the approximately 9 million recreational divers in the United States, aviators, astronauts, and compressed air workers are also exposed to changes in ambient pressure that may cause decompression illness. Among recreational divers, the annual incidence rate for either type I or type II decompression sickness is estimated at 1 case per 5000 to 10,000 dives. Approximately 1000 episodes of decompression illness severe enough to warrant recompression therapy occur each year, up to 10% of which are fatal. Well-recognized risk factors for decompression illness include long duration of dives, deep dives, repetitive dives, heavy exertion at depth, cold water, and rapid ascent. Additional risk occurs in individuals who experience further decreases in ambient pressure after the dive, such as on commercial or private aircraft or driving over mountainous areas.

PATHOBIOLOGY

The principles of Boyle's law and Henry's law describe the properties of gases during changes in ambient pressure. Boyle's law states that the volume of a gas varies inversely to changes in pressure, $P_1V_1 = P_2V_2$. During the descent of a dive, pain due to the "squeezes" is caused by increasing ambient pressures that are not equalized by an increase in gas volume. The resulting negative pressure causes a vacuum effect in the mask associated with engorgement of the blood vessels in adjacent tissues, such as periorbital and ocular vessels, and may result in swelling, pain, and subconjunctival hemorrhages. Facial sinuses, the middle ear, and the external auditory canal may also be affected.

Barotrauma in sinus, otic, or pulmonary tissues may be due to changes in ambient pressures and the resulting increase or decrease in the volume of gas. During descent, the decreasing volume of gas causes vascular engorgement in the sinuses and otic compartments and may result in rupture of the tympanic or inner ear membranes. During ascent, breath-holding, particularly with compressed air devices (SCUBA diving), and the presence of obstructive lung disease with delayed exhalation times and air trapping impair equilibration and increase the risk for pulmonary barotrauma. If the expanding volume of gas causes a pressure gradient between the alveoli and pulmonary interstitium that exceeds the compliance of the lung, alveolar disruption will lead to pulmonary interstitial emphysema. Further extension of gas along pulmonary tissues may cause additional barotrauma, leading to pneumothorax, mediastinal emphysema, pneumopericardium, and soft tissue emphysema.

Arterial gas embolism, which is a serious consequence of pulmonary barotrauma, results in the development of free gas in the pulmonary arterial circulation. The resulting bubbles may then enter the systemic circulation by overwhelming the filtering mechanism of the pulmonary capillaries or through a right-to-left intracardiac shunt (Chapter 69), such as a patent foramen ovale. Bubbles may then migrate to the brain, spinal cord, heart, lung, or kidney and lead to tissue ischemia or infarct.

Henry's law states that the solubility of a gas in liquid is proportional to the partial pressure of that gas above the liquid. An increase in partial pressure of gases during descent will therefore cause the amount of gas dissolved in the pulmonary capillaries to increase. Dissolved oxygen is used during normal body metabolism; however, inert nitrogen, which is abundant in inspired air, becomes dissolved in the blood and tissues, particularly in fat, where it is five-fold more soluble than in water. During ascent, decreasing ambient pressure causes tissues to become supersaturated with nitrogen, and nitrogen is subsequently released into blood vessels and tissues as gas bubbles. Decompression-induced gas bubbles cause decompression illness by either mechanical compression of tissues or embolization through blood vessels to end organs. Bubbles that obstruct capillaries or venules damage the endothelium and cause tissue ischemia, which leads to activation of inflammatory mediators or tissue reperfusion injury. Although not well understood, toxic effects due to increased partial pressure of gases also are likely to contribute to symptoms of decompression illness, possibly by denaturing of proteins and release of fatty acids from cell membranes.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms of decompression illness can occur within minutes and up to 24 hours or more after exposure to changes in ambient pressure associated with dives of 20 feet in depth or more. The severity of symptoms depends on the rate and the magnitude of the change of ambient pressure and can vary among individuals. Diagnosis is based on clinical manifestations, which can be classified according to whether they are caused by formation of inert nitrogen gas bubbles or the localized toxic effects of gas (associated with decompression sickness), barotrauma associated with descent (sinus or otic barotrauma), barotrauma associated with ascent (pulmonary barotrauma), or more severe arterial gas embolism syndromes.

Symptoms vary according to location of bubble formation. For example, type I decompression sickness, also known as the bends or caisson disease, is typically associated with pain in the joints, from mild to severe, and numbness of the extremities. Rashes and lymphedema may also occur. Symptoms of type II decompression sickness may be systemic (fatigue, hypovolemic shock), cardiopulmonary (cough, substernal chest pain, tachypnea, asphyxia), otic (vertigo, hearing loss), or neurologic (ataxia, aphasia, speech disturbances, incontinence, confusion, personality changes, depression, paralysis, and loss of consciousness).

Otic barotrauma, which typically occurs during descent, can affect the external, middle, or inner ear (Chapter 434). External ear symptoms, such as a sensation of ear fullness or otalgia, are caused by a blockage of the canal, for example, with the use of ear plugs or presence of cerumen. Middle ear symptoms of otalgia, vertigo, tinnitus, transient conductive hearing loss, and facial nerve palsy occur when inadequate equalization of pressures results from blocked eustachian tubes, typically in association with allergic rhinitis or upper respiratory infections. Inner ear barotrauma, which is a more serious form of otic barotrauma, is associated with elevated intracranial pressure and rupture of the inner ear membrane. Inner ear barotrauma causes symptoms of sensorineural deafness, tinnitus, vertigo, nausea, and vomiting. Sinus barotrauma typically occurs during descent, is associated with facial pain and

epistaxis, and occurs more frequently in individuals with mucosal inflammation from allergies or infection.

Pulmonary barotrauma, which is the second leading cause of death among divers, should be suspected in postdive individuals, particularly at-risk individuals, with symptoms of sudden pleuritic pain, dyspnea, or coughing. Physical examination findings include tachypnea, subcutaneous emphysema, and dullness to percussion or decreased breath sounds over a pneumothorax. Development of tension pneumothorax (Chapter 99) or severe pneumomediastinum may lead to decreased venous return of systemic blood and reduced cardiac preload, a situation that is characterized by hypotension and may lead to refractory shock or cardiac arrest. Chest and neck radiographs are recommended for diagnosis, particularly because pneumothoraces must be treated with chest tube thoracostomy before recompression therapy.

Because arterial gas embolism syndromes are caused by pulmonary barotrauma, careful neurologic assessment is critical. The neurologic findings are similar to those of an acute stroke (Chapter 414), with manifestations of focal or unilateral motor deficits, visual disturbances, sensory deficits, speech difficulties, and cognitive disturbances, including loss of consciousness. Symptoms typically occur within 10 minutes after ascent. Delayed neurologic symptoms are more likely to be due to type II decompression sickness.

PREVENTION

Education is the most effective method of preventing decompression illness. Before participation in diving-related activities, all individuals should undergo a thorough and intensive training program. Instruction of proper pressure equalization techniques is critical in the prevention of decompression illness. Persons with asthma who wish to dive should be assessed by a physician (preferably knowledgeable in the field of diving medicine), have no wheezing on physical examination, and have normal spirometry before and after exercise. The presence of structural lung disease (e.g., lung cysts or bullae) is associated with a significant increase in the risk for pneumothorax and is a contraindication to diving. Presence of a known right-to-left intracardiac shunt, such as a patent foramen ovale, is not an absolute contraindication to diving, although conservative diving is recommended, and patients should be cautioned that they are at increased risk for decompression illness.

TREATMENT Rx

Symptoms of decompression illness at altitude should be treated with supplemental oxygen and return to the lowest attainable altitude. Serious decompression illness associated with diving requires immediate medical evaluation by emergency personnel, including basic and advanced life support (Chapter 63) when hemodynamic instability is present. Pneumothorax (Chapter 99) should be treated immediately with needle decompression or chest tube thoracostomy. Symptoms that persist for more than 2 hours or increase in intensity require recompression therapy, preferably with 100% oxygen or transfer to a facility with a hyperbaric chamber, where standard protocols should be followed. Tenoxicam (20 mg daily) decreases the number of recompression treatments needed in divers with decompression illness.■

PROGNOSIS

Survival of patients with decompression illness depends on prompt medical evaluation and treatment. Immediate hyperbaric oxygen therapy per standard protocols is associated with resolution of symptoms in 95% of cases. However, symptoms of decompression illness, even neurologic deficits, may respond to recompression therapy after delays of 24 hours or more.

SMOKE INHALATION

Smoke Inhalation and Thermal Injury

DEFINITION

Pulmonary complications, largely caused by smoke inhalation, occur in a large proportion of burn victims (Chapter 112) and account for a substantial number of deaths in these patients. Even patients who do not sustain surface burns in a fire can inhale sufficient smoke to result in injury to the lungs or airways.

EPIDEMIOLOGY

Modern building codes and the widespread presence of firefighting personnel in communities have decreased the importance of fire as a cause of death in the United States. However, fire continues to cause several thousand deaths annually. Also, larger-scale fires with mass casualties and wildfires that affect large geographic areas still occur occasionally.

PATHOGENESIS

Smoke loses heat rapidly as it traverses the upper airway, so direct thermal injury is often limited to the mucosa of the supraglottic airway. A notable exception is steam inhalation, which can produce thermal injury throughout the airways. Smoke inhalation injury affects the entire respiratory tract. The pathogenesis of smoke inhalation is complicated by the wide variety of pulmonary irritants in smoke, many of which are directly toxic to respiratory epithelial or alveolar cells: aldehydes such as acrolein, acetaldehyde, and formaldehyde; acids such as hydrochloric, hydrofluoric, and hydrocyanic acid; and ammonia, nitrogen oxides, and phosgene.

Irritants can rapidly induce intense neutrophilic inflammation, which evolves during 12 to 24 hours after injury and is characterized by mucosal edema and ulceration, abnormally increased permeability of pulmonary capillaries with resultant capillary leak, and epithelial, alveolar, and immune cellular dysfunction. Bronchospasm or bronchorrhea may occur, and the processes may result in ARDS. In addition, because oxygen is consumed in fires, breathing of hypoxic air for prolonged periods may potentiate other injuries or cause clinically significant hypoxia in its own right.

CLINICAL MANIFESTATIONS

Thermal injury to upper airway mucosa can cause airway compromise, particularly due to laryngeal edema, sometimes rapidly and sometimes after 12 to 24 hours. Burns to the face, mouth, and neck can externally damage and distort structures of the upper airway and cause airway compromise, both subacutely and late in the course. Inhalation injury manifests primarily with bronchospasm and bronchorrhea, which cause cough, dyspnea, or wheezing and may progress rapidly to respiratory failure. Accumulation of secretions, failure of mucociliary clearance and immune mechanisms, and epithelial necrosis predispose to pulmonary infection, particularly 3 to 5 days after injury. Late pulmonary complications can also be caused indirectly by eschar formation and restriction of thoracic motion.

DIAGNOSIS

Patients with apparent or suspected burn injuries (Chapter 112) should be assessed emergently for airway patency. Head or neck burns, respiratory distress, stridor, or visibly erythematous or edematous oral mucosa should prompt immediate laryngoscopic evaluation of the oropharynx and supraglottic airway. Hypoxemia may develop and may be severe enough to meet criteria for ARDS. Chest radiography should be performed serially to detect the evolution of lung injury or superinfection.

TREATMENT Rx

If airway patency is threatened, endotracheal intubation should be performed immediately. Delay can result in increased edema and greater technical difficulty of intubation. Patients who cannot be intubated should have emergent tracheostomy performed surgically. Because of the risk for ARDS, mechanical ventilation with a goal tidal volume of 3 to 6 mL/kg of ideal body weight should be considered. All patients should receive supplemental oxygen with the goal of providing a high fractional concentration of inspired oxygen (FIO_2) to reverse the effects of hypoxia and carbon monoxide inhalation (see later).

Pulmonary toilet is essential to clear secretions in the face of bronchorrhea and epithelial sloughing. Because of the risk for superinfection, surveillance for infection should be vigilant, including diagnostic bronchoscopy if ventilator-associated pneumonia is suspected.

PROGNOSIS

Patients who survive burns and recover generally do not have long-term pulmonary sequelae. Tracheostomies placed at the time of injury can usually be removed later, unless airway structures are damaged or distorted. Impaired pulmonary function is uncommon but may be manifested as airway hyperresponsiveness that has been termed *reactive airway dysfunction syndrome*.

Carbon Monoxide Poisoning

DEFINITION AND EPIDEMIOLOGY

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-based fuels. Because of the ubiquity of these substances, carbon monoxide inhalation is often coincident with smoke inhalation in fires or

may occur accidentally in association with malfunctioning equipment or improper venting of emissions from heaters, stoves, combustion motors, or other similar devices. In addition, intentional inhalation of carbon monoxide is a method commonly used in suicide attempts (404). Carbon monoxide inhalation is the leading cause of death from poisoning (Chapter 110) worldwide.

PATHOBIOLOGY

Carbon monoxide readily diffuses across the alveolar-capillary interface and binds to hemoglobin with extremely high affinity. When the resulting carboxyhemoglobin molecule undergoes an allosteric change at oxygen-binding sites, the ability of bound oxygen to dissociate and to be delivered to peripheral tissues is greatly reduced. This tissue hypoxia can cause severe functional impairment and ischemic injury of oxygen-sensitive tissues, particularly in the brain and heart.

CLINICAL MANIFESTATIONS

Mild carbon monoxide intoxication may go unrecognized because the symptoms are nonspecific and may include headache, nausea, malaise, fatigue, and dizziness. With more severe intoxications, neuropsychiatric symptoms may range from minor disturbances in attention and cognition to agitation, confusion, hallucination, or, in the worst intoxications, seizures or frank coma. Physical findings, which are generally nonspecific, can include tachycardia or hyperthermia. The classic cherry-red skin thought to be associated with carbon monoxide intoxication is rarely seen. Other manifestations of severe intoxications may include lactic acidosis, cardiac dysfunction with arrhythmia or ischemia, pulmonary edema, and rhabdomyolysis.

DIAGNOSIS

A high index of suspicion is required for diagnosis because clinical findings are nonspecific. All patients known to have been involved in fires, suicide attempts, or other scenarios compatible with exposures should have arterial carboxyhemoglobin levels checked by co-oximetry. Although levels do not correlate well with clinical findings or risk for complications, symptoms generally occur at carboxyhemoglobin concentrations of 10% or higher.

TREATMENT Rx

All patients should be treated with 100% supplemental oxygen, which competes with carbon monoxide for hemoglobin-binding sites and gradually eliminates it from the blood. If patients require mechanical ventilation because of depressed neurologic status or respiratory problems, 100% oxygen should be administered by endotracheal tube. Treatment with hyperbaric oxygen at a pressure of 2.5 to 3.0 atm can increase the dissolved oxygen content of blood by more than ten-fold, and at least one treatment of approximately 2 hours should be considered in severe cases to reverse the effects of acute intoxication; three hyperbaric oxygen treatments within 24 hours of diagnosis reduce neurocognitive sequelae. A small, but intriguing, randomized trial of seven healthy volunteers examined normocapnic hyperpnea and CO elimination and showed that persons randomized to normocapnic hyperpnea (compared with those getting 100% O_2 at normal minute ventilation) had a significantly faster half-time of decrease in carboxyhemoglobin.

PROGNOSIS

The mortality rate is highly variable according to the severity of intoxication but can approach 30% in severe cases. Approximately two thirds of patients who survive acute intoxication will recover without sequelae. Many of the remainder will suffer from long-term neuropsychiatric symptoms including cognitive dysfunction, abnormal mood or affect, memory disturbances, and other motor or sensory abnormalities, which can often occur within the first month but may be delayed for up to 6 to 9 months.

Cyanide and Other Gases

PATHOBIOLOGY

In addition to carbon monoxide and pulmonary irritants, cyanide gas may be formed when a number of commonly found substances, particularly plastics and textiles, are combusted. This gas is highly toxic and can rapidly cause morbidity and death by binding to cytochrome enzymes and inhibiting cellular respiration.

Other inhaled gases that can injure the lungs in occupational settings include ammonia, chlorine, nitrogen dioxide, organic dust, paraquat, phosgene (which has also been used as a chemical weapon), sulfur dioxide, and toxic metal fumes such as cadmium and mercury.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cyanide intoxication typically includes shock, lactic acidosis, and coma; it can rapidly lead to death before results of laboratory studies are available. In the setting of possible exposure, an elevated venous oxygen saturation indicates that cyanide is preventing cells from extracting oxygen from arterial blood.

Other inhaled gases that can produce potent irritant responses include ammonia, chlorine, and nitrogen dioxide ("silo-filler's lung"). Phosgene is notable for its propensity to cause delayed symptoms, up to 24 hours after exposure. Other inhalants may produce an acute chemical pneumonitis with respiratory distress (Chapter 93). A diverse group of inhaled toxins can cause syndromes of inhalational fever, including heavy metal fumes, polymer fumes, and organic dust aerosols that contain thermophilic bacteria, gram-negative bacteria and their associated endotoxins, and fungal elements. These inhalations are characterized by fever and malaise with mild respiratory symptoms and are also notable for tachyphylaxis with repeated exposure (and thus referred to as Monday morning fever in some professions).

TREATMENT Rx

Cyanide intoxication is treated by use of a Taylor Cyanide Antidote Package (Taylor Pharmaceuticals) that contains amyl nitrite gas ampules (one 0.3-mL ampule each minute until sodium nitrite infusion begins) for inhalation. This treatment is followed by intravenous administration of sodium nitrite (300 mg), which acts by converting hemoglobin to methemoglobin. Finally, patients are treated with intravenous sodium thiosulfate (12.5 g), which converts cyanide to less harmful thiocyanate ions. If carboxyhemoglobinemia is present, sodium thiosulfate should be used alone because of the additive toxicity of this condition with methemoglobinemia.

Hydroxocobalamin, which directly binds cyanide, can be used in conjunction with sodium thiosulfate. It is thought to be safer than the amyl nitrate gas ampules because it does not cause methemoglobinemia and is better suited to prehospital care.

The mainstay for treatment of other irritating inhalations is to remove the patient immediately from the toxic environment and to provide supportive care for respiratory injury. Depending on the intensity and duration of exposure, most patients will recover completely without sequelae.

OXYGEN TOXICITY

DEFINITION

Hypoxic respiratory failure often requires treatment with supplemental oxygen to maintain tissue oxygenation. In some settings, such as ARDS, patients may require high F_{IO_2} for prolonged periods to combat severe hypoxia. However, it has long been recognized that oxygen may be toxic to the lungs when it is present in concentrations higher than those found in ambient air.

PATHOBIOLOGY

When the concentration of oxygen in the airways is high, formation of reactive oxygen species and free radicals is increased. Under normal circumstances, innate antioxidant mechanisms in airway epithelia and alveoli are sufficient to abrogate the effect of these molecules. However, under conditions of critical illness, prolonged exposure to increased concentrations of these toxins may overwhelm these defenses. Superoxide, hydrogen peroxide, and hydroxyl radicals may directly oxidize cellular components. Cellular damage potentiates inflammation and may be synergistic with inflammatory processes already under way in the diseased lung; the result can be alveolar edema, formation of hyaline membranes, hypoxemia, and progression to fibrosis and obliteration of alveolar and capillary structures. In addition, washout of nitrogen from air spaces can result in absorptive atelectasis if oxygen is removed by the circulation faster than it can be replenished by ventilation (especially in the setting of ventilation-perfusion mismatch). Hyperoxia can also worsen hypercapnia through multiple mechanisms, as occurs in patients with chronic obstructive pulmonary disease who suffer from carbon dioxide retention.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Although the exact levels of hyperoxia that cause lung injury are unclear, it appears to occur with exposure to F_{IO_2} of 50 to 60% after exposures as short

as 6 hours in duration. Because of the high flow of supplemental oxygen required to deliver this F_{IO_2}, oxygen toxicity is observed primarily in mechanically ventilated patients being treated for hypoxic respiratory failure. This level of exposure can cause a clinically detectable tracheobronchitis, demonstrable by symptoms of cough and dyspnea, as well as airway erythema that is visible macroscopically on bronchoscopy. This syndrome may impair mucociliary clearance and result in impaction of secretions, especially in conjunction with absorptive atelectasis.

Patients who may be susceptible to oxygen toxicity generally already have a significant degree of parenchymal injury from other processes. Thus, although some patients may appear to display a syndrome of worsening air space disease, atelectasis, consolidation, hypoxia, and diffuse alveolar damage, it is not clear when these changes are related to oxygen therapy or merely occur as part of the acute lung injury from other causes.

TREATMENT

Rx

Because the threshold level for oxygen toxicity is unknown, a general guideline for treatment of hypoxemic respiratory failure (Chapter 104) is that patients be ventilated with the lowest possible F_{IO_2} that is required to restore an acceptable oxygen saturation. An Sa_{O_2} of 90%, corresponding to Pa_{O_2} of 55 to 60 mm Hg, is generally considered the minimum acceptable level. Unfortunately, under conditions of severe hypoxia, as in ARDS, patients often require an F_{IO_2} approaching 100% to achieve this oxygen level. Maneuvers to improve oxygenation without increasing F_{IO_2} include red blood cell transfusions to improve the delivery of oxygen; alternative ventilatory strategies, such as high-frequency oscillatory ventilation, airway pressure-release ventilation, inverse-ratio ventilation, and prone positioning; and alveolar recruitment maneuvers using positive end-expiratory pressure or transiently increased inflation pressures (Chapter 105).

PROGNOSIS

Patients who sustain oxygen toxicity in the setting of prior bleomycin exposure may be left with residual pulmonary fibrosis. In other patients, the incremental impact of oxygen toxicity on prognosis is unknown.

LUNG INJURY

Radiation Lung Injury

DEFINITION

Accidental or occupational radiation exposures (Chapter 19) are generally characterized by systemic toxicity that outweighs any injury to the lungs. As such, radiation lung injury refers to a pneumonitis that can progress to pulmonary fibrosis and that results from therapeutic use of ionizing radiation, usually in the treatment of malignant neoplasms.

EPIDEMIOLOGY

As many as 50% of patients receiving thoracic radiation will display radiographic abnormalities after treatment; duration and dose of therapy affect the odds for development of lung injury. However, most of these patients will never have clinically significant radiation lung injury. For unclear reasons, the incidence of lung injury appears to vary by the type of underlying malignant disease and modality of treatment. The highest frequency appears to be found in patients with lung cancer (10 to 15%).

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

The pathogenesis of radiation lung injury is often divided into three or four phases on the basis of time course. Typically, the early phase occurs immediately after exposure and is characterized by injury to alveolar cells, resulting in mild alveolitis, recruitment of inflammatory cells, capillary leak, and pulmonary edema. These changes are usually asymptomatic; patients do not usually come to clinical attention, although the chest radiograph will be abnormal if it is performed. In most patients, these changes resolve without progression within 1 to 3 months.

A minority of patients will progress to the next phase, in which alveolar cells desquamate and the air spaces fill with protein-rich fluid. In this phase, referred to as radiation pneumonitis, patients complain of cough, dyspnea, and occasionally fever or pleuritic chest pain. Severe cases may present with hypoxemic respiratory failure. This phase generally resolves within 3 to 6 months after exposure and is followed by an organizing phase, in which alveolar edema resolves and the damaged alveoli heal. Clinically, patients generally show improvement in symptoms during this period. However, this phase is also characterized by fibroblast proliferation and deposition of collagen in the lung. In a minority of patients, this process will proceed unchecked and result in clinically significant fibrosis, with progressive loss of alveolar-capillary surface and development of restrictive lung disease.

DIAGNOSIS

Clinical history and radiographic evaluation are often sufficient for diagnosis of radiation lung injury because patients typically present with respiratory symptoms and opacities on chest radiography after undergoing radiation therapy. Radiography may show air space disease with alveolar filling or consolidation during the pneumonitis phase, which may progress to an interstitial pattern and eventual honeycombing with parenchymal distortion in the chronic phase. Because radiation characteristically causes injury only within directly affected lung tissue, radiography may show opacities that are well delineated and form straight lines that cross anatomically distinct regions of lung. This finding is rarely if ever seen in other conditions.

The differential diagnosis may include pneumonia, recurrence, and metastatic malignant disease. On occasion, invasive evaluation with bronchoalveolar lavage or even biopsy is required to exclude these possibilities if the clinical history and imaging do not provide a diagnosis.

TREATMENT AND PREVENTION

Rx

Corticosteroids such as prednisone, 1 mg/kg body weight/day followed by a slow taper over several weeks or months, are the mainstay of therapy. Patients often show a dramatic response to treatment, and symptoms may recur after treatment is discontinued. Other immunosuppressive agents have been used successfully in case reports of patients who failed to respond to corticosteroids. Prophylactic amifostine, a cytoprotective agent (340 mg/m^2 given 15 minutes before irradiation), significantly reduces the risk for radiation pneumonitis in patients who receive radiation treatment for lung cancer.■

PROGNOSIS

Within 2 years after initial exposure, progression will usually slow, and symptoms and lung function will stabilize and improve. After this time, further improvement or worsening is uncommon. In severe cases that become chronic, patients may develop features of advanced interstitial lung disease, including pulmonary hypertension and hypoxic respiratory failure.

Aspiration Injury

DEFINITION

Aspiration, which is defined as the inhalation of any nongaseous foreign substance into the lungs, generally refers specifically to the inhalation of gastric contents or secretions from the oropharynx. Aspiration is a common occurrence, and in most cases it resolves spontaneously without clinical manifestations. Clinically significant aspiration can range from acute pneumonitis and respiratory failure caused by a single massive aspiration to chronic symptoms of respiratory disease caused by recurrent small-scale aspiration. These syndromes may overlap with pneumonia that occurs when the lungs are exposed to bacteria from the gastrointestinal tract (Chapter 97).

PATHOBIOLOGY

The common element of clinically significant aspiration is impairment of normal airway protective mechanisms. Under normal circumstances, the airway is protected by the normal swallowing mechanism, the cough reflex, and the anatomy of the supraglottic airway. However, even healthy individuals experience microaspiration despite having functional protective mechanisms. These secretions are handled by normal pulmonary clearance mechanisms.

Any disturbance of these protective mechanisms can result in aspiration injury to the lungs. An altered level of consciousness can impair normal swallowing and suppress the cough reflex. Even in patients who are alert, neurologic injury can result in dysphagia and concomitant aspiration, as in patients who have bulbar neurologic deficits in association with ischemic stroke. Patients with altered airway or oropharyngeal anatomy, such as patients who have received surgical or radiation therapy for head and neck malignant neoplasms, may also be highly susceptible to aspiration of oral secretions.

The nature of the aspirated material is also important in determining whether an injury occurs. Materials with a pH lower than 2.5, such as acidic gastric contents, are much more likely to cause a significant chemical pneumonitis.

Particulate matter also increases the likelihood for development of clinically significant inflammation. A large-volume aspiration with distribution throughout the lungs is more likely to produce an acute, severe pneumonitis.

Once material has been aspirated into the lungs, the injury that occurs is similar to a chemical burn. Acid rapidly injures airway epithelial and alveolar cells; within hours, cells become dysfunctional and capillary leak occurs, resulting in profound noncardiogenic pulmonary edema. In severe cases, diffuse alveolar damage may result.

CLINICAL MANIFESTATIONS

The classic eponym applied to aspiration pneumonia is Mendelsohn's syndrome, which refers to a single, large-volume aspiration of gastric contents followed by rapidly progressive hypoxemic respiratory failure that develops within hours. Patients may suffer from cough, dyspnea, fever, and respiratory distress. Physical examination may reveal diffuse crackles, wheezing, cyanosis, and hypotension. Chest radiography may show a pattern of alveolar filling with diffuse bilateral involvement or involvement of dependent regions, particularly the right lower lobe. In many patients, this period of acute deterioration is followed by stabilization and resolution within 2 or 3 days. In other patients, deterioration may continue, and patients may meet clinical criteria for ARDS. If the volume of aspirated material is large enough, the initial aspiration may be sufficient to cause tracheal obstruction and asphyxiation.

In patients who initially improve, a small percentage will show further deterioration after 2 or 3 days. This deterioration should prompt an investigation for bacterial superinfection.

DIAGNOSIS

The clinical history and presentation are generally sufficient for diagnosis of aspiration pneumonitis. Bacterial pneumonia and other causes of ARDS also should be considered, as should cardiogenic pulmonary edema. Airway erythema and edema on bronchoscopy can be suggestive of aspiration. Bronchoalveolar lavage may help evaluate for the presence of bacterial infection.

PREVENTION

Prevention should focus on identification of patients who are at risk for aspiration and then use of strategies to minimize the risk. Patients with swallowing dysfunction or airway abnormalities can work with speech pathologists to learn effective strategies for swallowing. Patients who are unsuccessful or not suitable for this approach may benefit from tracheostomy or enteral tube feedings, which do not prevent microaspiration but can prevent large-volume aspiration. In hospitalized patients, particularly patients with an altered mental status due to illness or sedation, simple strategies such as avoidance of oral feeding and semirecumbent positioning can effectively reduce the risk for aspiration. Use of histamine-2 blockers or proton pump inhibitors (Chapter 141) can alter gastric pH to reduce the risk for injury from acidic secretions.

TREATMENT Rx

Because of the acuity and severity of aspiration pneumonitis, immediate attention should be paid to maintaining a patent airway. The oropharynx and trachea should be suctioned to clear any potentially obstructing material, and endotracheal intubation should be performed if necessary (Chapter 105). Bronchoscopy is often performed to clear residual particulate or solid matter, but it cannot remove acidic secretions, which damage airways and parenchyma quickly and then are rendered neutral. Oxygen supplementation should be provided as needed for hypoxia. Corticosteroids have not been shown to be beneficial. Antibiotics should be reserved for patients who appear to have developed bacterial superinfection (Chapter 97).

PROGNOSIS

For patients with severe respiratory failure or ARDS, mortality can be high. In others, improvement should be expected within days. If the underlying factor that led to aspiration is irreversible, patients have an increased likelihood of recurrent episodes.

Lipoid Pneumonia

DEFINITION

Lipoid pneumonia is a chronic inflammatory reaction of the lungs to the presence of lipid substances. Exogenous lipoid pneumonia results from the aspiration of vegetable, animal, or (most commonly) mineral oils.

PATHOBIOLOGY

The most frequently implicated agent is mineral oil used as a laxative and to reduce dysphagia, either in clear liquid form or as petroleum jelly. Mineral oil is bland and, when introduced into the pharynx, can enter the bronchial tree without eliciting the cough reflex. It also mechanically impedes the ciliary action of the airway epithelium. The risk for mineral oil aspiration is increased in debilitated or senile patients, in those with neurologic disease that interferes with deglutition, and in patients with esophageal disease. Mineral oil taken as nose drops to relieve nasal dryness can also cause lipoid pneumonia. Inhalation of mineral oil mist by airplane and automobile mechanics has also been implicated as a cause.

Mineral oils, which cannot be hydrolyzed in the body, provoke a chronic inflammatory reaction that may not become clinically overt until years later. In the alveolar spaces, macrophages accumulate and phagocytose the emulsified oil. Some macrophages disintegrate, releasing their lysosomal enzymes and oil. The alveolar septa become thickened and edematous, containing lymphocytes and lipid-laden macrophages. Oil droplets are seen in the pulmonary lymphatics and hilar nodes. Later, fibrosis develops, and the normal lung architecture is effaced. A single pathologic specimen may include both the early inflammatory and the later fibrotic picture, in keeping with repetitive aspirations during many months or years. Nodular lesions may grossly resemble tumor and be called paraffinomas.

CLINICAL MANIFESTATIONS

Most patients are asymptomatic and come to the physician's attention because of an abnormal chest radiograph. When patients are symptomatic, cough and exertional dyspnea are the most frequent complaints. Chest pain (sometimes pleuritic), hemoptysis, fever (usually low grade), chills, night sweats, and weight loss may occur. Findings on physical examination may be completely normal, but fever, tachypnea, dullness on percussion of the chest, bronchial or bronchovesicular breath sounds, rales, and rhonchi may be found. Clubbing and cor pulmonale are rare.

DIAGNOSIS

In mild lipoid pneumonia, arterial blood gas values may be normal with the patient at rest but may show hypoxemia after exercise. In more severe disease, resting hypoxemia, hypocapnia, and mild respiratory alkalosis develop. Pulmonary function testing reveals a restrictive ventilatory defect; lung compliance is decreased. The only specific laboratory finding is the presence in sputum of macrophages with clusters of vacuoles that are 5 to 50 μm in diameter and that stain deep orange with Sudan IV; extracellular droplets may stain similarly.

On radiographic examination, the earliest abnormalities are air space infiltrates, most often in the dependent portions of the lung. The infiltrates may be unilateral or bilateral, localized or diffuse. Air bronchograms may be seen. Hilar adenopathy and pleural reaction are rare. As fibrosis develops, volume loss occurs, and linear and nodular infiltrates appear. A solid lesion that closely resembles bronchogenic carcinoma may develop. High-resolution computed tomography usually shows consolidated areas of low attenuation and "crazy paving" (Fig. 94-1).

The differential diagnosis is extensive, particularly in the late phase, when multiple other causes of pulmonary fibrosis must be considered. The key to the correct diagnosis before biopsy is the history of chronic oral or intranasal use of an oil- or a lipid-based product or an occupational exposure to oil mists. The presence of lipid-laden macrophages in sputum or bronchoalveolar lavage fluid also can be used to confirm the diagnosis, particularly in conjunction with typical findings on high-resolution computed tomography.

TREATMENT AND PREVENTION Rx

Once the diagnosis has been made and the aspiration stopped, the subsequent course is variable. Because the only way the lung can dispose of mineral oil is by expectoration, the patient should be instructed in coughing exercises to be performed many times each day for months. Expectorants have not been shown to help. In some uncontrolled case reports, systemic corticosteroids at varying doses and durations have been associated with a successful outcome, but they cannot be routinely recommended for treatment.

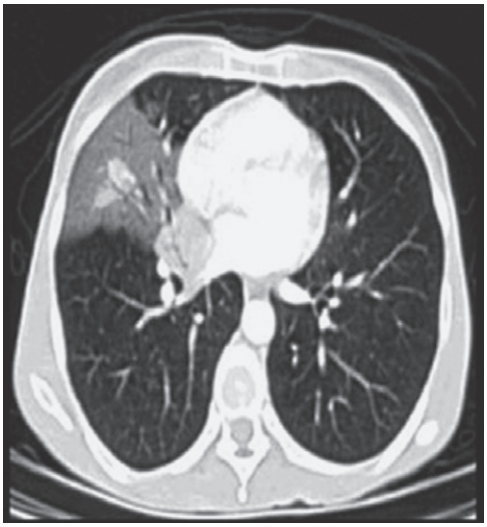

FIGURE 94-1. Lipoid pneumonia on a computed tomographic scan.

Transfusion-Related Acute Lung Injury

DEFINITION

The syndrome of transfusion-related acute lung injury (TRALI; Chapter 180) involves the rapid onset of respiratory distress within minutes to hours after the transfusion of blood products (fresh-frozen plasma, platelets, and red blood cells). The initial clinical picture is indistinguishable from acute lung injury or ARDS due to other causes, such as sepsis, multiple trauma, and lung injury. TRALI may similarly be confused with pulmonary edema due to volume overload (Chapter 58).

EPIDEMIOLOGY

The true incidence of TRALI is unknown; incidence rates are underestimated because of the difficulty in distinguishing TRALI from other causes of acute respiratory failure and the labor-intensive and costly diagnostic evaluation required. Reported incidences range from 1 in 1000 to 1 in 100,000 units of blood products transfused. The risk for TRALI varies according to the type of blood product transfused, with pooled products associated with a higher incidence. Only 8 to 21 TRALI-related deaths are reported to the U.S. Food and Drug Administration annually, and even liberal estimates accounting for under-reporting suggest the number may be only as high as 300 per year of an estimated 25 million transfusions in the United States.

PATHOBIOLOGY

The physiologic manifestations of TRALI are caused by alveolar filling with fluid and protein. This alveolar process is the result of increased microvascular permeability due to pulmonary endothelial damage mediated by either leukocyte antibodies or the priming and activation of neutrophils in the pulmonary circulation by bioactive substances.

TRALI most commonly occurs when human leukocyte antigen (HLA) type I or II or neutrophil-specific antigen antibodies from the donor attach to the recipient's leukocytes, leading to the release of injurious oxidative and nonoxidative products. Development of HLA antibodies occurs commonly in women during pregnancy, and increasing parity in female blood donors is associated with an increased risk for TRALI.

Episodes of TRALI occurring in patients without HLA or neutrophil-specific antigen antibodies in either the donor or recipient are thought to be caused by a two-hit process of neutrophil priming and activation. Neutrophils are primed and sequestered in the lung by conditions that often occur in patients requiring blood products, such as multiple trauma, surgery, or sepsis. Primed neutrophils are then activated by bioactive lipids and cytokines stored in the blood products, thereby leading to lung injury and alveolar damage. Levels of these bioactive lipids or cytokines may increase after prolonged storage of blood products.

CLINICAL MANIFESTATIONS

Although most cases of TRALI present within 1 to 2 hours after the transfusion of blood products, tachypnea, hypoxemia, cyanosis, dyspnea, and fever can develop during the transfusion or up to 6 hours later. Hypertension or hypotension commonly occurs, depending on the severity of the reaction. Copious amounts of pink, frothy edema fluid may be present. Lung auscultation generally reveals bilateral crackles and decreased breath sounds in dependent lung zones.

DIAGNOSIS

Bilateral patchy infiltrates consistent with alveolar edema are found on plain chest radiographs, typically without effusions. Arterial blood gas analysis demonstrates reduced Po_2, and further laboratory testing may reveal thrombocytopenia or a transient leukopenia. Diagnosis of TRALI requires the presence of the following: acute onset of hypoxemia with Pao_2/Fio_2 of 300 or less, or room air oxygen saturation less than 90% during or within 6 hours after a transfusion; bilateral infiltrates on the chest radiograph; no evidence of left atrial hypertension; no preexisting acute lung injury before transfusion; and no temporal relationship to an alternative risk factor for acute lung injury.

The diagnosis of "possible TRALI" is made in patients who have a concurrent diagnosis of another risk factor for acute lung injury, including (1) direct lung injury due to aspiration, pneumonia, toxic inhalation, lung contusion, or nonfatal drowning; and (2) indirect lung injury due to severe sepsis, shock, multiple trauma, burn injury, acute pancreatitis, cardiopulmonary bypass, or drug overdose. Absolute confirmation of the diagnosis requires testing for HLA and neutrophil-specific antigen antibodies, usually performed first in female donors, then in male donors, and finally in the recipient.

TREATMENT

Rx

Most cases are self-limited and resolve within hours to days with supplemental oxygen and supportive care. Volume resuscitation, with or without vasopressors, is required for hypotension. Mechanical ventilation should be managed as for any other case of acute lung injury, with the implementation of a low tidal volume ventilation strategy to prevent further ventilator-induced lung injury. Diuresis should be attempted cautiously and may even be detrimental because intravascular filling pressures are often low.

PROGNOSIS

The mortality rate of TRALI is approximately 5%. If an implicated donor can be identified, the recipient should not receive any further transfusions from that donor, but patients are not at increased risk for further episodes of TRALI from nonimplicated donor transfusions.

SARCOIDOSIS

MICHAEL IANNUZZI

DEFINITION

Sarcoidosis, a systemic granulomatous disease of unknown cause, is characterized by a variable clinical presentation and course. More than 90% of patients exhibit thoracic involvement with mediastinal and hilar lymph node enlargement or parenchymal lung disease, but any organ may be involved. The presentation and course vary from asymptomatic disease with spontaneous resolution to organ system failure and even death.

EPIDEMIOLOGY

Sarcoidosis occurs worldwide, affects people of all racial and ethnic groups, and may present at any age. Sarcoidosis usually develops before the age of 50 years with the incidence peaking at 20 to 39 years. The incidence of sarcoidosis fluctuates throughout the world, most likely because of differences in the presentation of the disease and the surveillance methods used. The annual incidence of sarcoidosis is highest in northern European countries, where it is 5 to 40 cases per 100,000 people. The incidence in Japan is about 1 to 2 cases per 100,000 people. In the United States, the adjusted annual incidence among black Americans is about 3.5 times higher than among white Americans (35.5 cases per 100,000 compared with 10.9 per 100,000). Regardless of ethnic or racial group, sarcoidosis affects women more often. The reportedly low incidence in certain regions such as Africa, China, India, and Russia may be due to decreased access to health care, minimal surveillance, and misdiagnosis of sarcoidosis as tuberculosis or leprosy.

Black women in the United States have the highest lifetime risk of developing sarcoidosis (2.7%). In both black men and women, sarcoidosis occurs later in life, peaks in the fourth decade, and is more likely to be chronic and fatal. Socioeconomic status does not affect the incidence of sarcoidosis, but low income and other financial barriers to care are associated with more severe sarcoidosis, even after adjustment for age, sex, and race or ethnic group.

Sarcoidosis clusters in families and monozygotic twins are more often concordant for disease than are dizygotic twins. Familial sarcoidosis occurs in 10% of cases from the Netherlands, 7.5% from Germany, 6% from the United Kingdom, 4.7% from Finland, and 0.8% from Spain. In the United States, sarcoidosis patients are five times as likely to have siblings or parents with sarcoidosis as control subjects. However, less than 1% of the first-degree relatives of patients with sarcoidosis are affected, so screening for disease in asymptomatic relatives is ineffective.

PATHOBIOLOGY

The development and accumulation of granulomas represent the basic pathologic abnormality in sarcoidosis. Sarcoidal granulomas are tightly organized collections of macrophages and macrophage-derived epithelioid cells encircled by lymphocytes. Fused epithelioid cells, which become multinucleated giant cells, are often found scattered throughout the granuloma. This appearance suggests that the granuloma is meant to contain an inciting agent, but no such agent has been identified.

Granuloma formation begins with HLA-mediated processing of antigens by macrophages. T-cell activation follows, with oligoclonal expansion of $CD4^+$ (helper-inducer) lymphocytes. These $CD4^+$ cells, primarily of the T_H1 phenotype, produce interleukin-2 (IL-2) and interferon-γ (IFN-γ). A complex interplay of cytokines, along with macrophage-derived tumor necrosis factor-α, organizes the inflammatory cells into granulomas. In some cases, fibroblasts and collagen encase the granulomas with subsequent fibrosis. Fibrosis has been associated with a shift in the involved lymphocytes from the T_H1 (IL-2 and IFN-γ) to the T_H2 phenotype (IL-4, -10, and -13). This fibrotic process irreversibly alters organ architecture and function. Increased 1-α hydroxylase activity in macrophages within granulomas and the alveoli converts 25-hydroxyvitamin D to the biologically active form 1,25-dihydroxyvitamin D (calcitriol), thereby resulting in increased intestinal absorption of calcium.

In sarcoidosis, an immune paradox exists: patients often develop anergy as indicated by a suppressed response to tuberculin, despite active granulomatous inflammation. This anergy results in part from an expansion of $CD25^{bright}$ regulatory T cells, which are a subgroup of $CD4^+$ T lymphocytes and which can abolish production of IL-2 and inhibit T-cell proliferation. Although sarcoidosis is predominantly a T-cell-driven disease, the presence of polyclonal hyperglobulinemia indicates that B lymphocytes may also play a role.

Multiple inciting agents rather than a single pathogen are likely to cause sarcoidosis. Airborne antigens are suspected because the lungs, followed by the eyes and skin, are the most commonly involved organs. A microbial origin of the antigens is favored because sarcoidosis occurs sporadically in clusters and is worldwide. Furthermore, sarcoidosis may recur in transplanted organs and can develop in recipients of tissues from donors with sarcoidosis.

Several environmental exposures are modestly associated with the risk for sarcoidosis, each with odds ratios of about 1.5: mold or mildew, musty odors at work, agricultural employment, and pesticide-using industries. Highly sensitive methods for detecting microbial DNA and proteins, such as polymerase chain reaction and mass spectrometry, have yielded potential etiologic agents. One promising candidate of microbial origin is the mycobacterial KatG protein.

Major histocompatibility complex (MHC) genes and non-MHC genes located on the short arm of chromosome 6p have been implicated as genetic risk factors for sarcoidosis. HLA-DQB1*0201 and HLA-DRB1*0301 alleles are strongly associated with acute disease and good prognosis. The HLA-DRB1*1501/DQB1*0602 haplotype predicts a chronic course and severe pulmonary sarcoidosis. Genome-wide scans have identified the gene candidates *BTNL2* (butyrophilin-like 2 gene) and *ANXA11* (annexin A11).

CLINICAL MANIFESTATIONS

Patients may present with any organ involved, with or without concomitant intrathoracic involvement. The severity of symptoms and organ dysfunction also varies, and as many as 30 to 50% of patients have no symptoms at the time of diagnosis. Clinical manifestations also vary by ethnicity, race, and sex as well as by the particular organ system predominantly affected.

Sarcoidosis often first comes to attention during routine screening when enlarged mediastinal and hilar lymph nodes are detected on a chest radiograph (Fig. 95-1). Symptomatic individuals commonly experience fatigue, night sweats, and weight loss. Fatigue often remains a prominent problem and can lead to impaired quality of life.

Symptomatic sarcoidosis may present insidiously or as an acute illness. Löfgren's syndrome, an acute form of the disease, consists of erythema nodosum (see Fig. 448-23 in Chapter 448), arthritis, and bilateral hilar adenopathy. Fever and uveitis may also accompany Löfgren's syndrome. Erythema nodosum occurs predominantly in women, whereas arthritis predominates in men.

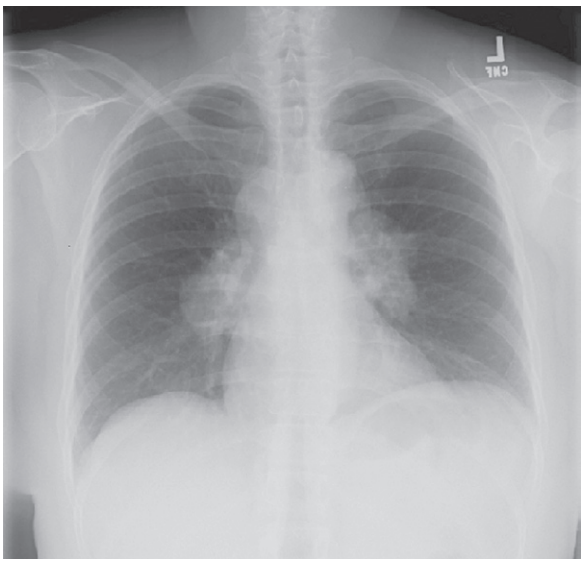

FIGURE 95-1. Chest radiograph demonstrating a stage I disease with enlarged mediastinal and hilar lymph nodes.

Respiratory System Disease

More than 90% of patients have respiratory tract involvement, sometimes with symptoms and sometimes with asymptomatic radiographic abnormalities. The most common respiratory symptoms are dry cough and dyspnea. Chest pain, when present, is vague and nonspecific.

Upper respiratory tract involvement occurs in from 2 to 6% of patients, with most having nasal mucosal involvement. Severe upper respiratory tract disease may lead to anosmia, erosion of septal cartilage, and nasal deformity. Supraglottic and glottic involvement can lead to stridor, dysphonia, cough, and dysphagia.

Examination of the chest often reveals few or no findings. Localized wheezing suggests endobronchial granulomatous disease, whereas diffuse wheezing suggests hyperreactive airways disease. Crackles may be heard when bronchiectasis and fibrosis are present. Hemoptysis may occur with bronchiectasis or cavitary disease.

The most common radiographic finding is intrathoracic lymph node enlargement with or without parenchymal lung involvement. Mediastinal lymphadenopathy without hilar adenopathy is extremely rare. Hilar lymph node enlargement is usually symmetrical, and less than 3% of patients have unilateral enlargement. Concurrent enlargement of right paratracheal and aortic-pulmonary window lymph nodes is common.

The chest radiograph is traditionally categorized into five stages (Table 95-1), but these stages do not necessarily denote the severity or chronologic progression of disease, particularly when extrathoracic involvement is present. Furthermore, 50 to 94% of patients will have hilar or mediastinal lymphadenopathy on computed tomographic (CT) scans irrespective of their stage on a plain chest radiograph.

Chest CT may demonstrate nodules, ground-glass opacities, bronchiectasis, cysts, and thickening of the pleural surface (Fig. 95-2). CT scanning, however, generally adds little to diagnosis and management, particularly for those with a stage I chest radiograph. CT scanning can be justified when atypical clinical and chest radiographic findings are present, a normal chest radiograph is found during the evaluation of suspected extrathoracic disease, or complications are suspected.

Endobronchial sarcoidosis may lead to bronchial stenosis and recurrent obstructive pneumonias. Pleural effusions on plain radiography are uncommon (1 to 3% of patients). Pulmonary hypertension (Chapter 68) may complicate sarcoidosis, particularly when pulmonary fibrosis is present.

TABLE 95-1 CHEST RADIOGRAPHIC STAGING

Stage 0: Normal
Stage 1: Bilateral hilar adenopathy, often with right paratracheal adenopathy
Stage 2: Bilateral hilar adenopathy and parenchymal infiltration
Stage 3: Parenchymal infiltration without lymphadenopathy
Stage 4: Advanced parenchymal disease demonstrating fibrosis and may include honeycombing, cysts, bullae, and traction bronchiectasis

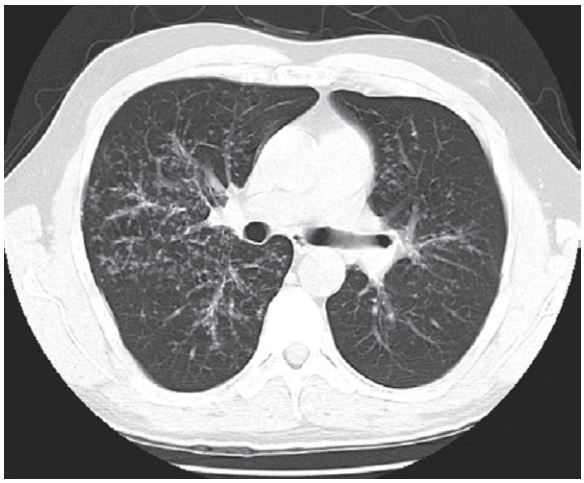

FIGURE 95-2. High-resolution chest computed tomography scan demonstrating numerous small nodules in a predominantly bronchovascular distribution.

Skin Disease

Skin involvement occurs in 25 to 35% of patients, but lesions are commonly misdiagnosed because they can present as macules, papules, plaques, subcutaneous lesions, areas of increased or decreased pigmentation, and ulcerations. Lesions are commonly found on the upper back, the nape of the neck, and extremities (Fig. 95-3) and have a predilection for scars and tattoos. The most common skin manifestation is a maculopapular eruption, consisting of firm, flesh-colored to violaceous lesions that have a predilection for the eyelids and perioral area. Scalp involvement with alopecia may occur. Skin lesions in black American patients frequently leave scars and pale or depigmented areas.

Erythema nodosum occurs in about 10% of patients and commonly occurs as part of Löfgren's syndrome. It presents as raised, red, hot, tender subcutaneous nodular lesions, most commonly on the shins, but sometimes also on the arms and buttocks (see Fig. 448-3 in Chapter 448). Lesions persist for 1 to 3 weeks and may recur. The lesions of erythema nodosum typically show nonspecific septal panniculitis without sarcoidal granulomas, so biopsy is not usually helpful. Erythema nodosum portends a good prognosis, with up to 85% of patients resolving their sarcoidosis within 2 years.

Lupus pernio (Fig. 95-4) consists of chronic, lumpy, violaceous, indurated plaques and nodules distributed around the nose, cheeks, lips, and ears; it is specific to sarcoidosis. Patients with lupus pernio more commonly have a chronic course, fibrotic lung disease, and upper respiratory tract involvement.

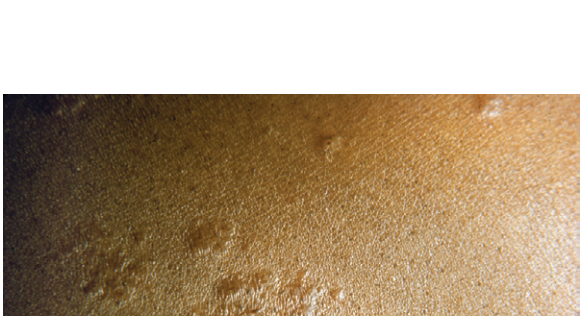

FIGURE 95-3. Skin lesions of sarcoidosis. Sarcoidal lesions may occur at any site. This patient's papules have a waxy appearance and are located on the upper part of the back.

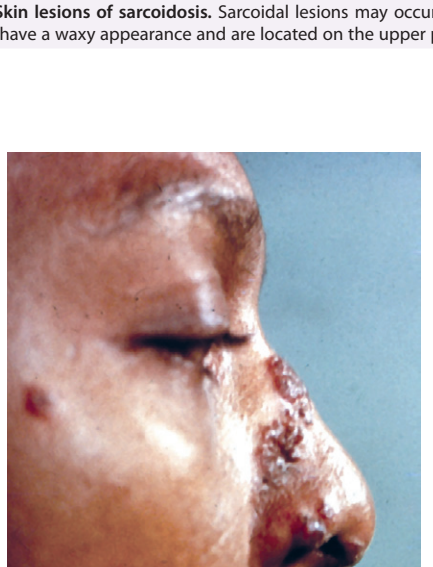

FIGURE 95-4. Lupus pernio is the term used to describe infiltrative skin lesions affecting the nose, cheeks, and ears in chronic sarcoidosis.

Eye Disease

More than 25% of patients have ocular involvement (Chapter 431), and any part of the eye and adnexa may be involved. Lacrimal gland enlargement and conjunctival involvement are common. Conjunctival involvement consists of pale yellow nodules, which demonstrate granulomas on biopsy. Corneal involvement is rare. Acute anterior uveitis presents with pain, photophobia, lacrimation, and redness. Chronic anterior uveitis, which is more common than acute uveitis, may have minimal symptoms. Posterior uveitis, which occurs in about 30% of patients with ocular sarcoidosis, is frequently accompanied by central nervous system involvement. Choroidal lesions may occur anywhere in the fundus and may be multifocal. In 10 to 15% of patients with uveitis, both the anterior and posterior segments are affected.

Uveitis can herald the nonocular signs of sarcoidosis and may precede the diagnosis of sarcoidosis by decades. Chronic anterior uveitis may lead to cataracts and glaucoma. Heerfordt's syndrome consists of anterior uveitis accompanied by parotid gland enlargement and fever.

Cardiac Disease

Cardiac granulomas are found in about 25% of sarcoidosis patients who are examined at autopsy, but cardiac sarcoidosis is suspected in only about 5% of patients. In cardiac sarcoidosis (Chapter 60), granulomas most often infiltrate the left ventricular free wall. Next most frequently, sarcoidal granulomas infiltrate the intraventricular septum, where they often involve the conduction system. Cardiac manifestations include atrioventricular block, ventricular arrhythmias, left ventricular dysfunction, and sudden death.

Neurologic Disease

Nervous system granulomas are found in up to 25% of sarcoidosis patients who undergo autopsy, but only 10% of patients present with neurologic symptoms (Table 95-2). In patients with neurologic involvement, the neurologic signs or symptoms precede the diagnosis of sarcoidosis in up to 75% of patients and may be the only manifestation of sarcoidosis.

Neurosarcoidosis has a predilection for the base of the brain, hypothalamus, and pituitary gland. Myelopathy may occur anywhere in the spinal cord and carries a poor prognosis. Peripheral neuropathy (Chapter 428) may manifest as mononeuropathy or polyneuropathy.

Liver and Spleen

Liver involvement is twice as common in black Americans as in white Americans. Symptoms due to liver disease are infrequent, but abdominal pain and pruritus are the most common symptoms. Fever, weight loss, and jaundice are present in less than 5% of those with liver involvement. About 20% of patients will have hepatomegaly on physical examination, and 35% will have an elevated serum aminotransferase or alkaline phosphatase level. Sarcoidosis can rarely (<1%) cause progressive liver disease that leads to portal hypertension with variceal bleeding; the hepatopulmonary syndrome, with refractory hypoxemia, cirrhosis, and liver failure, may also occur.

Splenomegaly is found on physical examination in 5 to 15% of patients with sarcoidosis. Massive splenomegaly is rare.

Bone and Joint

Most patients complain of arthralgias, but only about 35% develop arthritis. Acute sarcoid arthritis (Chapter 283) consists of large joint periarthritis, particularly involving the ankles and knees, and commonly occurs with Löfgren's syndrome. These patients often report difficulty walking related to joint pain. Acute sarcoid arthritis usually persists for up to 3 months but is self-limited. Chronic sarcoid arthritis with direct granulomatous synovial infiltration is rare. Osseous sarcoidosis usually does not produce symptoms.

TABLE 95-2 NEUROSARCOIDOSIS

Cranial neuropathies
VII—Facial nerve palsy (unilateral, bilateral)

Calcium Metabolism

Aberrant calcium and vitamin D metabolism occurs in up to 50% of patients and may result in renal stones (Chapter 128), nephrocalcinosis with renal insufficiency, and hypercalciuria (urine calcium > 300 mg/24 hours) with or without hypercalcemia (Chapter 253). In chronic sarcoidosis, 10 to 14% of patients have at least one symptomatic renal stone.

Renal Involvement

Renal involvement, other than as a result of dysregulated calcium metabolism, occurs in less than 1% of patients. Renal disease may include granulomatous interstitial nephritis, glomerular disease, renal tubular dysfunction, renal vascular disease, and obstructive uropathy. Granulomatous interstitial nephritis is more common in white men.

DIAGNOSIS

The diagnosis of sarcoidosis should be based on compatible clinical and radiographic findings supported by histologic evidence of noncaseating granulomas in one or more organs in the absence of any foreign particles or organisms. An occupational history consistent with beryllium exposure (Chapter 93), such as employment in the aerospace, automotive, ceramic, or computer industries, requires further investigation because chronic beryllium disease cannot be clinically or histologically distinguished from sarcoidosis.

A diagnosis of sarcoidosis is reasonably certain even without histologic confirmation in patients who present with Löfgren's syndrome. In all other cases, a biopsy specimen from an involved organ should be obtained. The organ for which biopsy is safest, such as the skin, peripheral lymph nodes, lacrimal glands, or conjunctiva, should be sampled.

If diagnosis requires intrathoracic sampling, transbronchial biopsy by means of bronchoscopy has a diagnostic yield of at least 85%. Even when pulmonary parenchymal involvement is not visible on plain chest radiography, transbronchial lung biopsy has an excellent diagnostic yield when multiple lung segments are sampled. Bronchoalveolar lavage sampling demonstrates lymphocytosis with normal or low granulocyte counts in more than 85% of patients (Chapter 85). The CD4/CD8 ratio is increased in bronchoalveolar lavage in about 50% of patients with sarcoidosis, but bronchoalveolar lavage findings are nonspecific and should not be used to diagnose sarcoidosis. Bronchoalveolar lavage findings also cannot predict prognosis or responsiveness to corticosteroid therapy.

Fine-needle aspiration of enlarged intrathoracic lymph nodes guided by endobronchial ultrasound has an 80% diagnostic yield and is significantly more likely to make the diagnosis than in unguided transbronchial biopsy.■ Endobronchial ultrasound allows visualization of mediastinal structures, including the subcarinal region, paraesophageal space, and aortopulmonary window. Bronchoscopy and endobronchial ultrasound-guided fine-needle aspiration generally make the need for more invasive approaches, such as mediastinoscopy or video-assisted thoracoscopic surgical biopsies, unnecessary.

Sarcoidal granulomas produce angiotensin-converting enzyme (ACE). Although serum ACE levels are elevated in 60% of patients with sarcoidosis, the value of a serum ACE level in diagnosing sarcoidosis remains limited because positive and negative predictive values are only about 84% and 74%, respectively.

Patients should routinely undergo pulmonary function testing, which often does not correlate with the chest radiographic stage. For example, pulmonary function tests may be abnormal even in patients with a normal chest radiograph. Diffusion capacity for carbon monoxide (D_{LCO}) is usually the first abnormality detected and the last to normalize on remission. A D_{LCO} of less than 50% of predicted is associated with exercise-induced oxygen desaturation and should prompt formal oxygen saturation testing with exercise.

About two thirds of patients have airflow limitation at presentation. Spirometry usually indicates restrictive ventilatory dysfunction with a reduced forced vital capacity (FVC) and reduced forced expiratory volume in 1 second (FEV_1). At least 50% of patients have concurrent obstructive airways disease. Airway hyperreactivity, as measured by increased responsiveness to methacholine, occurs in up to 83% of patients. In patients with abnormal spirometric findings at diagnosis, spirometry returns to normal in 80%.

Alterations in cardiopulmonary exercise testing have been reported in nearly 50% of patients with sarcoidosis. Abnormalities, including a ventilatory limitation with exercise and a widened alveolar-arterial O_2 gradient, may be present. FVC is the single best test for following respiratory involvement and correlates well with FEV_1, total lung capacity, and DLCO.

Because ocular involvement is common and vision loss may occur, complete ocular evaluation with slit lamp and funduscopic examinations should be routinely performed during the initial evaluation and then annually in patients with active systemic disease.

An electrocardiogram (ECG) should be performed at the initial encounter. Screening for cardiac symptoms (palpitations, dizziness, and syncope) should be performed during the initial evaluation and routinely during follow-up visits if the disease is active. Any cardiac symptoms or abnormalities on the ECG should prompt further cardiac event monitoring (Chapter 62) and testing by echocardiography (Chapter 55). Endomyocardial biopsy has less than 20% diagnostic yield because cardiac involvement is patchy and is usually most dense in the left ventricle and basal ventricular septum where endomyocardial biopsies are avoided. If cardiac involvement is suspected, positron emission tomography (PET) or cardiac magnetic resonance imaging (MRI) with contrast should be performed. For significant symptoms, such as arrhythmias, decreased ventricular function, or septal involvement detected on MRI or PET, electrophysiologic studies should be considered and the need for an automatic implantable cardioverter-defibrillator (AICD) should be evaluated (Chapters 65 and 66).

The criteria for the diagnosis of neurosarcoidosis in the absence of histologic confirmation are not established. Compatible MRI findings, a characteristic presentation, and exclusion of other neurologic diseases are required. Histologic confirmation of disease elsewhere supports the diagnosis of neurosarcoidosis. Cerebrospinal fluid (CSF) analysis typically demonstrates nonspecific lymphocytic inflammation (Chapter 420). The CSF glucose can be as low as 14 mg/dL, with a white blood cell count as high as 350 cells/μL and a protein concentration as high as 670 mg/dL. CSF ACE levels are neither sensitive nor specific. CSF oligoclonal immunoglobulin bands are elevated in one third of patients, thereby making it difficult to differentiate sarcoidosis from multiple sclerosis (Chapter 419).

Up to 65% of patients will have granulomas on liver biopsy, but hepatic granulomas (Chapter 154) occur commonly with other disorders such as infection and drug-induced hepatitis. As a result, the diagnosis of sarcoidosis should not be based solely on detection of hepatic granulomas.

On plain radiographic images, most skeletal lesions of sarcoidosis are seen in the small bones of the hands and feet. MRI and PET scanning show much greater involvement of the axial skeleton and long bones, and osseous sarcoidosis may appear similar to metastatic disease on a PET scan.

Sarcoidosis Complicating Type 1 Interferon Therapy

Type 1 interferons, IFN-α and IFN-β, used to treat viral hepatitis (Chapter 151), multiple sclerosis (Chapter 419), and autoimmune and malignant disease may increase the T_H1 cytokines, IFN-γ, and IL-2 and rarely (<1 to 5%) result in sarcoidosis. Most reported cases of interferon-induced sarcoidosis occur within 6 months of therapy and manifest primarily with lung and skin involvement.

TABLE 95-3 TREATMENT

ORGAN	CLINICAL FINDINGS	TREATMENT
Respiratory	Dyspnea, persistent cough, FVC < 70%	Prednisone, 20-40 mg/day
	Mild cough, wheezing	Inhaled corticosteroid
Skin	Lupus pernio	Prednisone, 20-40 mg/day Hydroxychloroquine, 400 mg/day Methotrexate, 10-15 mg/wk Infliximab, 3-5 mg/kg every 2-4 weeks
	Maculopapular eruptions	Topical corticosteroid Hydroxychloroquine, 400 mg/day Prednisone, 20-40 mg/day
	Erythema nodosum	NSAID*
Eyes	Anterior uveitis Posterior uveitis	Topical corticosteroid Prednisone, 20-40 mg/day
Cardiac	Complete heart block, ventricular arrhythmias	AICD, prednisone, 20-40 mg/day
	Decreased LVEF (<35%)	AICD, prednisone, 20-40 mg/day
Central nervous system	Cranial nerve palsies	Prednisone, 20-40 mg/day
	Myelopathy	Prednisone, 40-60 mg/day, and azathioprine, 150 mg/day (or mycophenolate mofetil, or cyclophosphamide)
	Intracerebral involvement	Prednisone, 40-60 mg/day, and azathioprine, 150 mg/day (or mycophenolate mofetil, or cyclophosphamide)
Liver	Cholestatic hepatitis	Prednisone, 20-40 mg/day
Bone and joint	Arthralgias	NSAID
	Granulomatous arthritis	Prednisone, 20-40 mg/day Methotrexate, 10-15 mg/wk
	Bone destruction/pain	Prednisone, 20-40 mg/day Methotrexate, 10-15 mg/wk
Hypercalciuria and hypercalcemia	Kidney stones	Prednisone, 20-40 mg/day Hydroxychloroquine, 400 mg/day

*For example, ibuprofen, 200-800 mg three times a day.
AICD = automatic implantable cardioverter-defibrillator; FVC = forced vital capacity; LVEF = left ventricular ejection fraction; NSAID = nonsteroidal anti-inflammatory drug.

PREVENTION AND TREATMENT

Rx

Because the inciting agent has not yet been identified nor genetic risk factors firmly established, no means exist to prevent sarcoidosis. Most patients with sarcoidosis are not disabled by their illness, so the decision to recommend treatment should weigh the risks of using corticosteroids (Chapter 34), which are the most common treatment, against potential benefits (Table 95-3). Hypercalcemia, cardiac disease, and neurologic disease are indications for treatment, and immediate treatment is appropriate whenever organ function is threatened or when symptoms are severe. Detection of granulomatous inflammation on physical examination, biopsy, or imaging or the presence of an elevated serum ACE level is not a mandate to provide treatment.

Oral prednisone at a dose of 20 to 40 mg per day for 3 months is usually the initial recommended therapy. Response to treatment is indicated by improvement in symptoms or objective measures, such as decreased size and number of skin lesions, increased FVC, or a reduction of detectable cardiac or brain lesions. For pulmonary involvement, steroids improve symptoms, pulmonary function test results, and chest radiographic findings.[2] If a response is noted at 3 months, the prednisone dose should be tapered to 10 to 15 mg per day for an additional 6 to 9 months and then tapered off. Because recurrence may occur, patients should be followed closely for 1 to 2 years after discontinuing treatment. The indications for restarting treatment are the same as those used to begin treatment. Lack of response after a 3-month trial suggests nonadherence to therapy, an inadequate dose of prednisone, or irreversible fibrotic disease. Inhaled corticosteroids should be used only in patients with bronchial hyperreactivity or persistent cough.

Cytotoxic and immunosuppressive drugs have been used to treat patients who do not respond to corticosteroid therapy or who cannot tolerate it (see Table 95-3), but data on their benefit are inconclusive,[3] and no large randomized trials confirm an optimal agent. Generally, 3 to 6 months of cytotoxic and immunosuppressive treatment is required to determine whether a response has occurred. For patients who respond, the duration of treatment should be 9 to 12 months. In patients who are steroid dependent but have ongoing extrapulmonary disease, the addition of infliximab, 3 to 5 mg/kg for 24 weeks, can be efficacious.[4]

Moderate doses of corticosteroids (15 to 20 mg prednisone) reduce the elevated serum and urinary calcium within a few days of starting treatment. Failure of serum calcium to normalize within 2 weeks should alert the clinician to an alternative diagnosis such as hyperparathyroidism or malignancy (Chapter 253). With treatment, most patients with granulomatous interstitial nephritis regain renal function but are often left with chronic kidney disease of varying severity.

Less than 1% of heart and liver and about 3% of lung transplantations are performed in patients with sarcoidosis. The 1- and 5-year graft survival rates for lung, liver, and heart transplantations in patients with sarcoidosis compare favorably with the results obtained for patients with other disorders.

PROGNOSIS

Patients with Löfgren's syndrome have a good prognosis characterized by spontaneous resolution with few consequences. Overall, spontaneous remission with few or no consequences occurs in more than 50% of patients within 3 years of diagnosis and in two thirds of patients within a decade. After one or more years of remission without treatment, recurrence occurs in fewer than 5% of patients. Up to one third of patients have unrelenting disease that leads to significant organ impairment, but less than 5% of patients die from sarcoidosis. Black Americans tend to have a worse prognosis with more chronic disease and more extrathoracic involvement of the eyes, liver, bone marrow, extrathoracic lymph nodes, and skin. Patients with neurologic and cardiac involvement have a poorer prognosis.

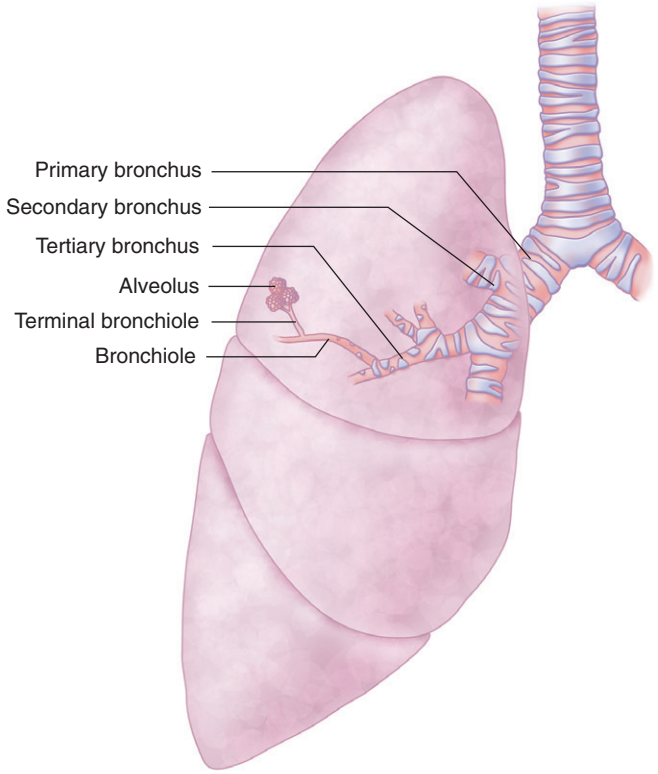

FIGURE 96-1. Many infecting agents that cause bronchitis and tracheitis can infect both large and small airways of the lung and occasionally the alveoli. Not surprisingly, a wide spectrum of signs and symptoms are associated with bronchitis, including cough, wheezing, and shortness of breath.

96 ACUTE BRONCHITIS AND TRACHEITIS

RICHARD P. WENZEL

DEFINITION

The term *acute bronchitis and tracheitis* defines a self-limited (1 to 3 weeks) inflammation of the large airways of the lung that extends to the tertiary bronchi (Fig. 96-1). In patients with a primary symptom of cough (Chapter 83), the diagnosis is made if there is no clinical or radiologic evidence of pneumonia. At the bedside, the absence of criteria for systemic inflammatory response syndrome (SIRS) (Chapter 108) suggests bronchitis and tracheitis and makes a diagnosis of pneumonia (Chapter 97) unlikely. The SIRS criteria are met if the patient has more than two of the following: temperature lower than 36° C or higher than 38° C, pulse greater than 90 beats/minute, respiratory rate higher than 20 breaths/minute, or white blood cell count less than 4000 cells/mm^3 or higher than 12,000 cells/mm^3 or with greater than 10% bands.

The definition of acute bronchitis and tracheitis also seeks to differentiate the illness from acute inflammation of the small airways (bronchiolitis), even though the accompanying symptoms with the former may include sputum production, wheezing, and shortness of breath. Among patients with primarily small airways disease, some might be expected to have prominently decreased breath sounds in the areas involved. Acute bronchitis and tracheitis is also different from bronchiectasis (Chapter 90), which is associated with permanent dilation of bronchi and a chronic cough. Furthermore, a diagnosis of chronic bronchitis (Chapter 88) is reserved for patients who have prolonged cough and sputum production: at least 3 months of the year for 2 consecutive years.

EPIDEMIOLOGY

Occurring at a rate of 44 per 1000 adults per year, acute bronchitis and tracheitis affects approximately 5% of adults annually. A higher incidence is observed in the winter and fall than in the summer and spring. In the United States, acute bronchitis and tracheitis is the ninth most common illness in outpatients as reported by physicians.

The disorder is thought to be viral in origin almost all the time. However, viruses have been isolated in only 8 to 37% of patients. Thus, the true causes of the illness are unknown in most cases. Nevertheless, at least 70% of patients with acute bronchitis and tracheitis in the United States receive antibacterial antibiotics after visiting a physician. Importantly, although the same bacteria that are commonly implicated in community-acquired pneumonia are also isolated from the sputum in half the patients, their role in the pathobiology of acute bronchitis and tracheitis or its attendant symptoms is unclear, and bronchial biopsies have not shown bacterial invasion.

PATHOBIOLOGY

Infections of the epithelium of the bronchi and trachea are thought to incite an inflammatory response. Pathologically, there is an accompanying microscopic thickening of bronchial and tracheal mucosa corresponding to the inflamed areas. Such pathologic findings are also consistent with the occasional case report of upper airway inflammation confined to the bronchi and trachea detected by ^{18}F-labeled fluorodeoxyglucose positron emission tomography (FDG-PET).

In human experimental rhinovirus infections (Chapter 369), virus was detected in all subjects in induced sputum samples and also in approximately one third of bronchial biopsy specimens, almost one fourth of bronchoalveolar lavage samples, and more than one third of biopsy and brushing samples. Such data indicating viral infection of the lower airways may help explain the relationship observed between rhinovirus infection and exacerbations of asthma (Chapter 87). Furthermore, pathologic islands of inflammation have been found in the trachea with rhinovirus infection, thus supporting the idea of a patchy distribution. The viruses implicated in acute bronchitis and tracheitis include influenza A and B (Chapter 372), parainfluenza (Chapter 371), respiratory syncytial virus (Chapter 370), coronavirus (Chapter 374), adenovirus (Chapter 373), and rhinoviruses (Chapter 369), usually in this order from the most to the least common. However, a recent French study of influenza-vaccinated adults found a viral cause in 37% of 164 cases of acute bronchitis, 21% of which were rhinovirus. Thus, at least three variables can influence the yield of specific pathogens: the presence of epidemics, the

season of the year, and the population's influenza vaccination status. More recently, human metapneumovirus (Chapter 369) has been identified as an etiologic agent.

Up to 10% of cases of acute bronchitis and tracheitis may be due to "atypical" bacteria: *Bordetella pertussis* (Chapter 321), *Chlamydophila (Chlamydia) pneumoniae* (Chapter 325), and *Mycoplasma pneumoniae* (Chapter 326). Severe bronchiolitis has also been reported with *M. pneumoniae,* even though this pathogen is usually associated with either pneumonia or acute bronchitis and tracheitis in adults. In children, bronchiolitis has been associated with respiratory syncytial virus, influenza virus, parainfluenza virus, and metapneumovirus (Chapter 369). Thus, there are probably wide variations in the anatomic distribution of all pathogens causing acute bronchitis and tracheitis, extending from the nasal mucosa to the bronchiolar epithelium.

CLINICAL MANIFESTATIONS

The cardinal clinical symptom is cough (Chapter 83) of recent onset. Because most upper respiratory infections resolve within 1 week, a more extended period of cough is useful for considering the diagnosis of acute bronchitis. Patients usually seek care from their physician after 4 to 7 days of coughing that is not resolving. With acute bronchitis, there is often a continued cough and sometimes a worsened cough that lasts an initial 1 to 3 weeks. Associated symptoms vary and include sputum production, fever, malaise, wheezing, and dyspnea. Adults with pertussis may exhibit paroxysms of coughing, whooping, or vomiting, although less commonly than seen in children with this infection.

DIAGNOSIS

Acutely ill patients may not be able to distinguish their early symptoms from those accompanying very mild upper respiratory infections. However, with acute bronchitis and tracheitis, a protracted phase of coughing persists beyond 1 to 5 days, during which time pulmonary function tests may become abnormal. A substantial proportion of patients will have significant declines in forced expiratory volume in the first second (FEV_1) (Chapter 85).

Rapid diagnostic tests exist for most viruses linked to acute bronchitis and tracheitis. However, their value lies in identifying a virus for which there is therapy or avoiding antibacterial antibiotics if any virus is identified. Not all rapid tests are widely available, and they are expensive and rarely cost-effective in an outpatient setting.

When "atypical" bacteria are identified by culture or serology, patients tend to be seen later in the course of their illness than patients with viral causes and more often have wheezing. In some studies, 12 to 32% of patients with coughing that persists for longer than 1 week had pertussis. In other studies, however, pertussis has been confirmed in only 1% of such patients.

Polymerase chain reaction (PCR) testing of nasopharyngeal swabs or aspirates is the easiest and most sensitive way to diagnose infections by *B. pertussis, M. pneumoniae,* and *C. pneumoniae;* most experts recommend calcium alginate swabs for pertussis because cotton inhibits growth. Dacron swabs with aluminum handles are preferred for specimens used to diagnose *Chlamydophila* because cotton, calcium alginate, and the wooden shaft can all inhibit growth of the organism. Cultures for *M. pneumoniae* are slow and insensitive. In general, testing for atypical organisms should not be done because of the cost of PCR and both the insensitivity and slowness of cultures. However, if the clinician suspects an outbreak in the community or the likelihood of pertussis, rapid testing with PCR may be quite beneficial.

TREATMENT

Rx

In a meta-analysis of nine randomized trials of antibacterial antibiotics for acute bronchitis, patients receiving antibiotics were significantly less likely to have a cough, but their 0.58 fewer days with cough, 0.52 fewer days of productive cough, and 0.58 fewer days of feeling ill were not statistically significant.[1] A large clinical trial in a population with a high prevalence of human immunodeficiency virus infection found that amoxicillin for 7 days was no better than placebo.[2]

These results are not surprising because, at most, about 50% of cases are probably caused by bacterial pathogens. Nevertheless, antibiotics are used in 50 to 85% of cases worldwide.

Antibiotics may be used in patients with known atypical pathogens, but even then their effect on outcomes is not clear except to limit the spread of pertussis, especially during a defined outbreak. In adults suspected of having pertussis, erythromycin, 500 mg four times a day for 14 days, is thought to be most effective. However, many patients cannot tolerate erythromycin, and either doxycycline, 100 mg every 12 hours, or a newer macrolide such as azithromycin, 500 mg on day 1 and 250 mg/day thereafter, is effective. The latter two drugs are also active against *C. pneumoniae* and *M. pneumoniae,* although the optimal duration of therapy for acute bronchitis is unknown. A useful range is 5 to 14 days.

During influenza season, anti-influenza agents may be useful in decreasing symptoms by approximately 1 day and may lead to a 0.5-day earlier return to normal activity in patients with influenza. The first-generation drugs amantadine and rimantadine are ineffective against H3N2 influenza A viruses and are not recommended. Second-generation drugs such as zanamivir (two inhalations of 5 mg each, twice a day) or oseltamivir (75 mg twice a day) can be given for 5 days. Up to 20% of patients given oseltamivir will have nausea or vomiting.

Antihistamines and over-the-counter antitussives and expectorants have no apparent value. Subsets of patients with bronchial hyperresponsiveness may benefit from β-agonists, but no data support the use of inhaled steroids. Mucolytic agents may be of small benefit.[3]

In experimental rhinovirus colds, nonsteroidal drugs, alone or in combination with antihistamines, reduce the severity of symptoms, including cough. However, the widespread use of either type of drug alone or as a combination in naturally occurring, community-acquired bronchitis and tracheitis has not been evaluated. In patients with acute bronchitis, a meta-analysis of four placebo-controlled clinical trials suggested that *Pelargonium sidoides* (a herbaceous perennial widely used in Europe) reduced bronchitis symptom scores by day 7.[4]

PROGNOSIS

Coughing usually lasts 10 to 14 days, during which time the illness causes significant transient decrements in vitality and social functioning. Limited data on short- and long-term outcomes show that up to 20% of patients have persistent or recurrent symptoms for a month. Antibiotics may reduce symptoms by a fraction of a day, but side effects, the emergence of antibiotic resistance, and cost must be weighed against their modest benefits. The mean duration of an office visit for adults in the United States with upper respiratory tract infections is 14.2 minutes when patients are prescribed antibiotics versus 15.2 minutes without prescription of antibiotics, but antibiotic use is not an independent predictor of visit length. Future widespread use of rapid diagnostic tests for specific bacterial and viral pathogens will be useful in targeting effective therapies.

OVERVIEW OF PNEUMONIA

ANDREW H. LIMPER

It is a useful distinction to separate pneumonias, which are infections of the lung parenchyma and thus distinct from infections limited to the trachea or large bronchi (Chapter 96), into those acquired in the community (community-acquired pneumonia) and those arising in institutional settings, with the second group being composed of hospital-acquired pneumonia, ventilator-associated pneumonia, and health care–associated pneumonia. These two major pneumonia categories are considered separately in this

chapter. Additional consideration should be given to pneumonia caused by recurrent aspiration of oropharyngeal contents.

The term *pneumonia* itself, however, includes other causes of inflammation of the lower respiratory air spaces, particularly the alveoli, such as acute or chronic eosinophilic pneumonia, cryptogenic organizing pneumonia, and usual interstitial pneumonia, all of which are presented in more detail elsewhere (Chapter 92).

COMMUNITY-ACQUIRED PNEUMONIA

DEFINITION

Community-acquired pneumonia includes cases of infectious pneumonia in patients living independently in the community. Patients who have been hospitalized for other reasons for less than 48 hours before the development of respiratory symptoms are also considered to have community-acquired pneumonia because it is likely that the inoculation had occurred before admission. However, patients who have previously been hospitalized for at least 2 days within the 90 days before infection; patients from nursing homes who received intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days; and patients from hemodialysis centers are considered to have health care–associated pneumonia and are therefore excluded from the case definition of community-acquired pneumonia. Patients contracting pneumonia more than 48 hours after the institution of endotracheal intubation and mechanical ventilation are also excluded inasmuch as they are considered to have ventilator-associated pneumonia. These distinctions are important because they help define the most likely infectious agents and hence strongly influence appropriate choices for the initial antibiotic therapy.

EPIDEMIOLOGY

More than 10 million cases of infectious pneumonia occur annually in the United States and result in more than 1 million hospitalizations. Pneumonia is a leading cause of death worldwide, the sixth leading cause of death in the United States, and the most common lethal infectious disease. The mortality rate associated with community-acquired pneumonia ranges from less than 5% in mildly ill outpatients to somewhat greater than 12% overall in patients who are admitted to a hospital. Mortality is even greater in patients who have severe invasive disease, which is often associated with bacteremia, and in elderly nursing home patients. Mortality from pneumonia can exceed 40% in patients who require management in the intensive care unit (ICU). It costs approximately $7000 to manage an uncomplicated case of pneumonia in the hospital, or about 20-fold more than treating it in the outpatient setting.

PATHOBIOLOGY

Aspiration of Oropharyngeal Contents

The most common mechanism by which the lung is inoculated with pathogenic organisms is through microaspiration of oropharyngeal contents, a process that occurs in otherwise healthy individuals during sleep (Chapter 94). Colonization of the oral pharynx with pathogenic organisms, such as *Streptococcus pneumoniae* (Chapter 297), can thereby lead to delivery of sufficient quantities of organisms to infect the lung. In contrast, gross aspiration normally occurs only in individuals with altered sensorium, depressed consciousness, abnormalities in protective cough or gag reflexes, or substantial gastroesophageal reflux. Gross aspiration, which can also deliver large numbers of anaerobic bacteria to the lower respiratory tract, is a major contributing factor to anaerobic lung infection and abscess formation (Chapter 90).

Inhalation of Aerosolized Droplets

The second most frequent mechanism of lung infection is the inhalation of small, suspended aerosolized droplets ranging in size from 0.5 to 1 μm that may contain microorganisms. In view of the limited number of organisms delivered in such a manner, only relatively aggressive pathogenic organisms such as *Mycobacterium tuberculosis* (Chapter 332), *Legionella pneumophila* (Chapter 322), *Yersinia pestis* (plague; Chapter 320), *Bacillus anthracis* (anthrax; Chapter 302), and some viral infections can be transmitted in this manner.

Blood Stream Infection

Less commonly, the lung may become infected as a consequence of a blood stream infection. Blood-borne pneumonia is seen especially in staphylococcal sepsis (Chapter 296) or right-sided endocarditis (Chapter 76), both of which are more common in intravenous drug users (Chapter 33), and in gram-negative bacteremias, particularly in an immunocompromised host. The lung may also rarely be inoculated directly by penetrating chest trauma or by local spread from a nearby infected organ (bacterial or amoebic liver abscess or paragonimiasis; Chapters 360 and 364) or a contiguous soft tissue infection.

Fortunately, the lung is well equipped to defend against inoculation with most microbes. When large droplets of infected material reach the airways, they are removed by the mucociliary escalator, which sweeps entrapped contents up to the oropharynx, where they are swallowed or expectorated. Smaller particles, in the range of 0.5 to 2.0 μm, are deposited in the alveoli, where alveolar macrophages phagocytize and destroy most pathogens. These macrophages are further activated to release potent cytokines and chemokines, including tumor necrosis factor-α, interleukin-8, and leukotriene B_4, which help recruit neutrophils from the blood stream into the alveolar spaces, where they participate in the uptake and degradation of microorganisms. For many microorganisms such as *S. pneumoniae* (Chapter 297), clearance of infection is greatly facilitated by the development of specific immunoglobulin G that binds the surface of the organisms or their polysaccharide capsule. These specific antibodies, which act as immune opsonins, greatly augment the ability of neutrophils and macrophages to phagocytize and destroy the bacteria. In addition, pattern recognition receptors and other nonimmune opsonins, including surfactant proteins A and D, fibronectin, and vitronectin, also bind to specific epitopes on the surface of organisms that reach the lower respiratory tract and assist in their recognition and elimination. Only when organisms overwhelm or evade these multiple host defense systems does inoculation of the lung result in clinically significant pneumonia.

CLINICAL MANIFESTATIONS

The possibility of pneumonia should be considered in any patient who has new respiratory symptoms, including cough, sputum, or dyspnea, particularly when these symptoms are accompanied by fever or abnormalities on physical examination of the chest, such as rhonchi and rales. The initial manifestation is frequently more subtle in patients who are elderly or have an altered immunologic status; in such patients, nonspecific symptoms, including loss of appetite, confusion, dehydration, worsening of symptoms or signs of other chronic illnesses, or failure to thrive, may be the initial manifestation of pneumonia. Pneumonia is also increasingly prevalent in patients with specific comorbid conditions, including smoking, chronic obstructive pulmonary disease (COPD; Chapter 88), diabetes mellitus, malignancy, heart failure, neurologic diseases, narcotic and alcohol use, and chronic liver disease.

The initial symptoms and signs are often variable from patient to patient and cannot be reliably used to establish a specific (microbiologic) diagnosis. The classic physical findings in lobar pneumonia include evidence of consolidation with altered transmission of breath sounds, egophony, crackles, and changes in tactile fremitus. However, in many patients, the physical findings are subtler and may be limited to scattered rhonchi. A thorough physical examination, posteroanterior and lateral chest radiographs, and a blood leukocyte count with a differential cell count should be performed when pneumonia is suspected. An assessment of gas exchange (oximetry or arterial blood gas determination) should be obtained for all patients who are admitted to the hospital. The clinician needs to be mindful of competing diagnoses that can mimic the findings of pneumonia, such as pulmonary embolism (Chapter 98), bronchogenic and bronchoalveolar carcinoma (Chapter 197), drug-induced lung diseases (Chapter 94), and idiopathic interstitial lung diseases (Chapter 92).

DIAGNOSIS

Even with intensive laboratory investigation, the specific microbiologic cause can be established with certainty only in approximately 50% of patients with pneumonia. The probable predominant organism varies with the host's epidemiologic factors, the severity of illness, and which laboratory approach is used to establish the diagnosis.

Bacterial Pneumonia

S. pneumoniae (Chapter 297) is the organism most frequently detected by culture of sputum or blood. In contrast, *Mycoplasma pneumoniae* (Chapter 325) is frequently detected with serologic tests. Additional bacterial agents include *Haemophilus influenzae* (Chapter 308), *Staphylococcus aureus* (Chapter 296), enteric gram-negative bacilli (Chapters 290 and 314), and *L. pneumophila* (Chapter 322). *Chlamydia* and respiratory viruses have also been implicated in up to 10% of cases. The so-called atypical pathogens,

TABLE 97-1 HOST FACTORS ASSOCIATED WITH SPECIFIC PATHOGENIC CAUSES OF PNEUMONIA

UNDERLYING CONDITION	ASSOCIATED MICROORGANISM
Active smoking/chronic obstructive lung disease	*Streptococcus pneumoniae, Haemophilus influenzae, Legionella pneumophila, Moraxella catarrhalis, Pseudomonas aeruginosa, Chlamydophila pneumonia*
Nursing home residents	*S. pneumoniae*, gram-negative bacilli, *H. influenzae, Staphylococcus aureus, Chlamydophila pneumonia*, anaerobes, *Mycobacterium tuberculosis*
Alcoholism	*S. pneumoniae* (including drug-resistant strains), gram-negative bacilli, anaerobes, *Mycobacterium tuberculosis, Klebsiella pneumoniae, Acinetobacter species*
Gross aspiration/poor dentition	Anaerobes, gram-negative enteric pathogens
Travel to southwestern United States	*Coccidioides immitis*
Exposure to bats	*Histoplasma capsulatum*
Exposure to birds	*Cryptococcus neoformans, Chlamydia psittaci, H. capsulatum*
Exposure to rabbits	*Francisella tularensis*
Exposure to farm animals	*Coxiella burnetii* (Q fever)
Viral influenza	Influenza, *S. aureus, S. pneumoniae, H. influenzae*
Bronchiectasis, cystic fibrosis	*Pseudomonas aeruginosa, Burkholderia cepacia, S. aureus, Aspergillus* species, *Mycobacterium avium* complex
Lung abscess	CA-MRSA, oral anaerobes, endemic fungal pneumonia, *M. tuberculosis*, atypical mycobacteria
Intravenous drug use	*S. aureus*, anaerobes, *M. tuberculosis*, *S. pneumoniae*
Endobronchial obstruction	Anaerobes
Recent antibiotic therapy	Drug-resistant *S. pneumoniae, P. aeruginosa*
HIV (early)	*S. pneumoniae, H. influenza, M. tuberculosis*
HIV (late)	The pathogens listed for early HIV infection, plus *Pneumocystis jirovecii, Cryptococcus, Histoplasma, Aspergillus*, atypical mycobacteria (especially *M. kansasii* and *M. avium* complex), *P. aeruginosa, H. influenza*
In the context of bioterrorism	*Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), *Francisella tularensis* (tularemia)

CA-MRSA = community-acquired methicillin-resistant *Staphylococcus aureus*; HIV = human immunodeficiency virus.
Adapted from Infectious Diseases Society of America/American Thoracic Society. Consensus guidelines on the management of community acquired pneumonia in adults. *Clin Infect Dis.* 2007;44:S27-S72.

including *M. pneumoniae, Chlamydia pneumoniae,* and *Legionella* species, are increasingly being recognized as important and prevalent causes of pneumonia. Mixed infections, particularly those related to coinfection with these "atypical" pathogens in addition to the usual bacterial pathogens, have been reported in up to one third of patients with lower respiratory tract infection.

Specific host factors also influence the relative risk for infection with specific microorganisms (Table 97-1). For instance, smokers and those with COPD are at increased risk for invasive *S. pneumoniae,* as well as *H. influenzae, Moraxella catarrhalis* (Chapter 308), and *Legionella* species. Alcoholism is associated with increased risk for drug-resistant *S. pneumoniae,* anaerobic lung infection, and tuberculosis.

The clinician also should solicit information about household and workplace exposure, such as to other ill persons. The clinician should ask about recent travel to specific geographic regions, such as the central United States, where histoplasmosis is endemic (Chapter 340), the Southwest, where coccidioidomycosis is found (Chapter 341), and selected northern and central regions of the United States, where blastomycosis is found (Chapter 342). Recent travel to regions with epidemic viral respiratory infections, including seasonal influenza, avian influenza, H1N1 (swine) influenza, and severe acute respiratory syndrome (SARS), or travel to Asia, Africa, and central and eastern Europe, which are highly endemic for tuberculosis, should be considered (Chapter 332). In addition, environmental exposure, such as to birds (psittacosis), bird droppings (histoplasmosis), bats (histoplasmosis), rabbits (tularemia, Chapter 319), and farm animals (Q fever, Chapter 335), is additional data that should be obtained during the history.

Viral Pneumonia

Although most attention traditionally focuses on bacterial causes of severe community-acquired pneumonia, viruses can also cause serious lower respiratory tract infections. The predominant respiratory viruses that can cause severe pneumonia include various influenza viruses and respiratory syncytial virus (RSV) (Chapter 370). Both influenza virus and RSV can be detected in respiratory secretions, which should be obtained in suspected cases. It is estimated that influenza infections are responsible for in excess of 36,000 respiratory- and circulatory-related deaths annually in the United States, predominantly in elderly patients and those with underlying cardiopulmonary or metabolic disease. Influenza-associated pneumonia should be considered in the differential diagnosis of respiratory infections in high-risk patients with underlying disease and in residents of nursing homes or other chronic care facilities during the season of October through May, especially in patients who have not received appropriate vaccination.

It is also increasingly being appreciated that RSV and parainfluenza (Chapter 371) viruses, although formerly considered mainly infections of pediatric populations, can lead to serious lower respiratory tract infections in adults during the winter season. Host immunity to RSV infection in childhood is incomplete, and recurrent infections can occur in both immune-competent and immune-impaired adults, particularly in elderly patients. It is estimated that RSV is associated with more than 11,000 deaths each year in the United States, with most deaths occurring in elderly people and in patients with chronic cardiopulmonary disease.

Emerging influenza infections must also be considered. Although typical seasonal influenza tends to occur in North America during the months of October to May, novel influenza viruses do not always follow that epidemiology. In particular in the spring and summer of 2009, a novel H1N1 (swine) influenza virus occurred in epidemic proportions in Mexico and rapidly spread over the world. In contrast to many other influenza outbreaks, the virus continued to circulate over the summer months in both the northern and southern hemispheres. H1N1 generally produced a typical syndrome with fever, headaches, cough, malaise, and myalgias. Most cases were mild or self-limited. However, excess hospitalization and mortality from H1N1 infection has been observed in infants, children, and adults younger than 24 years. Pregnant women and children, in particular those who are immunosuppressed, are at particular risk.

Avian influenza A (H5N1; Chapter 372) generally infects wild birds, which carry the H5N1 virus in their intestines, but usually are not made very sick by the virus. However, avian influenza can be highly contagious and fatal among domesticated birds, including chickens, turkeys, and ducks. Transmission to humans has been relatively uncommon, despite the lack of immunity against the virus, but human outbreaks have occurred from contact with infected birds (e.g., domesticated chicken and turkeys) or with secretions or excretions from infected birds.

SARS emerged as an additional form of life-threatening atypical pneumonia that was first detected in the Guangdong Province of China in late 2002, with major outbreaks in Hong Kong, Guangdong, Singapore, and Toronto and Vancouver, Canada. The disease is caused by a novel coronavirus (Chapter 374) with an incubation period of 2 to 10 days. The initial source of the infection remains uncertain, although palm civet cats and Chinese ferret badgers harbor a coronavirus with greater than 99% similarity to human SARS isolates. Worldwide, however, the illness is largely a nosocomial disease, with health care workers representing a significant fraction of the infected individuals. SARS is characterized by an insidious onset of fever, chills, headache, cough, malaise, and dyspnea, with radiologic evidence of pneumonia. Although upper respiratory symptoms are uncommon, voluminous watery diarrhea without mucus or blood develops in up to 70% of patients. SARS is believed to be principally transmitted by respiratory droplets. Current treatment is supportive, with no antiviral agent yet having been proved to be efficacious. SARS pneumonia tends to resolve slowly and spontaneously, usually by the third week of illness. However, the estimated case-fatality rate remains approximately 10%. SARS is highly contagious, and lethal transmission to health care workers has been documented. Isolation procedures and equipment appropriate for SARS include standard, contact, and airborne isolation precautions such as scrupulous hand hygiene, gowning, disposable gloves, the use of N95 respirators, and eye protection. Suspected

cases of SARS require notification of local public health departments and the Centers for Disease Control and Prevention.

Agents of Bioterrorism

Physicians should also be vigilant for clues of pneumonia related to agents of bioterrorism (Chapter 20). These clues can include outbreaks of severe illness and pneumonia in multiple, otherwise healthy individuals or the isolation of unusual organisms in patients with pneumonic illness. The microorganisms most likely to be associated with severe pneumonia during bioterrorism-related inhalation exposure include *B. anthracis* (Chapter 302), *Francisella tularensis* (Chapter 319), and *Y. pestis* (Chapter 320). Inhalational anthrax always indicates a bioterrorism threat, whereas pneumonic plague or tularemia may or may not be associated with bioterrorism.

Radiography

Clinical suspicion of pneumonia should prompt standard posteroanterior and lateral chest radiography. Although the pattern of infiltration can rarely establish a specific microbiologic etiology, chest films are most useful for providing essential information on the distribution and extent of involvement, as well as potential pneumonic complications. Many bacterial pneumonias result in localized alveolar infiltrates and consolidation. Even though pneumococcal pneumonia is classically described as having a lobar distribution, the pattern can be multilobar (Fig. 97-1) or bilateral. The "bulging" fissure sign, which represents lobar filling and consolidation, has traditionally been attributed to *Klebsiella pneumoniae,* but this finding is not specific and can be observed with *S. pneumoniae* and other bacteria and even with bronchoalveolar carcinoma. Diffuse interstitial and alveolar infiltrates should suggest viral infections (cytomegalovirus, influenza virus, or RSV), *L. pneumophila,* or enteric gram-negative pneumonia, particularly in neutropenic patients. These diffuse pulmonary infiltrations can be indistinguishable from other causes of acute respiratory distress syndrome. Diffuse alveolar and interstitial infiltration can also be observed in patients with *Pneumocystis jirovecii* pneumonia (Chapter 349) related to immune suppression, such as in those with acquired immunodeficiency syndrome. Cavitary lesions often indicate a necrotizing infection related to *S. aureus, M. tuberculosis* (Fig. 97-2), and certain endemic fungi such as *Coccidioides immitis, Aspergillus* species infection in an immunocompromised patient (Chapter 347), or anaerobic lung infection with abscess formation. Mediastinal adenopathy and widening have been observed in inhalational anthrax infections.

The chest radiograph provides further important information about potential infectious complications of pneumonia. Pleural effusions (Chapter 99), which occur in a variety of respiratory infections, are best documented with lateral decubitus views or with computed tomography (CT) imaging of the thorax. The discovery of any pleural effusion greater than 10 mm in thickness on a lateral decubitus film or any loculated effusion should prompt thoracentesis to aid in the identification of a complicated parapneumonic effusion or empyema, which may require definitive drainage (Chapter 99). Enlargement of mediastinal and hilar lymph nodes, which is rare in acute bacterial infection, suggests fungal or mycobacterial infection or an underlying lung cancer. Loss of volume of a lung segment or lobe should raise suspicion of postobstructive pneumonia distal to an endobronchial lesion caused by a neoplasm, occult foreign body, or broncholithiasis.

Laboratory Findings

Sputum Gram Stain and Culture

Considerable controversy exists over the appropriate microbiologic evaluation of patients with suspected pneumonia. Despite intensive microbiologic evaluation, a specific organism may not be discovered in half the patients with pneumonia. Furthermore, most patients with pneumonia satisfactorily respond to simple, relatively nontoxic antibiotic regimens based on the most likely organisms causing infection. Thus, the necessity to document the precise cause of the process remains uncertain.

Debate continues over the need to perform a sputum examination with Gram staining in every patient with community-acquired pneumonia. An American Thoracic Society consensus panel has recommended that a sputum Gram stain and culture be obtained primarily if an organism that is resistant to the usual empirical treatment regimens is suspected. To be useful, sputum should contain fewer than 10 squamous cells and more than 25 leukocytes per low-power field; a well-performed Gram stain may reveal a single, predominant organism such as encapsulated gram-positive cocci (pneumococci) or small pleomorphic gram-negative coccobacilli *(Haemophilus).* However, current data have not clearly correlated Gram stain findings with the results of culture of alveolar materials in large numbers of patients with community-acquired pneumonia. Nevertheless, sputum examination can strongly support the diagnosis of certain specific infections, including *M. tuberculosis* (acid-fast stain), endemic fungi (KOH preparations), *P. jirovecii* (methenamine silver or fluorescent antibody stain), or *Legionella* species (direct fluorescent antibody staining). In most cases of community-acquired pneumonia, the general intent of sputum Gram stain examination, if it is performed, should be to detect additional or unusual pathogens and hence to expand rather than narrow the initial antibiotic therapy. All too often, an adequate sputum specimen cannot be obtained, and the Gram stain interpretation may be equivocal. Therefore, the initial therapeutic plan must be based on the most likely pathogens responsible for the pneumonia.

If unusual or drug-resistant pathogens are suspected, sputum specimens should be sent for culture before antibiotic therapy is initiated. When the culture results are available, they should be compared with the predominant organisms observed on Gram stain. Unfortunately, the sensitivity and specificity of sputum culture are not optimal, each being roughly 50%. Antibiotic susceptibility information on an isolated pathogenic organism can, however, be useful both for epidemiologic surveillance and for management of patients who do not respond to initial empirical therapy.

Other Bacterial Cultures

Cultures of normally sterile body fluids such as blood, pleural fluid, or occasionally cerebrospinal fluid (CSF) are highly specific when positive.

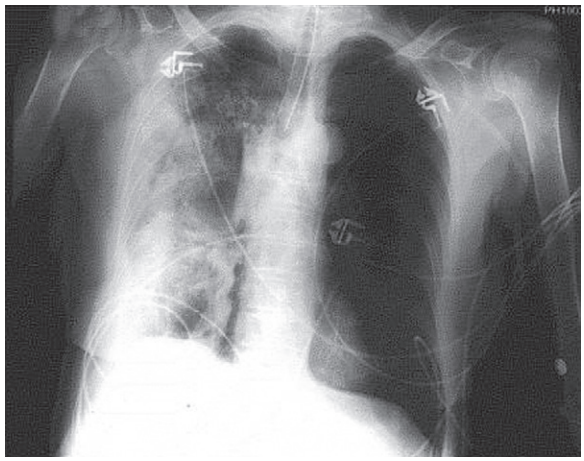

FIGURE 97-1. Radiologic diagnosis of pneumonia. A standard posteroanterior radiograph in a 70-year-old woman demonstrates chronic obstructive pulmonary disease complicated by right multilobar *Streptococcus pneumoniae* pneumonia and empyema.

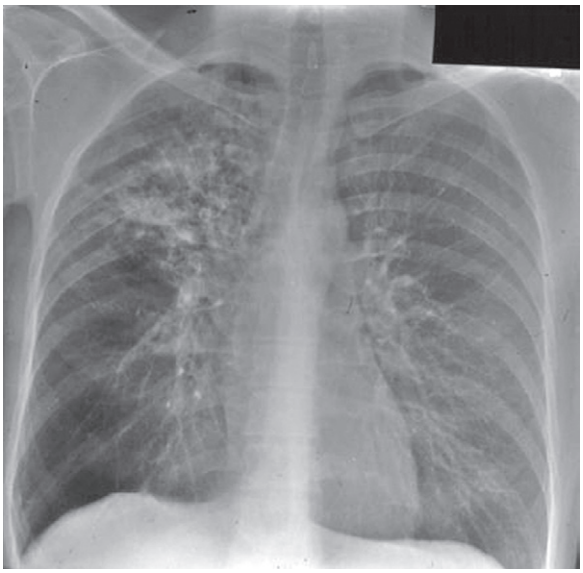

FIGURE 97-2. Cavitary lesions. A posteroanterior radiograph in a 54-year-old man with cough and fever shows a right upper lobe cavitary process caused by *Mycobacterium tuberculosis* infection.

Approximately one fourth of patients with bacterial pneumonia have demonstrable bacteremia. Blood should be drawn for culture before administration of antibiotics in patients with serious illness attributable to pneumonia, and diagnostic thoracentesis should be performed if an effusion is large enough to be aspirated safely. CSF examination is generally reserved for patients with additional signs and symptoms of meningeal irritation (Chapter 420) or abnormalities on neurologic examination.

Testing for Suspected Bioterrorism

Recommended testing for suspected anthrax includes blood culture and chest CT scanning. For the diagnosis of pneumonic plague, blood culture as well as sputum Gram stain and culture are advised. For tularemic pneumonia, cultures should be obtained from blood, sputum, and the pharynx. Culture of these extremely virulent organisms should be undertaken in a level 3 (BL3) biocontainment laboratory.

Immunologic Studies

Immunologic techniques such as immunofluorescence, enzyme-linked immunosorbent assay, antigen detection, polymerase chain reaction, and DNA hybridization may be considered when specific organisms are strongly suspected on clinical grounds, but these tests are not routinely indicated in most cases of community-acquired pneumonia. For example, *Legionella* urinary antigen screening and acute and convalescent serologic evaluation may be helpful when *L. pneumophila* pneumonia is suspected (Chapter 322). *Legionella* urinary antigen testing may underdiagnose infections caused by organisms other than *Legionella* serogroup 1. Furthermore, the judicious use of fungal serology can detect endemic mycoses, particularly histoplasmosis and coccidioidomycosis (Chapters 340, 341, and 342). Histoplasmosis can also be confirmed by urinary antigen testing with high sensitivity. The measurement of *Aspergillus galactomannan* antigen in serum can be a useful adjunct in the diagnosis of invasive *Aspergillus* pneumonia in various immunocompromised patients. Bronchoscopy with lavage for immunostaining may, in selected circumstances, provide enhanced sensitivity, such as in the diagnosis of *P. jirovecii* pneumonia (Chapter 349).

Viral Studies

Rapid antigen detection tests are now available, with tests that distinguish between influenza A and B being preferred. These tests are currently recommended for epidemiologic purposes in the community and also help direct individual therapy. RSV antigen detection tests are likewise available, but they are relatively less sensitive when applied to sputum in adult patients. A variety of other assays, including polymerase chain reaction (PCR) and specialized antigen testing, are available in reference laboratories for detection of diagnosis of novel H1N1 (swine) influenza, H5N1 (avian) influenza, and the SARS coronavirus.

Bronchoscopy

Invasive sampling of respiratory secretions is not usually necessary in patients with community-acquired pneumonia. Flexible fiberoptic bronchoscopy with a protected catheter brush and bronchoalveolar lavage (BAL) sampling has largely supplanted transtracheal and transthoracic needle aspiration. Bronchoscopy is indicated in selected clinical situations in which a delay in accurate diagnosis may have serious consequences, such as in immunocompromised hosts or patients whose condition has worsened despite initial antimicrobial therapy. Other indications for bronchoscopy in the setting of apparent community-acquired pneumonia include either lung abscess detected on a chest radiograph (Chapter 84) or evidence of volume loss and distal consolidation suggesting endobronchial obstruction.

PREVENTION

In light of the significant morbidity and potential mortality of pneumonia, appropriate measures should be instituted to reduce the possibility of lung infection. Important but often neglected interventions include smoking cessation (Chapter 31) and avoidance of illicit drugs (Chapter 33) or excess alcohol (Chapter 32), which may impair consciousness. Optimizing the patient's nutritional status is also important in that markedly underweight or obese patients are at increased risk. Finally, the appropriate and consistent use of vaccines can strongly reduce the risk for pneumonia in appropriate patient populations (Chapter 17). The current pneumococcal vaccine contains 23 purified capsular polysaccharides from the serotypes of *S. pneumoniae* that are responsible for more than 85% of invasive pneumococcal infections. Overall, this vaccine is approximately 50 to 80% effective in preventing death from invasive infection. Accordingly, current recommendations are that it should be administered to all patients older than 65 years and to patients younger than 65 years who have chronic pulmonary disease, heart disease, diabetes mellitus, alcoholism, chronic liver disease, CSF leaks, or asplenia and to patients who live in certain settings, including Alaskan natives, high-risk Native American populations, and patients in long-term care facilities. Current pneumococcal vaccines have little toxicity, limited mainly to local site irritation. Individuals generally receive one dose of vaccine, but a single revaccination 5 years later should be considered in those who received their vaccination before 65 years of age or who are at increased risk for severe pneumonia. Pneumococcal vaccine can safely be administered at the time of hospitalization for community-acquired pneumonia.

Vaccination (Chapter 17) should also be considered for viral influenza (Chapter 372). Although usually manifested as an upper respiratory tract infection, influenza can itself cause pneumonia in both immunocompetent and immunosuppressed individuals. More commonly, influenza may precipitate a subsequent bacterial infection, often with *S. aureus, H. influenzae,* and *S. pneumoniae*. Influenza vaccines are developed annually against the current influenza strains, so annual revaccination is necessary (Chapter 17). Influenza vaccines are estimated to be roughly 80% effective in preventing mortality related to influenza. The vaccine should be considered in all patients older than 50 years; residents of nursing homes and chronic care facilities; persons with chronic pulmonary, cardiac, or other diseases requiring ongoing medical care; pregnant women in the second or third trimester during influenza season; and all health care workers with direct patient contact. A weakened virus vaccine, which is administered through a nasal application, does not cause influenza and is approved for healthy people 2 years to 49 years of age who are not pregnant. An inactivated vaccine containing killed virus, administered by injection, is approved for people 6 months of age and older, including healthy people, people with chronic medical conditions, and pregnant women. Both have demonstrated efficacy in preventing influenza and its related complications, including pneumonia.

Contraindications to influenza vaccine include allergy to raw eggs or thimerosal. Side effects are generally self-limited and include injection site soreness, myalgias, mild fever, and malaise. Seasonal influenza vaccination does not lead to exacerbations of asthma. The vaccine should be administered in the fall of the year, but it can also be administered during local epidemics.

TREATMENT Rx

Oversight agencies are increasingly focused on objective measures of optimal care for community-acquired pneumonia, particularly in the hospital setting. Although recommendations are evolving and sometimes vary, current recommendations are that hospitalized patients with community-acquired pneumonia should undergo assessment of oxygenation, initiation of antibiotic therapy in the emergency department, drawing of blood for culture before antimicrobial initiation, smoking cessation intervention, and review and update of immunization status. Most experts also advise chest radiography at the time of admission. The use of biomarkers for bacterial infection, such as levels of procalcitonin, may prove to be helpful when determining which patients can avoid immediate antibiotics or discontinue initial empirical antibiotics because of a low likelihood of bacterial infection.

Initial Empirical Therapy

Because the microbiologic etiology of community-acquired pneumonia is determined in only approximately 50% of cases and the diagnosis may take a day or two, the clinician must institute appropriate empirical therapy based on the most likely agents contributing to the lung infection (Table 97-2). When possible, empirical therapy should be initiated as soon as possible after the diagnosis is established—immediately in the outpatient setting and in the emergency department if the patient is hospitalized. Empirical antimicrobial therapy is based on the severity of illness (inpatient or outpatient setting) and should broadly cover the most likely organisms. The most common bacterial pathogens are *S. pneumoniae* (Chapter 297) and *H. influenzae* (Chapter 308); however, the so-called atypical pathogens, including *M. pneumoniae, C. pneumoniae,* and *Legionella* species (Chapters 325, 326, and 322, respectively), can be the primary or coinfecting agents in up to 40% of community-acquired pneumonia and must be covered in empirical antibiotic regimens. Therapy can be narrowed later after any relevant culture information is obtained.

Guidelines for Hospital and Intensive Care Unit Admission and Treatment

Under current guidelines, patients are stratified with respect to where treatment is initiated (outpatient, inpatient, or ICU setting), the presence of underlying cardiopulmonary disease, and other modifying factors, such as whether

TABLE 97-2 MOST COMMON MICROBIOLOGIC CAUSES OF COMMUNITY-ACQUIRED PNEUMONIA IN APPROXIMATE ORDER OF FREQUENCY

OUTPATIENTS	HOSPITALIZED PATIENTS	SEVERE PNEUMONIA/ICU
Streptococcus pneumoniae	*S. pneumoniae*	*S. pneumoniae*
Mycoplasma pneumoniae	*M. pneumoniae*	*Staphylococcus aureus*
Haemophilus influenzae	*C. pneumoniae*	*Legionella* species
Chlamydophila pneumoniae	*H. influenzae*	Gram-negative bacilli
Respiratory viruses	*Legionella* species Aspiration Respiratory viruses	*H. influenzae*

TABLE 97-3 TRIAGE GUIDELINES FOR COMMUNITY-ACQUIRED PNEUMONIA

DECISION TO ADMIT TO THE HOSPITAL

Follow CURB-65 Guidelines and admit patients who have two or more of the following:
- Confusion
- Uremia (with blood urea nitrogen ≥20 mg/dL)
- Respiratory rate >30 breaths/min
- Blood pressure ≤90 mm Hg systolic or <60 mm Hg diastolic
- Age ≥65 yr

INDICATIONS FOR ICU ADMISSION (1 MAJOR AND ≥3 MINOR)

Major Criteria

Hypotension requiring vasopressors
Respiratory compromise requiring mechanical ventilation

Minor Criteria

Respiratory rate >30 breaths/min
PaO_2/FIO_2 ratio ≤250
Multilobar infiltrate
Confusion/disorientation
Uremia (blood urea nitrogen ≥20 mg/dL)
Leukopenia (white blood cell count ≤4000 cells/mm^3)
Thrombocytopenia (platelets ≤100,000 cells/mm^3)
Hypothermia (≤36° C)
Hypotension requiring aggressive fluid resuscitation

TABLE 97-4 EMPIRICAL TREATMENT GUIDELINES FOR COMMUNITY-ACQUIRED PNEUMONIA

OUTPATIENT MANAGEMENT

1. Previously healthy patients without comorbidities and no use of antimicrobials within the prior 3 months
   A macrolide (preferred) (e.g., clarithromycin, extended release, 1000 mg orally each day for at least 5 days, or azithromycin, 500 mg orally on day 1, followed by 250 mg orally each day on days 2-5)
   Doxycycline, 100 mg orally twice daily for at least 5 days
2. Presence of comorbidities such as chronic cardiopulmonary, liver, or renal disease; diabetes mellitus; alcoholism; malignancies; asplenia; immunosuppressive conditions or drugs; or use of antimicrobials in the prior 3 months (if so, select an alternative agent from a different class)
   A respiratory fluoroquinolone (oral moxifloxacin, 400 mg/day, or gemifloxacin, 320 mg/day, or levofloxacin, 750 mg daily for at least 5 days), *or*
   A β-lactam (e.g., ceftriaxone, 1-2 g IM each day for at least 5 days) *plus* a macrolide (e.g., azithromycin, 500 mg orally on day 1, followed by 250 mg orally each day on days 2-5)
3. In regions with a high rate (>25%) of infection with high-level (MIC ≥16 mg/mL) macrolide-resistant *Streptococcus pneumoniae*, consider an alternative agent as noted under (2) for patients without comorbidities.

INPATIENTS, NON-ICU MANAGEMENT

1. A respiratory fluoroquinolone (moxifloxacin, 400 mg/day, or gemifloxacin, 320 mg/day, or levofloxacin, 750 mg IV for 2 days followed by oral for at least 5 days total), *or*
2. A β-lactam (e.g., ceftriaxone 1-2 g IV daily for at least 1-2 days, followed by 1-2 g IM daily for at least 5 days total), *plus*
   A macrolide (azithromycin, 500 mg IV each day for at least 2 days, followed by 500 mg orally each day for a total of at least 5 days)

INPATIENTS—ICU MANAGEMENT

1. A β-lactam (cefotaxime, 1-2 g IV every 6-8 hr, or ceftriaxone, 1-2 g IV each day, or ampicillin-sulbactam, 1.5-3 g IV every 6 hours, up to maximum of 4 g of sulbactam/day, for 7-14 days, *plus*
   Either azithromycin, 500 mg IV each day for at least 2 days, followed by 500 mg orally each day for a total of at least 5 days, or a respiratory fluoroquinolone (e.g., moxifloxacin, 400 mg/day, or gemifloxacin, 320 mg/day, or levofloxacin, 750 mg IV daily for 7-14 days)
2. For penicillin-allergic individuals, a respiratory fluoroquinolone (e.g., moxifloxacin, 400 mg/day, or gemifloxacin, 320 mg/day, or levofloxacin, 750 mg IV daily for 7-14 days) and aztreonam, 2 g IV every 6-8 hr for 7-14 days, are recommended.

SPECIAL CONCERNS

If *Pseudomonas* species infection is a concern:
1. An antipneumococcal, antipseudomonal β-lactam (piperacillin-tazobactam, 3.375 g IV every 6 hr, or cefepime, 1-2 g every 12 hr, or imipenem, 500 mg every 6 hr or 1 g every 8 hr, or meropenem, 1 g IV every 8 hr), *plus* either ciprofloxacin, 400 mg IV every 8 hr, or levofloxacin, 500-750 mg IV every day, for 7-14 days, *or*
2. The above β-lactam plus an aminoglycoside (e.g., gentamicin, 7 mg/kg/day in three divided doses, with monitoring to maintain trough levels lower than 1 μg/mL, or tobramycin, 7 mg/kg/day in three divided doses, with monitoring to maintain trough levels lower than 1 μg/mL) and azithromycin (500 mg IV each day for at least 2 days, followed by 500 mg orally each day) for 7-14 days, *or*
3. The above β-lactam plus an aminoglycoside (as described above) and an antipneumococcal fluoroquinolone (ciprofloxacin, 400 mg IV every 8 hr, or levofloxacin, 500-750 mg IV every day) for 7-14 days

For penicillin-allergic patients, use aztreonam, 2 g IV every 6-8 hr for 7-14 days, instead of the β-lactam.
If community-acquired methicillin-resistant *Staphylococcus aureus* is a consideration, add vancomycin, 15 mg/kg every 12 hr with monitoring to maintain trough at 15-20 μg/mL, or linezolid, 600 mg every 12 hr, for 7-14 days.

Adapted from Infectious Diseases Society of America/American Thoracic Society. Consensus guidelines on the management of community acquired pneumonia in adults. *Clin Infect Dis.* 2007;44:S27-S72.

the patient is likely to be infected with drug-resistant *S. pneumoniae,* gram-negative enteric bacilli, or *Pseudomonas aeruginosa.* Following these guidelines reduces the number of hospital admissions without adversely affecting outcomes.

The decision to admit a patient to the hospital must be made on clinical grounds. Patients can be effectively and safely managed as outpatients if they are mildly ill, are younger than 65 years, and do not have coexisting cardiopulmonary disease, malignancy, immune compromise, or renal, liver, or other significant systemic diseases (Table 97-3).

In general, outpatients who are mildly ill and do not have any underlying cardiopulmonary disease or other modifying factors are usually infected with *S. pneumoniae, M. pneumoniae, C. pneumoniae, H. influenzae,* respiratory viruses, or *Legionella* species. These uncomplicated outpatient cases can be managed with an oral advanced-generation macrolide, such as azithromycin or clarithromycin, both of which are better tolerated and provide better coverage of *Haemophilus* species than erythromycin.[2] Alternatively, doxycycline may be used in patients who are intolerant of macrolides, although this option is less optimal because of increasing levels of tetracycline resistance in *S. pneumoniae* isolates. Outpatients who have underlying comorbidities (e.g., chronic heart, lung, liver, or renal disease, diabetes mellitus, alcoholism, asplenia, immunosuppressive conditions or drugs, use of antibiotics within the past 3 months, or exposure to a child in a daycare center) are at higher risk of having drug-resistant *S. pneumoniae*. If their pneumonia is not sufficiently severe to warrant admission, and any comorbid illnesses are stable and compensated, patients can be treated either with respiratory fluoroquinolones (e.g., moxifloxacin, gemifloxacin, or levofloxacin) or with a β-lactam plus a macrolide (e.g., high-dose amoxicillin or amoxicillin-clavulanate is preferred; alternatives include ceftriaxone, cefpodoxime, and cefuroxime; doxycycline is an alternative to the macrolide) (Table 97-4). In regions that have a high incidence of macrolide-resistant (>25%) *S. pneumoniae,* the alternative agents should be used. When pneumonia is treated on an outpatient basis, patients require careful monitoring to be certain that they respond over the first 72 hours of therapy. The clinician must maintain vigilance about the need to hospitalize patients who deteriorate or fail to respond to the initial empirical therapy.

Patients who have more severe respiratory illnesses, significant unstable or uncompensated comorbid illnesses, or a poor initial response to otherwise

appropriate outpatient therapy generally should be admitted to the hospital promptly. Patients who require hospitalization but not intensive care should be treated initially with either an intravenous respiratory fluoroquinolone, such as levofloxacin or moxifloxacin, or with the combination of an intravenous β-lactam plus a macrolide.

Patients who have respiratory insufficiency, septicemia, shock, or significant multiorgan dysfunction, with or without the need for mechanical ventilatory support, require management in an ICU and evaluation to exclude infection with *P. aeruginosa* (Chapter 314). ICU admission should also be considered for patients who exhibit three or more of the minor criteria for severe community-acquired pneumonia (see Table 97-3).

Among patients with severe community-acquired pneumonia, those at increased risk for *P. aeruginosa* infection include patients with structural lung disease (particularly bronchiectasis), greater than 10 mg/day of previous corticosteroid therapy, neutropenia, malnutrition, or previous broad-spectrum antibiotics for more than 7 days in the past month. ICU patients who are *not* considered at risk for *P. aeruginosa* infection can be treated initially with a β-lactam (cefotaxime, ceftriaxone, or ampicillin-sulbactam) plus either azithromycin or a respiratory fluoroquinolone (moxifloxacin or levofloxacin) (see Table 97-4). In penicillin-allergic patients, a respiratory fluoroquinolone and aztreonam is a reasonable regimen. Fluoroquinolone monotherapy is not considered appropriate in the setting of severe community-acquired pneumonia. In the ICU population considered to be at risk for *P. aeruginosa* infection, combination antipseudomonal therapy should be used, including an antipneumococcal, antipseudomonal β-lactam (piperacillin-tazobactam, cefepime, imipenem, or meropenem) plus either ciprofloxacin or levofloxacin or a β-lactam plus an aminoglycoside and azithromycin. If community-acquired methicillin-resistant *S. aureus* (MRSA) infection is a consideration, vancomycin or linezolid should be added to the regimen.

Suspected or Proven Viral Infection

Therapies for suspected and proven viral infection are relatively limited when compared with those for bacterial infections. Early treatment of influenza A or B within the first 48 hours of symptoms with oseltamivir (75 mg orally taken twice daily for 5 days), or zanamivir (two inhalations of 5 mg per inhalation every 12 hours for 5 days) is effective in reducing symptoms and the duration of illness (Chapter 368). Both agents have been used for novel H1N1 swine influenza, and oseltamivir may also have activity against H5N1 bird flu. Empirical antibiotic treatment of possible bacterial superinfection in addition to influenza should include agents effective against *S. pneumoniae* (Chapter 297), *S. aureus* (Chapter 296), and *H. influenzae* (Chapter 308). In these considerations, amoxicillin-clavulanate, cefpodoxime, cefprozil, cefuroxime, or a respiratory fluoroquinolone would be appropriate. Pneumonias caused by varicella-zoster and herpes simplex virus should be treated with parenteral acyclovir (10 mg/kg intravenously every 8 hours for 7 days) (Chapters 382 and 383). No antiviral agents have established efficacy against RSV in adults, parainfluenza virus, adenovirus, metapneumovirus, the SARS coronavirus, or hantavirus. Treatment is largely supportive, with oxygen and ventilator therapy as necessary.

Duration of Therapy

Most patients respond to empirical antibiotic regimens over the first 3 days of therapy. In general, it is not advisable to alter the antibiotic program in the first 72 hours unless the patient is deteriorating or culture results indicate alternative therapy. Patients initially begun on parenteral therapy may be switched to an oral regimen when they are afebrile (temperature less than 38° C [100° F] on two occasions 8 hours apart) and demonstrate improvement in cough, dyspnea, and leukocytosis.

Patients with community-acquired pneumonia should be treated for at least 5 days, should be afebrile for at least 48 to 72 hours, and should not show signs of clinical instability before discontinuation of antibiotic therapy. Accordingly, the total duration of antimicrobials should be individualized to the patient's clinical response. Initial multiagent regimens of a β-lactam with the addition of macrolides for the coverage of *Legionella* and *Mycoplasma* can frequently be de-escalated after several days to the β-lactams alone if *Legionella* urinary antigen and *Mycoplasma* serology prove negative. The clinical caveat remains, however, that macrolides may still be required in clinical situations in which a strong clinical suspicion for *Legionella* persists because urinary antigen testing does not detect organisms other than *Legionella* serogroup 1. Furthermore, in situations in which a causative organism is isolated from a normally sterile site, such as blood or pleural fluid, antibiotic therapy should be simplified and directed by susceptibility testing. Finally, when alternative clinical diagnoses other than pneumonia are proved to be the cause of the respiratory symptoms and all cultures remain negative over the first 72 hours, antibiotic therapy may be safely discontinued.

Treatment Failure

Treatment failures occur in approximately 10% of patients with community-acquired pneumonia, and complications occur in roughly 25% of patients. Adherence to treatment guidelines, such as those described earlier, increases the likelihood of a good outcome.

For patients who do not respond to initial empirical coverage, an aggressive search should be undertaken to detect unusual pathogens, alternative diagnoses such as pulmonary embolism (Chapter 98), or complications of pneumonia such as a complicated pleural effusion (Chapter 99), empyema, or lung abscess (Chapter 90). Additional diagnostic testing may include a chest CT scan, sampling of pleural fluid, and bronchoscopy with collection of respiratory secretions, brushings, and BAL fluid for microbiologic analysis.

Follow-Up after Treatment

Even when the patient appears to respond to the initial antibiotic regimen, the chest radiograph signs resolve more slowly (over a period of 6 to 8 weeks) than other clinical signs and symptoms. The physician must document that abnormalities on the chest radiograph have resolved completely or, in some cases, have led to the formation of a fibrotic scar. Usual practice includes performing repeat radiography 6 to 8 weeks after completion of the antibiotic regimen. Persistence of abnormalities on the chest radiograph or the development of recurrent pneumonia in a similar distribution should prompt a careful search for an underlying endobronchial obstruction such as an occult neoplasm (Chapter 197), foreign body, bronchostenosis, or broncholithiasis. Follow-up CT scanning is usually the prelude to formal pulmonary consultation for consideration of bronchoscopy and other further diagnostic tests.

ASPIRATION PNEUMONIA

EPIDEMIOLOGY AND PATHOBIOLOGY

Although microaspiration is the mechanism underlying most cases of pneumonia, the clinician is occasionally confronted with recurrent bacterial pneumonia in a patient experiencing repeated gross aspiration of oropharyngeal contents. Most of these patients have difficulty swallowing related to either underlying neuromuscular disorders or altered sensorium as a result of medications, drugs or alcohol, or underlying neurologic diseases. Common clinical scenarios associated with recurrent aspiration pneumonia include tracheobronchial fistulas secondary to esophageal or tracheal malignancies, esophageal obstruction related to esophageal cancer and its treatment (Chapter 198), and a wide variety of neurologic disorders, including amyotrophic lateral sclerosis (Chapter 418), multiple sclerosis (Chapter 419), stroke (Chapter 414), and other myopathic processes. Other patients with severe esophageal reflux (Chapter 140) may also experience significant aspiration during sleep despite apparently normal deglutition mechanisms and protective reflexes during wakefulness. Patients with neuromuscular disorders tend to have greater difficulty swallowing thin or liquid materials, whereas patients with obstruction from either malignancy or benign strictures tend to have the greatest difficulty swallowing solid food.

CLINICAL MANIFESTATIONS

Aspiration pneumonias tend to have a less acute manifestation than the usual bacterial pneumonias, with the onset of fever, dyspnea, purulent sputum, malaise, and other systemic symptoms, including loss of appetite, evolving over a number of days. Physical examination of the chest generally reveals only coarse rhonchi in the lower lobes or dependent lung regions.

DIAGNOSIS

The diagnosis of aspiration pneumonia relies foremost on maintaining a high clinical index of suspicion. Recovery of tracheal secretions containing food particles or lipid-laden macrophages strongly supports the diagnosis. In patients receiving tube feedings, the respiratory secretions should be tested for glucose because these secretions normally contain low levels of glucose. Alternatively, methylene blue or similar tracer dyes can be added to tube feeding materials to confirm the presence of aspiration. Additional diagnostic modalities include the use of cineradiographic swallowing studies with thin liquid water-soluble contrast agents to confirm the aspiration event. Radionuclide imaging studies may also document aspiration in adults whose neurologic status precludes them from cooperating fully with the cineradiographic studies. Overnight esophageal pH monitoring may be undertaken in individuals who are suspected of having recurrent esophageal reflux and aspiration events at night. However, except in the most severe cases, it remains difficult to predict which patients with gastroesophageal reflux will actually experience aspiration pneumonia.

Chest radiographs should be reviewed in light of the patient's probable position during aspiration. The lower lobes, particularly the superior segments of the right lower lobe, and the posterior segments of the upper lobes are frequently involved. However, unilateral aspiration or aspiration into

virtually any pulmonary segment has been reported, depending on the patient's position during the aspiration event. The radiographic appearance usually reflects a parenchymal bronchopneumonia process. Pleural involvement is uncommon initially, unless aggressive anaerobic infection is present. Nonresolving or inadequately treated aspiration pneumonia can result in lung abscess and empyema formation.

Bronchoscopy, although not routinely necessary, can confirm the presence of aspiration by recovering food particles or lipid-laden macrophages derived from fats present in the aspirated food. Bronchoscopy with BAL can be useful in providing quantitative counts of aerobic bacteria, and protected specimen brush sampling can document anaerobic organisms, although negative cultures do not exclude the presence of anaerobes.

Microbiology

Oropharyngeal secretions contain massive numbers of microorganisms, with counts of aerobic bacteria ranging between 10^6 and 10^8 and anaerobic organisms being as high as 10^9 per milliliter of saliva. Accordingly, aspiration pneumonia should be viewed as a polymicrobial infection, with the clinical manifestations being driven by the predominant and most aggressive organisms in the mixture. Oropharyngeal colonization is strongly influenced by the clinical setting in which the patient was dwelling at the time of aspiration (outpatient versus hospital or institutional). In otherwise healthy outpatients, aggressive organisms such as *S. pneumoniae, S. aureus,* and *H. influenzae* may also be present. In contrast, the oropharyngeal secretions of hospitalized patients and residents of long-term care facilities include aerobic gram-negative bacteria and *P. aeruginosa.* Anaerobic organisms, which are a major consideration in both settings, include anaerobic and microaerophilic streptococci, *Bacteroides* species, *Fusobacterium nucleatum,* and *Prevotella* species. Cultures of sputum and tracheal secretions probably document such mixed flora.

TREATMENT

Rx

Empirical antibiotic therapy should be initiated rapidly once the diagnosis of aspiration pneumonia is made; the regimen can be modified later after culture information from sputum, tracheal secretions, or bronchoscopic sampling is available. Otherwise healthy individuals with isolated aspiration pneumonia related to trauma, seizures, or oversedation may be treated initially with either oral amoxicillin-clavulanate (amoxicillin, 875 mg, and clavulanate acid, 125 mg, orally every 12 hours for at least 5 days), intravenous clindamycin (600 mg intravenously [IV] every 8 hours for at least 5 days), or intravenous piperacillin-tazobactam (3.375 g IV every 6 hours for at least 5 days), depending on the severity of illness. In uncomplicated mild to moderate aspiration pneumonia in elderly patients, intravenous clindamycin is as effective, less expensive, and associated with a lower rate of post-treatment occurrence of MRSA.[5] For patients with underlying chronic diseases, intravenous piperacillin-tazobactam (3.375 g IV every 6 hours for 7 to 14 days) or intravenous fluoroquinolones that cover anaerobes, such as moxifloxacin (400 mg IV each day for 7 to 14 days), can be considered. In seriously ill individuals, particularly patients requiring intubation and mechanical ventilation, as well as patients experiencing aspiration in the hospital or long-term care setting, coverage must be extended to aerobic gram-negative bacteria and *Pseudomonas* species; treatment considerations would include extended-spectrum β-lactam/β-lactamase inhibitor combinations such as piperacillin-tazobactam (3.375 g IV every 6 hours for 7 to 14 days) or ticarcillin-clavulanate (3 g of ticarcillin, and 0.1 g of clavulanic acid IV every 4 to 6 hours for 7 to 14 days), or carbapenems such as imipenem (500 mg IV every 6 to 8 hours for 7 to 14 days). Intravenous clindamycin (600 mg IV every 8 hours) can also be added in these settings, or alternatively, intravenous clindamycin can be given in combination with ciprofloxacin (400 mg IV every 8 hours for 7 to 14 days) or aztreonam (2 g IV every 6 to 8 hours for 7 to 14 days). In patients with concern about organisms with high levels of antibiotic resistance, such as *P. aeruginosa,* an antipseudomonal β-lactam such as ceftazidime (2 g IV every 8 hours for 7 to 14 days) or cefepime (1 to 2 g every 12 hours for 7 to 14 days) can be combined with an antipseudomonal fluoroquinolone such as ciprofloxacin or an aminoglycoside (e.g., gentamicin 7 mg/kg/day in three divided doses IV for 7 to 14 days, measuring drug levels and adjusting doses to achieve a trough level of <1 µg/mL). Again, addition of extended anaerobic coverage with clindamycin should be considered. Finally, if the patient is known or suspected to harbor MRSA, intravenous vancomycin (15 mg/kg every 12 hours IV and measuring drug level and adjusting doses to achieve trough levels of 15 to 20 µg/mL) or linezolid (600 mg IV every 12 hours) for 10 to 14 days should be added to the regimen.

Surgical Therapy

Adequate nutrition is a concern in patients with multiple episodes of aspiration pneumonia and underlying neurologic disease or malignancy. Endoscopic or surgical placement of a gastrostomy or jejunostomy feeding tube can be considered to aid in providing nutrition, fluids, and medications in the palliation of such patients. Of greater challenge are patients who continue to have pneumonia related to aspiration of saliva, sometimes around cuffed endotracheal and tracheostomy tubes. If aggressive therapy is considered appropriate, ligation of the submaxillary and parotid salivary ducts can decrease the production of saliva.

HOSPITAL-ACQUIRED PNEUMONIA, VENTILATOR-ASSOCIATED PNEUMONIA, AND HEALTH CARE–ASSOCIATED PNEUMONIA

EPIDEMIOLOGY

Hospital-acquired pneumonia, ventilator-associated pneumonia, and health care–associated pneumonia represent the second most common nosocomial infections in the United States. Hospital-acquired pneumonia on average increases the length of hospital stay from 7 to 9 days, at an additional cost of more than $40,000 per patient; it is responsible for one fourth of all ICU infections and half of all antibiotic use. Early-onset hospital-acquired pneumonia and ventilator-associated pneumonia, defined as infections occurring within the first 4 hospital days, tend to be caused by antibiotic-susceptible bacteria, whereas late-onset infections are more frequently caused by multidrug-resistant (MDR) organisms (Table 97-5), which are associated with greater morbidity and mortality. The overall mortality attributed to hospital-acquired pneumonia may be as high as 30 to 50%.

PATHOBIOLOGY

Gram-negative bacterial pneumonias are fairly uncommon in previously healthy outpatients, except in patients with impaired immunity or underlying structural lung disease such as chronic obstructive pulmonary disease. However, aerobic gram-negative bacilli, including *P. aeruginosa, Escherichia coli, K. pneumoniae,* and *Acinetobacter* species, play major roles in patients with hospital-acquired pneumonia, ventilator-associated pneumonia, and health care–associated pneumonia. Many cases are polymicrobial, and gram-positive agents such as *S. aureus,* particularly MRSA strains, are also increasingly common. The frequency of MDR bacteria varies by the patient population, hospital, ICU, and local use of antimicrobial agents, so routine surveillance and monitoring of local pathogens and drug susceptibilities are key to adjusting antibiotic use appropriately.

P. aeruginosa, Acinetobacter species, *Stenotrophomonas maltophilia,* and *Burkholderia cepacia* complex are of particular concern because these organisms rapidly become resistant to multiple classes of antibiotics. MDR organisms are most commonly found in patients with severe underlying chronic disease, in patients with health care–associated pneumonia, and in those with late-onset hospital-acquired pneumonia and ventilator-associated pneumonia. Although considerable emphasis is placed on gram-negative bacteria in the hospital setting, more traditional bacterial pathogens such as *S. pneumoniae* and *H. influenzae* must also be considered as potential causes.

TABLE 97-5 HOST RISK FACTORS ASSOCIATED WITH DEVELOPMENT OF MULTIDRUG-RESISTANT INFECTION DURING HAP, VAP, AND HCAP

Antibiotic therapy in the past 90 days
High incidence of antibiotic resistance in the community or in the specific hospital unit
Current hospitalization for 5 or more days
Immunosuppressive disease or therapy
Presence of risk factors for HCAP
Hospitalization for 2 or more days in the past 90 days
Resident in a nursing home or extended care facility
Home infusion therapy (including antibiotics)
Chronic dialysis within the past 30 days
Home wound care
Family member with an MDR pathogen

HAP = hospital-associated pneumonia; HCAP = health care-associated pneumonia; MDR = multidrug resistant; VAP = ventilator-associated pneumonia.
Adapted from American Thoracic Society and Infectious Diseases Society of America. Guidelines for management of adults with hospital-acquired, ventilator-associated, and health care-associated pneumonia. *Am J Respir Crit Care Med.* 2005;171:388-416.

L. pneumophila also occasionally occurs as a nosocomial infection, particularly where there is contaminated water or during construction.

CLINICAL MANIFESTATIONS

Hospital-acquired pneumonia, ventilator-associated pneumonia, and health care–associated pneumonia are often first suspected with the demonstration of new or worsening radiographic infiltrates along with other clinical signs of infection, including fever, leukocytosis, and purulent sputum. Oxygenation may have also worsened. In general, two of the three major clinical features (fever, leukocytosis, purulent sputum) should be present. In patients with acute respiratory distress syndrome, however, a single clinical factor alone should prompt additional investigation and microbiologic culture.

DIAGNOSIS

All patients with suspected hospital-acquired pneumonia, ventilator-associated pneumonia, and health care–associated pneumonia should receive a comprehensive history and physical examination to define the severity of disease and potential sources of infection. Chest radiography is essential to determine the extent of pneumonia, particularly whether it is focal or multilobar. Some patients without new or evolving radiographic infiltrates but with other signs of infection may have purulent tracheobronchitis (Chapter 96), which may require antibiotic therapy if clinical signs of infection are present. Arterial blood gases, complete blood count, electrolytes, and liver and renal function should also be evaluated. Blood should be obtained for culture, although it is positive in only a minority of patients, before instituting new antibiotics whenever possible.

Lower respiratory tract secretions should be obtained for culture from all patients by endotracheal aspiration, BAL, or protected specimen brush whenever possible before changes in antibiotic therapy; a reliable Gram stain can help direct initial empirical therapy. A sterile culture of lower respiratory tract secretions in the absence of a new antibiotic in the past 72 hours essentially excludes most bacterial pneumonias with a 94% negative predictive value, although *Legionella* and viral infection are still possible in this situation. The quantitative diagnostic threshold for significant bacterial infection, in the absence of recent (<72 hours) changes in antibiotic regimens, is as follows: greater than 10^6 colony-forming units (cfu)/mL for tracheal aspirates, greater than 10^4 or 10^5 cfu/mL for quantitative BAL fluid, and greater than 10^3 cfu/mL for protected specimen brushings. The use of bronchoscopically obtained specimens and quantitative bacterial culture in directing therapy reduces the 14-day mortality in suspected ventilator-associated pneumonia.

TREATMENT

Initial Empirical Therapy

If the patient is unstable or has evidence of sepsis, or if there is a high suspicion for hospital-acquired pneumonia, ventilator-associated pneumonia, or health care–associated pneumonia, prompt antibiotic therapy is required regardless of whether bacteria are found on the initial microscopic examination of lower respiratory tract samples because delays in antimicrobial therapy increase mortality. The choice of initial empirical therapy is based on several factors, including whether the pneumonia is early onset, whether there are risk factors for MDR bacterial infections (Table 97-6), and local surveillance data on bacterial prevalence and susceptibilities.

Suspected or Early-Onset Disease

For patients with suspected hospital-acquired or ventilator-associated pneumonia, with early-onset disease, and with no identifiable risk factors for MDR organisms, initial empirical therapy can include either ceftriaxone, an intravenous fluoroquinolone (levofloxacin, moxifloxacin, or ciprofloxacin), ampicillin/sulbactam, or ertapenem. These options will cover *S. pneumoniae,*

TABLE 97-6 EMPIRICAL ANTIBIOTIC TREATMENT OF HOSPITAL-ACQUIRED PNEUMONIA, VENTILATOR-ASSOCIATED PNEUMONIA, AND HEALTH CARE–ASSOCIATED PNEUMONIA

GROUP A: PATIENTS WITH EITHER HAP OR VAP, WITHOUT RISK FACTORS FOR MDR PATHOGENS, AND WITH EARLY-ONSET PNEUMONIA	
POTENTIAL PATHOGENS	**RECOMMENDED THERAPY**
Streptococcus pneumoniae *Haemophilus influenzae* Methicillin-sensitive *Staphylococcus aureus* Antibiotic-sensitive enteric gram-negative bacilli *Escherichia coli* *Klebsiella pneumoniae* *Enterobacter* species *Proteus* species *Serratia marcescens*	Ceftriaxone, 1-2 g IV/IM every 12-24 hr, maximum of 4 g/day, with duration dependent on clinical response and individualized, as discussed in text *or* Levofloxacin, 500-750 mg IV every day, with duration dependent on clinical response and individualized; or ciprofloxacin, 400 mg IV every 8 hr, with duration dependent on clinical response and individualized; or moxifloxacin, 400 mg IV or orally every 24 hr, with duration dependent on clinical response and individualized *or* Ampicillin-sulbactam, 1.5-3 g (1-2 g ampicillin and 0.5-1 g sulbactam) IV/IM every 6 hr, maximum of 4 g sulbactam/day, depending on type and severity of infection, with duration dependent on clinical response and individualized *or* Ertapenem, 1 g IV/IM once a day, with duration dependent on clinical response and individualized
GROUP B: PATIENTS WITH HAP, VAP, OR HCAP AND WITH LATE-ONSET PNEUMONIA OR WITH RISK FACTORS FOR MDR PATHOGENS	
ORGANISMS	**THERAPY**
Streptococcus pneumoniae *Haemophilus influenzae* Methicillin-sensitive *S. aureus* Antibiotic-sensitive enteric gram-negative bacilli *E. coli* *K. pneumoniae* *Enterobacter* species *Proteus* species *S. marcescens* MDR pathogens *Pseudomonas aeruginosa* *K. pneumoniae* (extended spectrum β-lactamase producing) *Acinetobacter* species Methicillin-resistant *S. aureus* *Legionella pneumophila*	Antipseudomonal cephalosporin (ceftazidime, 2 g IV every 8 hr, or cefepime, 1-2 g every 8-12 hr, with duration dependent on clinical response and individualized) *or* Antipseudomonal carbapenems (meropenem, 1 g every 8 hr, or imipenem, 500 mg every 6 hr or 1 g every 8 hr, with duration dependent on clinical response and individualized) *or* β-Lactam/β-lactamase inhibitor (piperacillin-tazobactam, 4.5 g IV every 6 hr, with duration dependent on clinical response and individualized) *plus* Antipseudomonal fluoroquinolone (levofloxacin, 750 mg IV every day, or ciprofloxacin, 400 mg IV q8h, with duration dependent on clinical response and individualized) *or* Aminoglycoside (amikacin, 15-20 mg/kg/day, divided every 8-12 hours, with monitoring to maintain trough lower than 4-5 μg/mL; or gentamicin, 7 mg/kg/day as a single daily dose, with monitoring to maintain trough levels lower than 1 μg/mL; or tobramycin, 4-7 mg/kg/day as a single daily dose, with monitoring to maintain trough levels lower than 1 μg/mL and duration dependent on clinical response and individualized) *plus* Vancomycin (15 mg/kg IV every 12 hr, with monitoring to maintain trough at 10-15 μg/mL and duration dependent on clinical response and individualized) or linezolid (600 mg IV every 12 hr, with duration dependent on clinical response and individualized)

HAP = hospital-associated pneumonia; HCAP = health care–associated pneumonia; MDR = multidrug resistant; VAP = ventilator-associated pneumonia.

H. influenzae, MRSA, and most antibiotic-sensitive gram-negative bacilli, including *E. coli, K. pneumoniae, Proteus* species, *Enterobacter* species, and *Serratia marcescens.*

Late-Onset Disease

In contrast, with late-onset hospital-acquired pneumonia, ventilator-associated pneumonia, or health care–associated pneumonia, or when risk factors for MDR infection have been identified, multiagent regimens should be used initially. Options include an antipseudomonal cephalosporin such as ceftazidime or cefepime, an antipseudomonal carbapenem (meropenem or imipenem), or a β-lactam/β-lactamase inhibitor agent such as piperacillin-tazobactam; in addition, either an antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin) or an aminoglycoside such as amikacin, gentamicin, or tobramycin should be used. In combination, these agents should empirically address most MDR pathogens, including *P. aeruginosa, Acinetobacter* species, and *K. pneumoniae* strains with extended-spectrum β-lactamase production. Most *L. pneumophila* isolates will also be covered, but if *Legionella* is strongly suspected, a macrolide such as azithromycin should be included. Finally, either vancomycin or linezolid should be added for coverage of MRSA if risk factors are present or the risk for MRSA is high locally.

Duration of Treatment

The initiation of empirical antibiotic therapy mandates careful daily reassessment. If the patient improves over the first 48 to 72 hours, strong consideration should be given to de-escalating antibiotic therapy based on culture results. If lower respiratory cultures remain negative but the patient has not improved, an extrapulmonary site of infection should be considered. Additional radiographic imaging and cultures from the lung, pleura, and other sites may be helpful. The total duration of therapy, therefore, must be individualized. In general, aminoglycoside use should be limited to 5 to 7 days. Overall antibiotic therapy can be as short as 7 days if the patient has improved, but patients with sluggish improvement may require 14 to 21 days of therapy.

PREVENTION

Sources of pathogens for hospital-acquired pneumonia include the environment, health care devices, and transfer of microbes by patients, staff, and visitors. Thus, scrupulous hand hygiene is essential for reducing these infections. Colonization plus aspiration of oropharyngeal pathogens or leakage of secretions around endotracheal tubes is the usual route of inoculation. The stomach and sinuses may be additional sites harboring pathogens. Infected biofilms on endotracheal tubes may also serve as an important reservoir for these infections. In this light, aggressive measures should be enforced to reduce the risk for hospital-acquired pneumonia and ventilator-associated pneumonia. Prevention centers first on staff education and compliance with alcohol-based hand disinfection, which must be used before and after each patient interaction. In addition, patients with documented MDR organisms should be isolated to reduce the risk for patient cross-contamination. Microbiologic surveillance within the hospital environment is also necessary to identify MDR organisms and determine antibiotic use and susceptibility patterns. Within the ICU, intubation and reintubation rates should be monitored and reduced as feasible, the duration of mechanical ventilation should be minimized to reduce the risk for ventilator-associated pneumonia, and methods known to reduce infection rates should be followed (Chapter 105). Ventilator-associated pneumonia can be reduced by elevation of the head of the patient's bed, daily "sedation vacations," daily assessment of the patient's readiness for extubation, peptic ulcer disease prophylaxis, and deep vein thrombosis prophylaxis. In addition, continuous aspiration of subglottic secretions is a safe procedure that also reduces the use of antimicrobial agents and the incidence of ventilator-associated pneumonia in patients who are at risk.■

PULMONARY EMBOLISM

JEFFREY I. WEITZ

DEFINITIONS

Pulmonary embolism (PE) refers to an obstruction of a pulmonary artery by material that has traveled to the lungs from elsewhere in the body through the blood stream. Thrombus from the deep veins of the legs or arms represents the most common type of material to embolize to the lungs—a process known as venous thromboembolism (VTE). In addition to thrombotic pulmonary emboli, nonthrombotic material also can embolize to the lungs. Such material includes fat, air, amniotic fluid, tumor cells, talc in intravenous drug users, and various medical devices. Regardless of the type of embolic material, blockage of blood flow through the lungs and the resultant increased pressure in the right ventricle are responsible for the symptoms and signs of PE.

THROMBOTIC PULMONARY EMBOLISM

EPIDEMIOLOGY

VTE, which includes deep vein thrombosis (DVT; Chapter 81) and PE, represents the third most common cause of cardiovascular death after myocardial infarction and strokes. A first episode of VTE occurs in about 1 person per 1000 each year in the United States. The incidence rises exponentially with age, with 5 cases per 1000 persons per year by the age of 80 years. Although men and women are affected equally, the incidence is higher in whites and African Americans than in Hispanic persons and Asian-Pacific Islanders.

Approximately one third of patients with symptomatic VTE present with PE, whereas the remainder present with DVT alone. Up to half of the patients with a first episode of VTE have no identifiable risk factors and are described as having unprovoked or idiopathic VTE. The remainder develop VTE secondary to well-recognized, transient risk factors, such as surgery or immobilization. PE accounts for an estimated 15% of deaths in hospitalized patients, with at least 100,000 deaths from PE each year in the United States.

PATHOBIOLOGY

PE and DVT are part of the spectrum of VTE and share the same genetic and acquired risk factors, which determine the intrinsic risk of VTE for each individual (Fig. 98-1). Genetic risk factors include abnormalities associated with hypercoagulability of the blood (Chapter 174), the most common of which are factor V Leiden and the prothrombin 20210 gene mutation. Acquired risk factors include advanced age, history of previous VTE, obesity, and active cancer, all of which limit mobility and may be associated with hypercoagulability. Superimposed on this background risk, VTE often occurs in the presence of a triggering factor, which increases the risk above the critical threshold. The triggering factors, including surgery and pregnancy or estrogen therapy, lead to vascular damage, stasis, and hypercoagulability, which are the components of Virchow's triad.

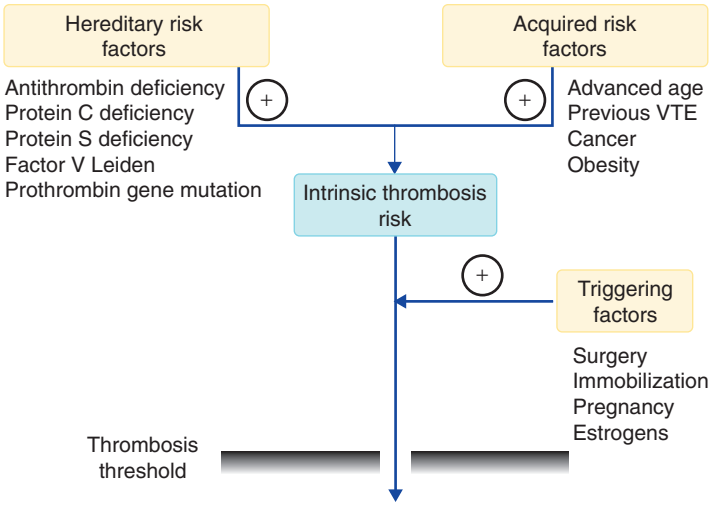

FIGURE 98-1. Thrombosis threshold. Hereditary and acquired risk factors combine to create an intrinsic risk of thrombosis for each individual. This risk is increased by extrinsic triggering factors. If the intrinsic and extrinsic forces exceed a critical threshold where thrombin generation overwhelms protective mechanisms, thrombosis occurs. VTE = venous thromboembolism.

In at least 90% of patients, PE originates from DVT in the lower limbs, and up to 70% of patients with proven PE still have demonstrable DVT on presentation. Thrombi usually start in the calf veins. About 20% of these calf vein thrombi then extend into the popliteal and more proximal veins of the leg, from which they are more likely to embolize. Although often asymptomatic, PE can be detected in about 50% of patients with proximal DVT (Chapter 81). Upper extremity DVT involving the axillary or subclavian veins also can give rise to PE, but only 10 to 15% of such patients develop PE. Upper extremity DVT most often occurs in patients with cancer (Chapter 187), particularly those with indwelling central venous catheters. Unprovoked upper extremity DVT, usually involving the dominant arm, can occur with strenuous effort—the so-called Paget-Schroetter syndrome.

PE often involves both lungs, with the lower lobes affected more frequently than the upper. Larger emboli tend to lodge in the main pulmonary artery or its branches, whereas smaller emboli occlude in more peripheral arteries. Peripheral PE can lead to pulmonary infarction, which is characterized by intra-alveolar hemorrhage and necrosis that may be pleura based. Because the circulation to the lungs arises from bronchial as well as pulmonary arteries, pulmonary infarction occurs in only about 10% of patients without underlying cardiopulmonary disease. In contrast, pulmonary infarction occurs in up to 30% of patients who have compromised oxygenation of the affected areas of lung because of preexisting disorders such as airways disease or increased pulmonary venous pressure because of left ventricular dysfunction.

The clinical impact of PE depends on the extent of reduction in pulmonary blood flow, the time frame over which vascular obstruction occurs, and the absence or presence of underlying cardiopulmonary disease. With acute PE, most patients develop tachypnea and some degree of hypoxemia. Stimulation of irritant receptors in the lungs likely accounts for the increase in respiratory rate. Obstruction of pulmonary arteries contributes to the hypoxemia and the increase in alveolar-arterial oxygen tension gradient, which reflects inefficient oxygen transfer across the lungs. These abnormalities result mainly from the increase in alveolar dead space that occurs because ventilation to alveoli exceeds blood flow in the adjacent capillaries in parts of the lung affected by PE. Other contributing factors to the hypoxemia include ventilation-perfusion mismatch because of relative overperfusion of normal areas of the lung, and shunting of blood through nonventilated atelectatic or collapsed areas of lung that retain at least some perfusion.

Pulmonary vascular resistance increases with PE because of vascular occlusion by thrombi. In addition, humoral mediators, such as serotonin and thromboxane, are released from activated platelets and may trigger vasoconstriction in unaffected areas of lung. Consequently, the increase in pulmonary vascular resistance may be disproportionate to the extent of pulmonary vascular occlusion. With obstruction of less than 50% of the pulmonary vascular bed, the mean pulmonary artery pressure rarely exceeds 25 mm Hg. Under these circumstances, the right ventricle maintains its output, so cardiac output and systemic blood pressure remain normal.

With acute occlusion of more than 50% of the pulmonary circulation, the pulmonary artery systolic pressure increases, thereby increasing right ventricular afterload. The pulmonary artery systolic pressure rarely exceeds 55 mm Hg with sudden occlusion because of insufficient time for right ventricular hypertrophy to occur. If the thin-walled right ventricle fails to maintain output in the face of the increased pulmonary artery pressure, it dilates, and right heart failure ensues. Right ventricular end-diastolic and right atrial pressures increase as the right ventricle fails. Dilation of the right ventricle may result in tricuspid regurgitation, which can compromise left ventricular filling and lead to reduced cardiac output and subsequent hypotension. Rightward bulging of the interventricular septum may also contribute to left ventricular diastolic dysfunction. The decrease in aortic pressure, together with the increase in right ventricular pressure, can produce right ventricular ischemia because of decreased perfusion of the right coronary artery despite increased demand by the dilated right ventricle. If this process occurs over a rapid time frame, syncope or sudden death, often associated with electromechanical dissociation, may be the first manifestation of severe PE.

With multiple pulmonary emboli over an extended period of time, the right ventricle has an opportunity to adapt to the increased pulmonary vascular resistance. The subsequent increase in right ventricular systolic pressure results in less right heart failure than occurs with acute large PE. Patients with multiple smaller PEs over an extended period of time often have increasing dyspnea with progressively decreasing exercise tolerance. With maintained cardiac output, hypotension does not develop. Additional emboli, however, may convert the clinical picture to one of severe acute PE.

Patients who have underlying cardiopulmonary disease or who are elderly, frail, and debilitated will be more sensitive to the effects of PE than patients who were previously healthy. Consequently, even a small PE may be fatal in patients with limited reserve.

CLINICAL MANIFESTATIONS

Patients with PE most often present with a history of dyspnea, which may be sudden in onset and tends to progress in severity over time. Dyspnea may be associated with pleuritic chest pain, cough, and hemoptysis, particularly in patients with pulmonary infarction. Although the symptoms and signs of PE can be nonspecific, the diagnosis should be suspected in patients with risk factors for VTE, such as prolonged immobility, recent surgery, or active malignancy. Patients with associated DVT (Chapter 81) may present with recent onset of leg pain or with swelling and tenderness along the course of the deep veins. The superficial veins of the leg may be dilated, and the affected leg may be warm to touch, with skin that is red or dusky blue in color.

Most patients with PE have tachypnea and tachycardia associated with hypoxemia, but these findings also can occur with disorders such as heart failure, pneumonia, or chronic obstructive pulmonary disease. Other nonspecific symptoms include palpitations, anxiety, and lightheadedness.

Patients with acute severe PE often complain of dyspnea at rest or with minimal exertion, and they may present with syncope (Chapters 50 and 62) because of hypoxemia and low cardiac output. The combination of hypotension, hypoxemia, and increased cardiac work load may trigger angina (Chapter 72) or overt myocardial infarction (Chapter 73).

Central and peripheral cyanosis can occur, and a gallop rhythm may develop as a consequence of heart failure. The jugular veins may be distended if right heart failure develops. The second heart sound can be widely split, with a loud pulmonic component because of delayed emptying of the right ventricle. A right ventricular heave may be present with massive PE and acute pulmonary hypertension.

DIAGNOSIS

Most patients with PE will have one or more of the following clinical features: dyspnea, often of sudden onset; tachypnea, with a respiratory rate of more than 20 breaths per minute; and chest discomfort, which is usually substernal and often pleuritic in nature. When patients present with these features, the differential diagnosis includes pulmonary disorders, such as pneumonia (Chapter 97), an exacerbation of chronic obstructive lung disease (Chapter 88), or asthma (Chapter 87); pleurisy secondary to connective tissue disease (Chapter 99); cardiac disorders, such as heart failure (Chapter 58), acute coronary syndrome (Chapter 72), or pericarditis (Chapter 77); and musculoskeletal disorders, such as rib fracture.

Because the clinical features are nonspecific, the diagnosis of PE requires objective testing. Patients who require such testing can be identified by their pretest likelihood of PE using validated clinical prediction rules (Table 98-1) that include components of the clinical assessment, presence of risk factors

for VTE, and absence of an alternative diagnosis to explain the symptoms and signs. Some clinical prediction rules also include the results of simple tests, such as the electrocardiogram (ECG) and the chest radiograph.

Based on the results of such an assessment, the pretest likelihood of PE can be designated as low, moderate, or high, and this likelihood then guides the subsequent selection of blood tests, such as the D-dimer assay, and noninvasive or invasive tests for diagnosis of PE or DVT (Fig. 98-2) (Chapter 81). Tests for diagnosis of DVT are relevant because a diagnosis of DVT in patients with suspected PE provides sufficient grounds for initiation of treatment, and the treatment of DVT and PE is usually the same. Noninvasive tests include computed tomography (CT) pulmonary angiography or ventilation-perfusion lung scanning for diagnosis of PE and venous compression ultrasound for diagnosis of DVT. These tests have largely replaced pulmonary angiography to diagnose PE and venography to diagnose DVT.

Diagnostic Tests

D-Dimer

A plasmin-derived degradation product of cross-linked fibrin, D-dimer can be measured in whole blood or plasma to provide an indirect index of ongoing activation of the coagulation system. An elevated D-dimer level has an 85% to 98% sensitivity for the diagnosis of PE, but all available D-dimer assays have low specificities. False-positive D-dimer elevations can occur with advanced age, chronic inflammatory conditions, and malignancy. In addition, hospitalized patients are more likely to have an elevated D-dimer level than outpatients. Because of this lack of specificity, the value of the D-dimer assay resides with its high negative predictive value and the ability of a normal D-dimer to reduce the probability of PE sufficiently to avoid further diagnostic testing in patients with a low or moderate pretest likelihood, who represent up to 30% of patients with suspected VTE.

Computed Tomography Pulmonary Angiography

Multidetector CT pulmonary angiography has largely replaced ventilation-perfusion lung scanning for PE diagnosis because of its wide availability and the rapidity of its results. In contrast to lung scanning, CT pulmonary angiography not only permits direct visualization of thrombi in the pulmonary arteries of patients with PE (Fig. 98-3) but also provides an alternative diagnosis in many of those who prove not to have PE. With the evolution from single-detector to multidetector CT scanners, the sensitivity and specificity of CT pulmonary angiography are sufficient for its use as a stand-alone test: a CT pulmonary angiogram showing thrombus in pulmonary arteries up to

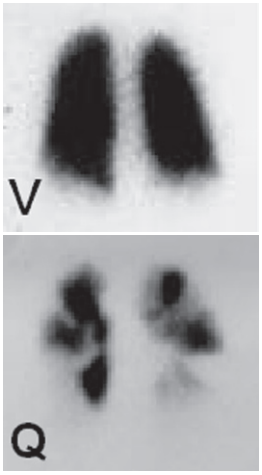

FIGURE 98-4. Ventilation-perfusion lung scan demonstrating pulmonary emboli.

the segmental level provides evidence of PE, whereas a negative CT pulmonary angiogram excludes PE with subsequent clinical outcomes at least as good as with lung scanning.■ Compared with lung scanning, CT pulmonary angiography detects more isolated subsegmental thrombi in about 1 to 5% of patients, but the importance of such thrombi is unclear because patients with isolated subsegmental defects have uneventful outcomes despite withholding treatment. A negative D-dimer or a normal venous compression ultrasound examination may help to exclude the possibility of VTE in this setting.

Ventilation-Perfusion Lung Scanning

In this two-part test; the ventilation phase involves inhalation of an aerosol form of xenon or technetium to assess air delivery to the various parts of the lung, whereas the perfusion phase involves the intravenous injection of technetium-labeled macroaggregates of albumin, which enables assessment of blood flow within the lungs once the aggregates lodge in the pulmonary microcirculation. Images for both parts of the test are acquired using a gamma counter. Areas of lung affected by PE do not light up on the perfusion scan because the macroaggregates of albumin fail to reach sites where the pulmonary arteries are occluded (Fig. 98-4). In contrast, areas with abnormal perfusion ventilate normally yielding a ventilation-perfusion mismatch.

A normal lung scan effectively excludes the diagnosis of PE, but only 25% of patients with suspected PE have a normal scan. One or more segmental or larger perfusion defects that ventilate normally characterize a high probability lung scan, which establishes the diagnosis of PE, but even use of single-photon emission CT technology identifies only about 10% of patients with suspected PE as having a high probability lung scan. The remaining 65% of lung scans exhibit smaller areas of mismatch or matched defects and fall within the non-high-probability category. Because up to 40% of patients with non-high-probability scans have PE, such patients require additional investigations to exclude the diagnosis.

Although CT pulmonary angiography has largely replaced lung scanning, the lung scan remains the diagnostic test of choice for patients with renal impairment or a history of allergy to angiographic contrast media. For diagnosis of PE in pregnancy, lung scanning produces less maternal and fetal radiation exposure and is preferred over CT pulmonary angiography.

Magnetic Resonance Imaging

In contrast to CT pulmonary angiography, gadolinium-enhanced magnetic resonance imaging (MRI) does not subject patients to ionizing radiation, and gadolinium can safely be given to patients with a history of allergy to contrast dye. Although originally promoted as the test of choice to diagnose PE in patients with renal impairment, the emergence of nephrogenic systemic fibrosis (Chapter 275) as a complication of gadolinium administration in patients with renal impairment has tempered enthusiasm for the test. The accuracy of MRI for the detection of PE appears to be similar to that of CT pulmonary angiography, but magnetic resonance (MR) pulmonary angiography is more technically demanding. The combination of MR pulmonary angiography with MR venography has a higher sensitivity than MR pulmonary angiography alone for the diagnosis of PE. With these limitations, MRI should be used to diagnose PE only in centers with experience with the test and in patients for whom standard tests are contraindicated.

Pulmonary Angiography

Pulmonary angiography requires direct contrast injection into the pulmonary arteries, followed by imaging using digital subtraction technology to provide high-quality images. Presence of a thrombus, which appears as a filling defect or as a sudden cutoff of blood flow in a pulmonary arterial branch, establishes the diagnosis of PE. Although direct angiography allows visualization of small thrombi in subsegmental pulmonary arteries, high interobserver variability in the interpretation of isolated findings at this level limits the specificity of this finding. As an invasive test, the mortality rate associated with pulmonary angiography is 0.2%, with deaths usually occurring in patients with hemodynamic compromise or respiratory failure. Because of its associated risks and because CT pulmonary angiography offers similar or better information, direct pulmonary angiography is now rarely performed, except in the patient who may undergo pulmonary embolectomy.

Diagnostic Strategies

The diagnosis of DVT (Chapter 81) is usually based on venous compression ultrasound, which has a sensitivity and specificity of about 95% for the diagnosis of proximal DVT. In patients with suspected PE, the venous compression ultrasound examination can be limited to the proximal veins, which are the sources of most PE.

CT venography can be combined with CT pulmonary angiography as a simple test to diagnose DVT because both tests require only one injection of contrast dye. Compared with CT pulmonary angiography alone, the combination of CT pulmonary angiography and CT venography increases the sensitivity from 83 to 90%, but the specificity remains unchanged, thereby resulting in only a modest increase in negative predictive value. CT venography adds significant radiation exposure and only marginally increases the overall detection rate, so venous compression ultrasound is preferred because it provides the same information without exposing patients to ionizing radiation. Standard venography is not recommended in patients with suspected PE.

In summary, patients with a low to moderate pretest likelihood should undergo D-dimer testing (see Fig. 98-2). A negative D-dimer test excludes the diagnosis of PE in these patients, whereas a positive test should prompt multidetector CT pulmonary angiography. Patients with a high pretest likelihood of PE should be sent directly for multidetector CT pulmonary angiography. A positive CT pulmonary angiogram establishes the diagnosis of PE, whereas a negative test excludes it.

The role of venous compression ultrasound remains controversial. Because of the suboptimal sensitivity of single-detector CT pulmonary angiography for the diagnosis of PE, bilateral venous compression ultrasound should also be performed if multidetector technology is not available. Although a negative multidetector CT pulmonary angiogram safely excludes PE, at least in patients with low to moderate pretest likelihood, bilateral venous compression ultrasound can still be helpful. For example, the finding of proximal DVT obviates the need for further testing, a result that can be particularly helpful in patients who are poor candidates for CT pulmonary angiography, such as those with renal impairment or a history of allergy to contrast dye. Patients with a non-high-probability lung scan or with equivocal CT pulmonary angiographic findings should undergo serial venous compression ultrasound examination to exclude the possibility of calf DVT, which then extends into the proximal veins.

Other Tests

Blood markers of right ventricular dysfunction, which is seen in more severe pulmonary emboli, include brain natriuretic peptide (BNP) or its precursor, N-terminal proBNP, which are released in response to myocardial stretching. Although elevated levels of these markers in patients with PE are associated with a worse prognosis, their positive predictive value is low.

Elevated levels of troponin I or T and fatty acid–binding protein provide evidence of myocardial injury in PE patients with right ventricular infarction. In PE patients without hemodynamic compromise, elevated levels of these markers are associated with increased mortality.

The ECG may show new changes suggestive of right ventricular strain, such as T wave inversion in leads V_1 to V_4; the classic S1, Q3, T3 pattern (Fig. 98-5); and complete or incomplete right bundle branch block. However, these ECG changes have limited sensitivity and are seen predominantly in patients with more severe pulmonary emboli.

Echocardiography findings suggestive of right ventricular dysfunction include right ventricular dilation or hypokinesis, increased right ventricular

diameter relative to that of the left ventricle, and increased velocity of the jet of tricuspid regurgitation. Echocardiography can also detect a right-to-left shunt through a patent foramen ovale and may provide evidence of right ventricular thrombus, both of which are associated with increased mortality in patients with PE. With no universal criteria for the diagnosis of right ventricular dysfunction, however, the utility of routine echocardiography remains uncertain. In general, routine echocardiography is recommended only in patients with severe hypoxia or other evidence to suggest hemodynamic compromise.

Other routinely ordered tests should include a complete blood count, platelet count, and international normalized ratio (INR) to help guide anticoagulation. A creatinine level and blood urea nitrogen level provide useful baseline information, as do serum electrolytes and liver enzymes.

TREATMENT

Rx

Although anticoagulant therapy remains the mainstay of treatment of PE, patients with severe PE may require reperfusion therapy to increase blood flow quickly to the pulmonary arteries and to reduce pulmonary artery pressure.[3] Therefore, rapid risk stratification is crucial to help guide treatment. PE patients who have contraindications to anticoagulant therapy may require insertion of a filter.

Severe Pulmonary Embolism

High-risk patients can be identified at the bedside (Table 98-2) based on the presence or absence of hemodynamic compromise, right ventricular dysfunction, and elevated biomarkers. Patients with severe PE usually die because they develop acute right ventricular failure, which causes low systemic output. Patients with severe PE require hemodynamic and respiratory support and may require reperfusion therapy. Patients with right ventricular failure often require modest fluid expansion and may need inotropic agents, such as dobutamine (starting at a dose of 0.5 to 1.0 µg/kg/minute and then titrated according to the blood pressure), dopamine (starting at a dose of 5 µg/kg/minute and then increased gradually in 5- to 10-µg/kg/minute increments, according to the blood pressure, up to 20 to 50 µg/kg/minute) or norepinephrine (starting at a dose of 2 to 4 µg/minute and then titrated according to the blood pressure) for severe hypotension or shock. Emerging data raise the possibility that endothelin antagonists and phosphodiesterase-5 inhibitors may attenuate the pulmonary hypertension in patients with severe PE, but these drugs are not currently approved for use in PE.

Patients with PE frequently have hypoxemia and hypocapnia. Hypoxemia can usually be reversed with nasal oxygen. Measures to reduce fever and agitation with acetaminophen and mild sedation may help minimize oxygen consumption. In patients who have severe PE and who require mechanical ventilation, low tidal volumes should be used, and positive end-expiratory pressure should be applied with caution because it can reduce venous return and worsen right ventricular failure (Chapter 105).

Reperfusion Therapy

Patients with severe PE associated with hypotension or shock may benefit from pharmacologic, mechanical, or surgical reperfusion therapy. Pharmacologic reperfusion therapy involves the systemic administration of a fibrinolytic agent (Table 98-3), preferably within 48 hours of the onset of symptoms, but later treatment may still be of benefit. Up to 13% of patients who receive fibrinolytic therapy experience a major bleed, and the rate of intracranial or fatal bleeding can reach 1.8%. Consequently, fibrinolytic therapy currently is justified only in patients who have severe PE and no contraindications (Table 98-4). It remains unclear whether the benefits of fibrinolytic therapy outweigh the risks in patients at intermediate risk.

Mechanical reperfusion includes percutaneous catheter embolectomy with thrombus fragmentation, an approach that avoids the need for fibrinolytic drugs altogether, or catheter-directed fibrinolytic therapy, which requires lower doses of fibrinolytic agents than used for systemic administration. In some centers, surgical pulmonary embolectomy may be an option for patients who have severe PE and who are at high risk for bleeding with systemic fibrinolytic therapy or who have failed such treatment. Mechanical techniques require skilled operators but provide useful alternatives to systemic fibrinolytic therapy for patients who have severe PE and who are at high risk for bleeding.

Anticoagulation Therapy

Anticoagulation therapy is the cornerstone of PE treatment and should be initiated immediately with parenteral anticoagulants, such as heparin, low-molecular-weight heparin (LMWH), or fondaparinux, even while patients with suspected PE are awaiting the results of confirmatory tests. Patients with severe PE should be treated with heparin because neither LMWH nor fondaparinux has been extensively evaluated in this setting. Heparin should be used in patients with severe renal impairment (creatinine clearance < 30 mL/minute) because LMWH and fondaparinux are cleared by the kidneys. If LMWH or fondaparinux is used in patients with moderate renal impairment (creatinine clearance of 30 to 50 mL/min), anti–factor Xa levels should be measured at trough to ensure there is no accumulation.

TABLE 98-3 APPROVED REGIMENS FOR FIBRINOLYTIC THERAPY FOR TREATMENT OF SEVERE PULMONARY EMBOLISM

AGENTS	RECOMMENDED REGIMENS
Streptokinase	250,000 IU as a loading dose over 30 min, followed by 100,000 IU/hr over 12 to 24 hr
Tissue plasminogen activator	100 mg over 2 hr, or 0.6 mg/kg over 10 to 15 min (maximal dose of 50 mg)

TABLE 98-2 RISK STRATIFICATION OF PATIENTS WITH PULMONARY EMBOLISM AND TREATMENTS IN ADDITION TO ANTICOAGULATION

CLASSIFICATION	HEMODYNAMIC COMPROMISE	RIGHT VENTRICULAR DYSFUNCTION	INCREASED TROPONIN AND/OR BNP LEVELS*	TREATMENT
Severe	Yes	Yes	Yes	Fibrinolytic therapy
Moderate	No	Yes	Yes	May consider fibrinolytic therapy if very symptomatic
Mild	No	No	No	Consider outpatient treatment

*Blood markers include troponin, brain natriuretic peptide (BNP), and N-terminal proBNP.

TABLE 98-4 CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

ABSOLUTE CONTRAINDICATIONS
Any hemorrhagic stroke or stroke of unknown origin
Central nervous system damage or neoplasm
Major trauma, surgery, or head injury in past 3 weeks
Gastrointestinal bleeding in past month
Significant ongoing bleeding
RELATIVE CONTRAINDICATIONS
Ischemic stroke or transient ischemic attack in past 6 months
Treatment with a vitamin K antagonist
Pregnancy or within 1 week of delivery
Noncompressible puncture site
Traumatic resuscitation
Advanced liver disease
Infective endocarditis
Active peptic ulcer disease

TABLE 98-5 LOW-MOLECULAR-WEIGHT HEPARIN AND FONDAPARINUX REGIMENS FOR TREATMENT OF PULMONARY EMBOLISM

AGENT	DOSE	INTERVAL
Enoxaparin	1 mg/kg 1.5 mg/kg	Twice daily Once daily
Dalteparin	100 U/kg 200 U/kg	Twice daily Once daily
Tinzaparin	175 U/kg	Once daily
Fondaparinux	5 mg (weight < 50 kg) 7.5 mg (weight 50-100 kg) 10 mg (weight > 100 kg)	Once daily Once daily Once daily

Heparin should be administered by continuous intravenous infusion and dosed using weight-based nomograms (see Table 81-4 in Chapter 81). Typically, an 80 U/kg bolus is followed by an infusion at the rate of 18 U/kg per hour, and subsequent doses are adjusted based on the results of the activated partial thromboplastin time (aPTT). Rapid achievement and maintenance of a therapeutic aPTT are important to reduce the risk of recurrent PE. In addition to monitoring the aPTT, the platelet count should be measured frequently because of the risk of heparin-induced thrombocytopenia (Chapter 37).

LMWH or fondaparinux can be used for intermediate- or low-risk PE patients (see Table 98-2) using the regimens illustrated in Table 98-5.[4,5] Unlike heparin, these agents do not require coagulation monitoring. In addition, the risk of heparin-induced thrombocytopenia is lower with LMWH than with heparin, and the risk is minimal with fondaparinux. Outpatient management of PE is safe for low-risk PE patients. In PE patients at intermediate risk (see Table 98-2), outpatient management can be considered, but brief admission to hospital may be a safer approach.

After initial treatment with a parenteral anticoagulant, most patients with PE receive extended therapy with a vitamin K antagonist, such as warfarin (Chapter 81), to prevent recurrent DVT and PE. In PE patients at low or intermediate risk (see Table 98-2), warfarin can be started on the same day that parenteral anticoagulant therapy is initiated. Parenteral anticoagulant therapy should be continued for at least 5 days and should only be stopped when the INR has been within the therapeutic range of 2 to 3, which is needed for long-term therapy, for 2 consecutive days. Initiation of warfarin therapy should be delayed in patients with severe PE; such patients should receive heparin until they have stabilized.

An emerging option is unmonitored, fixed-dose dabigatran etexilate (150 mg twice daily) for patients with VTE, including PE. The rates of recurrent VTE and bleeding are similar with dabigatran and warfarin, but dabigatran is superior to warfarin for preventing stroke in patients with atrial fibrillation.[6] This agent and oral factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban) have the potential to replace warfarin, thereby simplifying long-term anticoagulant treatment.

Patients who develop PE as a complication of a reversible risk factor, such as surgery, trauma, or medical illness, have a low risk of recurrence when anticoagulant therapy is stopped. Consequently, a 3-month course of warfarin therapy represents adequate treatment in such patients provided that their risk factors have resolved. Women who develop PE with estrogen therapy also can be treated for 3 months, provided that hormonal treatment is withdrawn. In contrast, patients with unprovoked PE have a higher rate of recurrent VTE when anticoagulant therapy stops and require longer treatment; some experts recommend indefinite anticoagulant therapy provided that the risk of bleeding remains low. One month after stopping anticoagulant therapy, an elevated D-dimer level or residual venous compression ultrasound abnormalities identify patients at higher risk for recurrence who require indefinite anticoagulation therapy.[7,8] After a minimum 3-month course of usual-intensity warfarin (target INR between 2 and 3), a lower-intensity regimen (target INR between 1.5 and 2.0) may simplify management by decreasing the frequency of INR monitoring and reducing the risk of bleeding,[9] but the risk of recurrent VTE is slightly higher with this lower-intensity warfarin regimen.[10]

Caval Filters

Filters, which are inserted percutaneously, are usually placed below the level of the renal veins but can be placed higher for thrombus in the inferior vena cava. Both permanent and retrievable filters reduce the risk of recurrent PE but have not been shown to prolong survival, in part because permanent filters can be associated with long-term complications, including inferior vena cava occlusion because of thrombus, recurrent DVT, and post-thrombotic syndrome.[11] Retrievable filters, designed to be removed within 2 to 4 weeks of implantation, can circumvent these long-term complications, but device migration or thrombosis occurs in up to 10% of patients with temporary filters because most are not removed. Because of these potential problems, caval filters should be restricted to patients who have high risk for recurrent PE and an absolute contraindication for anticoagulation, such as patients who develop a PE after major surgery, patients who experience major bleeding with anticoagulant therapy, and pregnant women who have a PE shortly before delivery. Retrievable filters should be used in these cases, and the devices should be removed as soon as anticoagulant therapy can safely be administered. Permanent filters are suitable for patients who have ongoing contraindications to anticoagulation.

Specific Patient Subgroups

Patients with PE in the setting of active cancer, women who suffer a PE during pregnancy, and patients with chronic thromboembolic pulmonary hypertension (Chapter 68) require special treatment.

Cancer

Active cancer and its treatment with chemotherapy, radiation therapy, and growth factors or other biological agents increase the risk of VTE (Chapter 187). Patients with advanced cancer often have limited mobility, which adds to their risk of VTE. In addition, indwelling central venous access catheters can trigger upper extremity DVT, which can lead to PE. Therefore, the index of suspicion should be high in cancer patients who present with symptoms and signs suggestive of PE or DVT, or both. With advances in diagnostic imaging, incidental PE may be discovered on CT scans performed for staging purposes or for monitoring response to treatment. Although 20% of patients with VTE have an underlying malignancy, patients with PE should not undergo routine extensive screening for cancer.

Like patients without cancer, initial treatment of PE in cancer patients involves administration of a rapidly acting parenteral anticoagulant. For extended treatment, however, LMWH reduces the risk of recurrent VTE to a greater extent than warfarin. In addition, in the face of poor nutritional intake, severe nausea and vomiting, transient thrombocytopenia, or invasive procedures, LMWH is easier to manage than warfarin.

Cancer patients who develop PE after curative surgery or with adjuvant chemotherapy for limited-stage disease should be treated for at least 3 months or until they have completed their chemotherapy. Those with PE on the background of advanced cancer have a risk of recurrence of at least 20% in the first year after stopping anticoagulant therapy, so they require lifelong treatment.

Pregnancy

Treatment of PE in pregnancy (Chapter 247) centers mainly on heparin or LMWH because, unlike warfarin, these agents do not cross the placenta. Although both agents can be given subcutaneously, weight-adjusted LMWH has advantages over heparin because it can be given once daily without routine monitoring and because the risks of heparin-induced thrombocytopenia and osteoporosis are lower with LMWH than with heparin. Anti–factor Xa monitoring of LMWH should be considered in women at extremes of body weight and in those with renal impairment. Fondaparinux should be considered for pregnant women who have a history of heparin-induced thrombocytopenia or who develop injection-site reactions to heparin or LMWH.

Heparin or LMWH should be continued throughout pregnancy. Warfarin must be avoided because it crosses the placenta and can cause bone and central nervous system abnormalities, fetal hemorrhage, or placental abruption. During labor and delivery, epidural analgesia should be avoided unless prophylactic LMWH has been stopped at least 12 hours before insertion of the epidural catheter and therapeutic LMWH has been stopped at least 24 hours before. Treatment can be resumed within 6 hours of catheter withdrawal. After delivery, anticoagulation therapy should be continued for at least 3 months; warfarin can be used because it does not appear in breast milk.

Fibrinolytic agents have been used successfully for treatment of severe PE in pregnancy but can cause bleeding, usually from the genital tract. If PE

develops late in pregnancy, a retrievable filter may prevent recurrence during delivery when anticoagulant therapy must be withheld.

Chronic Thromboembolic Pulmonary Hypertension

A complication of PE, chronic thromboembolic pulmonary hypertension develops in 0.5 to 5% of patients over the course of months or years when emboli in major pulmonary arteries are replaced by fibrous tissue that becomes incorporated into the vessel wall, thereby narrowing or obstructing it. Chronic obstruction of the pulmonary vascular bed increases pulmonary arterial resistance and can lead to right heart failure. Although patients initially may be asymptomatic, they experience increasing dyspnea on exertion and hypoxemia as the disease progresses. Chronic thromboembolic pulmonary hypertension should be suspected in patients with pulmonary hypertension (Chapter 68), and the diagnosis can be established with a combination of echocardiography and lung scanning or CT pulmonary angiography.

Medical therapy focuses on treatment of right heart failure and the use of prostacyclin, endothelin receptor antagonists, or phosphodiesterase-5 inhibitors, or a combination of these, to lower pulmonary artery pressure (see Table 68-2 and Fig. 68-7 in Chapter 68). These agents may be of limited utility, however, because of the fibrotic nature of the obstructing material. Definitive treatment involves surgical thromboendarterectomy to remove the occluding material from the pulmonary arteries. This procedure is associated with a perioperative mortality rate that can be as high as 4%, depending on the severity of the disease, and a 3-year survival rate of about 80%.

PREVENTION

At least half of the outpatients with newly diagnosed VTE have a history of recent hospitalization, and most failed to receive thromboprophylaxis during their hospital stay; as a result, PE is the most common preventable cause of death in hospitalized patients in the United States. Guidelines for primary prophylaxis are available and should be followed (see Tables 37-2 and 37-3 in Chapter 37).

PROGNOSIS

With the diagnosis established and adequate anticoagulant therapy initiated, most patients with PE survive. Case-fatality rates 1 month after diagnosis of DVT or PE are 6% and 12%, respectively. Patients with severe PE who present with shock have the highest mortality rate, and many die within an hour of presentation. Although the case-fatality rate in patients with PE is twice that in those with DVT, many of the deaths are the result of comorbid conditions rather than the PE itself. Factors associated with early mortality after VTE include presentation as PE, advanced age, cancer, and underlying cardiovascular disease. The most serious long-term complication of PE is chronic thromboembolic pulmonary hypertension (Chapter 68), a rare condition associated with significant morbidity and mortality.

Despite anticoagulant therapy, recurrent VTE occurs in about 6% of patients during the first 6 months. While on anticoagulation treatment, patients with unprovoked VTE and those with secondary VTE have similar risks of recurrence. In contrast, when anticoagulant therapy is stopped, patients with unprovoked VTE have a risk of recurrence of 10% at 1 year and 30% at 5 years, whereas those with secondary VTE have recurrence rates of 3% at 1 year and 10% at 5 years. Recurrent events often mirror the index events; after an initial PE, about 60% of recurrences are PE. Because of the high risk of recurrence in patients with unprovoked VTE, many experts recommend indefinite anticoagulant therapy for such patients. In contrast, because of the lower risk of recurrence, anticoagulation therapy can be stopped after 3 months in patients with secondary VTE whose risk factors have resolved.

NONTHROMBOTIC PULMONARY EMBOLISM

DEFINITION

Nonthrombotic material that can embolize to the lungs includes fat, air, amniotic fluid, tumor cells, talc in intravenous drug abusers, and medical devices.

Fat Embolism Syndrome

EPIDEMIOLOGY

Fat embolism syndrome usually occurs in the setting of trauma, particularly after fracture of long bones or the pelvis. The risk increases with the number of fractured bones, and the syndrome occurs more often with closed fractures than with open ones. Fat embolism also can complicate orthopedic surgery or trauma to tissues rich in fat, such as may occur with liposuction.

PATHOBIOLOGY

Characterized by a combination of respiratory, neurologic, hematologic, and cutaneous manifestations, fat embolism syndrome reflects a combination of vascular obstruction by fat globules, as well as the deleterious effects of free fatty acids released from these fat globules by the action of lipoprotein lipases. These free fatty acids increase vascular permeability, induce a capillary leak syndrome, and can trigger platelet aggregation.

CLINICAL MANIFESTATIONS

Symptoms typically develop 24 to 72 hours after trauma or surgery. Patients often complain of vague chest pain and shortness of breath. Tachypnea and fever associated with disproportionate tachycardia are common. The syndrome can rapidly progress to severe hypoxemia that requires mechanical ventilation. Neurologic manifestations, which often start after the respiratory distress, include drowsiness, confusion, decreased level of consciousness, and seizures. Patients may have petechiae, particularly involving the conjunctiva, oral mucosa, and upper half of the body.

DIAGNOSIS

Fat embolism syndrome should be suspected when respiratory distress occurs a day or more after major trauma or orthopedic surgery, particularly when there are associated neurologic defects and petechiae. The chest radiograph may reveal diffuse alveolar infiltrates. Although fat droplets may be found in bronchoalveolar lavage fluid, this finding lacks specificity for the fat embolism syndrome.

PREVENTION, TREATMENT, AND PROGNOSIS Rx

Early stabilization of long bone fractures reduces the risk of fat embolization. Supportive treatment should be provided, including oxygen and mechanical ventilation. The utility of corticosteroids remains controversial.

Although mortality rates as high as 10% have been reported, the prognosis is generally good.

Venous Air Embolism

EPIDEMIOLOGY

Venous air embolism, which involves entrapment of environmental air or exogenous gas in the venous system, requires direct communication between the air and a vein, as well as a pressure gradient that favors entry of the air into the vein. Air can be introduced through indwelling central venous catheters as a consequence of invasive surgical or medical procedures or after barotrauma.

PATHOBIOLOGY

Large venous air emboli obstruct the right ventricular pulmonary outflow tract, whereas mixtures of air bubbles and fibrin thrombi can obstruct pulmonary arterioles. In either case, right ventricular failure can result. With a patent foramen ovale (Chapter 69), venous air emboli can enter the coronary, cerebral, or systemic circulation.

CLINICAL MANIFESTATIONS

Symptoms and signs depend on the volume of air and the rapidity of its entry into the circulation. Large, rapid boluses of air are tolerated less well than slow entry of smaller amounts. Small air emboli may be asymptomatic. With larger emboli, patients often complain of dyspnea and retrosternal chest discomfort, and they may feel lightheaded. Physical findings include tachypnea, tachycardia, and evidence of respiratory distress. Patients may have signs of right heart failure. A continuous, drumlike, mill-wheel murmur, which reflects air in the right ventricle, may be heard.

DIAGNOSIS

Patients may present with ECG evidence of right ventricular dysfunction associated with elevated levels of troponin, indicative of myocardial injury. Echocardiography or chest CT may reveal air in the right ventricle. Patients may have hypoxemia and hypercapnia, and the platelet count may be low.

PREVENTION AND TREATMENT

Rx

All catheters should be removed using techniques that minimize air embolism, air should be removed from syringes before injection, and care should be taken during surgery to ensure that air bubbles do not form in blood vessels. To avoid air embolism associated with barotrauma, divers require training in how to dive and surface safely (Chapter 94).

The source of any air embolism should be identified so that further embolism can be prevented. Left lateral decubitus positioning may benefit patients who have a large air bubble trapped in the right ventricular outflow tract; such positioning places the outflow tract below the right ventricular cavity, thereby allowing the air bubble to migrate into a nonobstructing position. Aspiration of the right ventricle through a central venous catheter may also be of benefit. Patients should receive high-flow supplemental oxygen, and hyperbaric oxygenation should be considered for patients with cardiac or neurologic dysfunction.

PROGNOSIS

The outcome depends on the extent of air embolism. With good supportive care, the mortality rate can be less than 10%, even in patients with major air emboli. However, residual neurologic defects often persist.

Amniotic Fluid Embolism

EPIDEMIOLOGY AND PATHOBIOLOGY

Amniotic fluid embolism is a rare but catastrophic complication of pregnancy, occurring in about 1 in 8000 to 1 in 80,000 pregnancies. The syndrome develops when amniotic fluid and fetal cells enter the maternal blood stream through small tears in the uterine veins during labor. Emboli to the heart and lungs cause cardiac dysfunction and respiratory distress. In addition, amniotic fluid and other debris activate the coagulation system, and the resultant thrombin then triggers fibrin formation and platelet activation to induce disseminated intravascular coagulation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The syndrome often starts with the abrupt onset of dyspnea, cyanosis, and hypotension that can rapidly progress to cardiovascular collapse and death. Patients who survive this stage often develop manifestations of disseminated intravascular coagulation (Chapter 178) characterized by diffuse bleeding, petechiae, and ecchymoses.

The diagnosis should be suspected in women late in pregnancy, often in labor, who present with sudden onset of respiratory distress followed by cyanosis, hypotension, and shock. These findings are often associated with confusion or reduced level of consciousness, seizures, and evidence of a consumptive coagulopathy.

TREATMENT

Rx

Supportive measures include oxygen, mechanical ventilation, and hemodynamic support. Fresh-frozen plasma, cryoprecipitate, and platelets transfusion can be given to replace consumed clotting factors and platelets. Heparin, often in low therapeutic doses, may be useful in some cases. If amniotic fluid embolism occurs before or during delivery, the fetus often has a poor outcome. As soon as the mother stabilizes, therefore, every attempt should be made to deliver the fetus.

PROGNOSIS

Although rare, amniotic fluid embolism remains the leading cause of maternal death during labor and the first few hours after delivery. Despite advances in critical care management, maternal and fetal mortality rates continue to be about 60% and 20%, respectively, with up to half of the survivors, both mother and baby, suffering from permanent hypoxia-induced neurologic dysfunction.

Other Embolic Material

Many substances, such as talc, starch, and cellulose are used as fillers in the manufacture of drugs. Some of these drugs are ground up by drug users (Chapter 33), mixed in liquids, and then injected intravenously. The filler particles can then be trapped in the pulmonary vasculature, where they can induce granuloma formation.

Tumor emboli (Chapter 179) in the lung can mimic pneumonia, tuberculosis, or interstitial lung disease on the chest radiograph. Cancers of the prostate and breast are the most common sources of such emboli, followed by hepatoma and cancers of the stomach and pancreas. Although found in up to 26% of autopsies in patients with advanced cancer, tumor emboli are infrequently identified before death.

Various types of intravascular devices can embolize to the lungs, including vena cava filters, broken catheter tips, guidewires, stent fragments, and coils used for embolization. Many of these devices lodge in the right atrium, right ventricle, or pulmonary arteries. Intravascular retrieval can recover most of these devices; open surgery may be required for the remainder.

DISEASES OF THE DIAPHRAGM, CHEST WALL, PLEURA, AND MEDIASTINUM

F. DENNIS MCCOOL

DIAPHRAGM

The diaphragm is a dome-shaped structure that separates the thorax from the abdomen. It consists of a central tendon and a peripheral muscular component that inserts into the rib cage laterally along the inner surface of the lower six ribs, the costal cartilages anteromedially, and the upper three lumbar vertebral bodies posteriorly. The diaphragm is innervated by the phrenic nerve, which originates from cervical nerve roots 3 through 5.

DIAPHRAGMATIC WEAKNESS AND PARALYSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

When the diaphragm is activated, it contracts and descends caudally. The downward descent of the diaphragm expands the lower rib cage and lowers pleural pressure, thereby resulting in lung inflation. It is the major muscle of inspiration, and its action accounts for approximately 70% of the inspired tidal volume in the normal individual. Diaphragm function can be impaired by disorders that affect the brain (Chapter 411), spinal cord (Chapter 407), phrenic nerve (Chapter 428), neuromuscular junction (Chapter 430), and muscle itself (Chapter 429). The incidence and prevalence of diaphragm paralysis and weakness are unknown.

CLINICAL MANIFESTATIONS

Diaphragmatic weakness or paralysis can involve either one or both hemidiaphragms. With unilateral diaphragmatic paralysis, patients are generally asymptomatic at rest but may have dyspnea with exertion or when supine. If they are asymptomatic, the abnormality may be discovered as an incidental finding of an elevated hemidiaphragm on chest radiography.

Bilateral diaphragmatic paralysis is not as common as unilateral paralysis. Generally, the disability with bilateral paralysis is more dramatic than with unilateral paralysis. Orthopnea is an especially prominent symptom, and patients are often unable to sleep in the supine position. These individuals also experience significant dyspnea with exertion and are at an increased risk to hypoventilate during sleep, especially during rapid eye movement (REM) sleep. Consequently, initial symptoms of individuals with bilateral or unilateral diaphragm weakness or paralysis may be related to nocturnal hypoventilation and include frequent nocturnal awakenings, nocturia, vivid nightmares, night sweats, daytime hypersomnolence, depression, and morning headaches.

The physical examination is remarkable for use of accessory muscles of inspiration and paradoxical inward motion of the abdominal wall during inspiration, which is especially noticeable when these individuals are asked to lie flat. Percussion during inspiration and expiration can detect the absence of diaphragmatic movement.

DIAGNOSIS

Disorders that can cause unilateral diaphragmatic weakness or paralysis (Table 99-1) include traumatic phrenic nerve injury, herpes zoster (Chapter 383), cervical spinal disease (Chapter 407), compressive tumors, and phrenic nerve injury related to cardiac or thoracic surgery. Diagnosis is often suggested by elevation of a hemidiaphragm on a chest radiograph. The diagnosis can be confirmed by performing a "sniff test" using fluoroscopy, in which paradoxical (cephalad) movement of the hemidiaphragm occurs during a sniff maneuver.

The presence of bilateral diaphragmatic paralysis can be much more difficult to ascertain than unilateral paralysis. Chest radiography, which typically shows elevation of both hemidiaphragms, may be interpreted as a "poor inspiratory effort" or "low lung volumes."

Tests that can support or refute the diagnosis include pulmonary function testing (Chapter 85), which typically shows a moderate to severe reduction of vital capacity (VC) and total lung capacity (TLC) (30 to 60% predicted). The restriction becomes more severe (10 to 30% further decrease for unilateral and 30 to 50% further decrease for bilateral paralysis) when the individual assumes the supine position. Maximal static inspiratory pressure measured at the airway opening (PI_{max}) is reduced to 20 to 30% of predicted in individuals with bilateral diaphragmatic paralysis. The diagnosis can be confirmed if measurements of transdiaphragmatic pressure (the pressure difference between the thoracic and abdominal cavity) do not change with inspiration. Diaphragm electromyography and phrenic nerve conduction studies may be useful to distinguish neuropathy or myopathy. Unlike unilateral diaphragmatic paralysis, a sniff test is not helpful in individuals with bilateral diaphragmatic paralysis because it can yield both false-negative and false-positive results. Using two-dimensional ultrasound, the normal thickening of the diaphragm during inspiration will not be observed. If the diagnosis of bilateral diaphragmatic paralysis is confirmed, an evaluation for nocturnal hypoventilation (Chapter 86) should be undertaken.

TREATMENT AND PROGNOSIS

Rx

Bilateral diaphragmatic paralysis may not be reversible unless the underlying cause is treatable. For example, myopathies (Chapter 429) related to metabolic disturbances may be improved by correcting electrolyte imbalances or replacing thyroid hormone. Toxic or metabolic disturbances related to diabetes, alcohol, or viral infections may resolve with treatment of the underlying disease. Idiopathic diaphragmatic paralysis or paralysis due to neuralgic amyotrophy (brachial plexus neuritis) may spontaneously improve or resolve completely in approximately 60% of individuals, but recovery can take 18 months to 3 years. Phrenic nerve damage related to cardiac surgery usually resolves spontaneously. For a high spinal cord injury, in which the phrenic nerve roots remain intact (injury above C-3), phrenic nerve pacing can provide ventilation.

As in sleep-disordered breathing (Chapter 100), noninvasive positive-pressure ventilation (NPPV) is the preferred method of treatment for patients with diaphragmatic paralysis because it can improve both symptoms and physiologic derangements.

Nocturnal positive-pressure ventilation is associated with a number of benefits■ in patients with neuromuscular disease (Table 99-2). The improvement in ventilation may be related to resting the diaphragm during periods of mechanical ventilation; this reduced work appears to reverse chronic respiratory muscle fatigue and improve daytime function. Other benefits may be related to changes in the control of breathing by reversing the brain's adaptation to high levels of CO_2 by "resetting" the central controller toward normal. When patients with unilateral paralysis have severe symptoms, surgical plication of the paralyzed hemidiaphragm may improve vital capacity.

TABLE 99-1 CAUSES OF DIAPHRAGMATIC WEAKNESS AND PARALYSIS

Cervical spondylosis
Poliomyelitis
Amyotrophic lateral sclerosis
IDIOPATHIC

MISCELLANEOUS DIAPHRAGMATIC DISORDERS

Diaphragmatic eventration results from localized atrophy of the diaphragm muscle or from part of the diaphragm being replaced with fibroelastic tissue. Eventration most often results in an elevation of the right anteromedial portion of the diaphragm. Metastatic tumors to the diaphragm usually are related to direct extension of lung cancer. Primary tumors of the diaphragm are very rare. Lipomas are the most common benign tumor, and fibrosarcomas are the most common malignant neoplasm.

CHEST WALL

The chest wall is a key component of the "inspiratory pump" and allows for maintenance of normal alveolar ventilation. It consists of the bony structures

TABLE 99-2 THERAPEUTIC BENEFITS OF NONINVASIVE MECHANICAL VENTILATION IN PATIENTS WITH CHEST WALL AND NEUROMUSCULAR DISORDERS*

GAS EXCHANGE INDICES	
Pa_{O_2}	Increase
Pa_{CO_2}	Decrease
Bicarbonate	Decrease
RESPIRATORY MECHANICS

Survival	Increase

*Efficacy data derived from mostly nonrandomized, noncontrolled studies.
MEP = maximal expiratory pressure; MIP = maximal inspiratory pressure; PAP = pulmonary artery pressure.

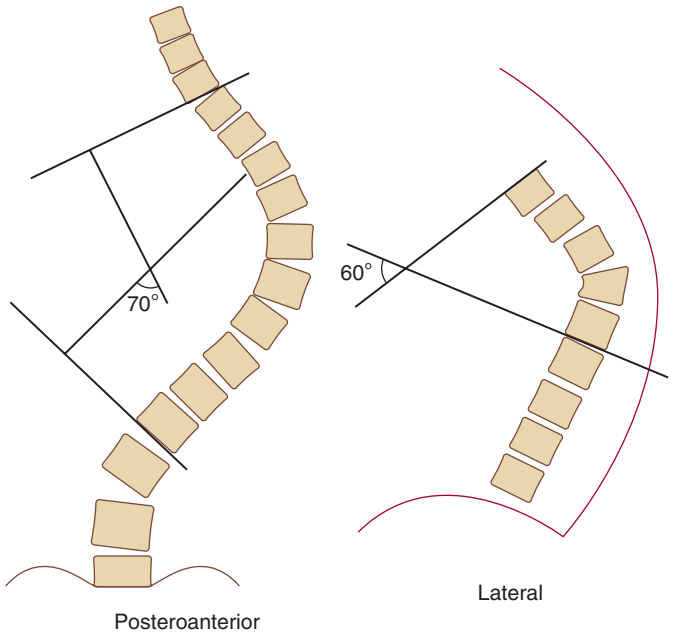

FIGURE 99-1. Schematic drawings of the spine illustrating the lines constructed to measure the Cobb angle of scoliosis and kyphosis. The angle can be calculated either from the intersection of the lines parallel to the vertebrae (as shown for kyphosis, on the *right*) or from the intersection of lines perpendicular to these lines (as shown for scoliosis, on the *left*).

of the rib cage, the articulations between the ribs and the vertebrae, the diaphragm, intercostal muscles, and the abdomen. Disorders that affect any of the components of the chest wall can result in impaired breathing.

KYPHOSCOLIOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Kyphoscoliosis, which is a common spinal disorder, affects approximately 1 in 1000 individuals, and about 1 in 10,000 affected individuals has a severe spinal deformity. Deformities include excessive spinal curvature in the coronal (scoliosis) and sagittal (kyphosis) planes as well as rotation of the spinal axis. Kyphoscoliosis can be idiopathic or can be secondary (paralytic) and associated with neuromuscular diseases, such as muscular dystrophy and polio (Chapters 423 and 429).

Idiopathic kyphoscoliosis, in which there may be a familial predominance, usually manifests in late childhood or early adolescence and involves females more than males with a ratio of 4:1. Although a defect in the chromatin-remodeling gene family (*CHD7*) has been associated with idiopathic kyphoscoliosis, other genes have also been identified.

Kyphoscoliosis produces one of the most severe restrictive impairments of all the chest wall diseases. Total lung capacity and vital capacity may be reduced to as low as 30% of predicted values. This restrictive pathology becomes most severe as the degree of spinal angulation increases. The patient's age, degree of spinal rotation, presence of respiratory muscle weakness, and involvement of the thoracic vertebrae are all factors that promote the restrictive process. Respiratory failure is a common cause of morbidity and mortality in patients with kyphoscoliosis.

CLINICAL MANIFESTATIONS

Individuals with mild to moderate kyphoscoliosis may have complaints of back pain and have psychosocial problems as a result of their deformity. Adolescents with mild idiopathic kyphoscoliosis usually have normal exercise capacity, whereas those with moderate idiopathic kyphoscoliosis have reduced exercise capacity with additional exercise limitation due to deconditioning. With severe deformities, patients may experience dyspnea with minimal exertion or at rest.

Severe kyphoscoliosis can be readily diagnosed on physical examination. Typical findings are the dorsal hump, which is due to the angulated ribs and shoulder asymmetry, as well as the hip tilt that is related to the spinal rotation. In younger individuals with milder spinal deformities, the initial changes may be subtle. The Adams forward bend test, in which the examiner observes for thoracic or lumbar region asymmetry while the patient bends forward at the waist until the spine becomes parallel to the floor, can help detect minor deformities. With severe kyphoscoliosis, signs of right heart failure (Chapter 58) may be present such as cyanosis, distended neck veins, peripheral edema, and hepatomegaly.

Individuals with kyphoscoliosis are particularly prone to hypoventilation during sleep, especially REM sleep. Because sleep-related abnormalities and their effects on cardiorespiratory function are potentially treatable, individuals with kyphoscoliosis should be evaluated for nocturnal hypoventilation well in advance of the development of daytime hypercapnia.

DIAGNOSIS

Although spinal deformity is often readily apparent on physical examination, the degree of spinal deformity should be assessed by calculation of the angle of spinal curvature (the Cobb angle) from radiographs. This angle is formed by the intersection of lines parallel to the top and bottom vertebrae of the scoliotic or kyphotic curves (Fig. 99-1). Angles more than 100 degrees are usually associated with respiratory symptoms, and angles more than 120 degrees with respiratory failure. Factors associated with progression of the spinal deformity include inspiratory muscle weakness, a large spinal curvature at the time of presentation, skeletal immaturity, and a thoracic location of the curve apex. Individuals with inspiratory muscle weakness and kyphoscoliosis are more prone to develop respiratory failure than those with normal inspiratory muscle strength.

TREATMENT

Rx

Patients should be encouraged to remain physically active to minimize peripheral muscle deconditioning. In addition, general supportive measures including immunizations against influenza and pneumococci (Chapter 17), smoking cessation (Chapter 31), maintenance of a normal body weight (Chapter 227), and treatment of respiratory infections in a timely fashion should be instituted. Patients with severe kyphoscoliosis and Cobb angles of more than 100 degrees should be monitored closely for respiratory complications. Respiratory failure may be precipitated by respiratory infections or by medications that produce central nervous system depression.

Nocturnal hypoventilation typically precedes findings of daytime hypercapnia and hypoxemia and should be treated with NPPV. Indications for instituting NPPV include symptoms of nocturnal hypoventilation or signs of cor pulmonale (Chapter 68) with either an elevated daytime Pa_{CO_2} or nocturnal oxygen saturation of less than 89% for 5 consecutive minutes. Supplemental oxygen will be needed if hypoxemia persists despite correction of hypoventilation. NPPV can reduce the number and duration of hospitalizations and improve gas exchange, daytime blood gases, quality of life, and survival (see Table 99-2).

Surgical and nonsurgical (back-brace) treatments have been used in skeletally immature patients with idiopathic kyphoscoliosis in an effort to correct or prevent progression of the spinal deformity. Braces have been used for growing children with Cobb angles between 25 and 40 degrees, whereas surgery has been used for adolescents with a Cobb angle of more than 45 degrees. The overall role of surgical management in restoring function to that of nonscoliotic individuals and minimizing the possibility of respiratory failure is not clear.

PROGNOSIS

Idiopathic kyphoscoliosis has a better prognosis than kyphoscoliosis secondary to neuromuscular diseases. In general, individuals with mild idiopathic kyphoscoliosis have an overall benign course. Patients with moderate or severe deformities are at higher risk of developing respiratory complications.

In secondary kyphoscoliosis, factors such as an early age of onset, rapid curve progression during growth, progression of scoliosis after skeletal maturity, large curves at the time of presentation, and a thoracic rather than a thoracolumbar or lumbar location of the curve apex are risk factors for respiratory complications. Respiratory failure may occur in individuals with mild or moderate kyphoscoliosis owing to concurrent respiratory muscle dysfunction. Muscle strength should be evaluated in individuals with respiratory failure and Cobb angles of less than 100 degrees. When cor pulmonale develops (Chapter 68), the prognosis is poor, and death may occur within 1 year without therapy.

PECTUS EXCAVATUM

EPIDEMIOLOGY AND PATHOBIOLOGY

Pectus excavatum, a chest wall deformity that occurs in approximately 0.5 to 2% of the population, is characterized by excessive depression of the sternum and its adjacent costal cartilages. The ratio of affected males to females is 4:1, and a family history is common. Pectus excavatum produces minimal functional impairment of the respiratory system. Occasionally, a restrictive defect will be present with mild reductions in VC and TLC. Individuals with the most severe pectus deformities may exhibit a mild reduction in maximal exercise capacity.

CLINICAL MANIFESTATIONS

Cosmetic concerns are the usual reason for seeking medical attention. Dyspnea with activity or exercise may be present but is usually out of proportion to any measurable abnormality in cardiopulmonary function. On physical examination, sternal depression is readily apparent, and there is normal excursion of the rib cage during inspiration. A mild degree of scoliosis may be present in 40 to 60% of individuals.

DIAGNOSIS

Chest computed tomography (CT) is the best means of assessing the sternal deformity. The anteroposterior diameter of the rib cage and the transverse diameter of the rib cage are measured at the level of the deepest sternal depression. Normally, the transverse-to-anteroposterior diameter ratio is 2.5. A ratio of greater than 3.5 signifies a significant pectus deformity.

TREATMENT AND PROGNOSIS Rx

Surgical correction of the deformity is considered for patients with a CT ratio of more than 3.5 in conjunction with symptoms of dyspnea or laboratory evidence of cardiac or pulmonary restriction. However, there is no convincing evidence that correction of the deformity improves either cardiopulmonary function or exercise capacity. Invasive surgical approaches include resecting costal cartilage and repositioning the sternum. Sternal necrosis and infection may complicate invasive surgical procedures, and sternal osteotomy should be avoided in early childhood because it may be complicated by arrested growth of the rib cage. Minimally invasive approaches insert curved metal rods into the sternum through small incisions on each side of the rib cage; over time, the rod is rotated to force the sternum outward. After approximately 2 years, the rods are removed. The prognosis is excellent in individuals who have only mild deformity and patients who have undergone minimally invasive surgical correction of more severe deformities.

FLAIL CHEST

EPIDEMIOLOGY AND PATHOBIOLOGY

Flail chest occurs following trauma in which there have been either double fractures of three or more contiguous ribs or combined sternal and rib fractures. The result is an unstable segment of the chest wall, which moves paradoxically inward with inspiration and outward with expiration. In adults, flail chest is most commonly a consequence of blunt chest wall trauma owing to automobile accidents or falls (Chapter 112).

With a flail chest, inspiratory capacity is limited, and VC may be reduced by 50% or more. Reductions in lung compliance, owing to concomitant pulmonary contusion or microatelectasis, will worsen the restrictive dysfunction and impair gas exchange. The most common location for a flail segment is the lateral chest wall, and this location is generally associated with more clinical derangement. By contrast, a posterior flail segment has less impact on the respiratory system because of splinting provided by the paraspinal muscles.

Hypoventilation and flail-induced changes in respiratory muscle function are key factors to the development of respiratory failure in individuals with flail chest (E-Fig. 99-1). Excessive shortening of the inspiratory muscles related to the flail segment increase the work of breathing. The increased work, in concert with reduced oxygen supplies due to pulmonary contusion or hypoventilation, predisposes these individuals to developing respiratory muscle fatigue. Pain associated with the rib fractures and the disordered motion of the flail segment during expiration impair cough.

DIAGNOSIS

Bedside inspection and gentle palpation of the rib cage and abdomen can reveal the characteristic paradoxical movement of the flail segment during spontaneous breathing. Chest radiographs will confirm the presence of multiple rib fractures, but a three-dimensional reconstruction of a thoracic CT can provide better visualization of thoracic injuries, including lung contusion. The diagnosis may be less apparent in a sedated mechanically ventilated patient, in whom paradoxical motion of a segment of the rib cage may not occur because the positive alveolar and pleural pressures act as a "pneumatic splint" and allow for uniform inflation of the chest wall. However, after withdrawal of sedation, spontaneous breathing should reveal the flail segment.

TREATMENT Rx

Nonsurgical management of flail chest consists of adequate analgesia, clearance of bronchial secretions, and mechanical ventilatory assistance if needed. Pain relief (Chapter 29) can be accomplished by oral medications, patient-controlled analgesic pumps, intercostal nerve blocks, or epidural anesthesia. These interventions often produce a successful outcome with avoidance of respiratory failure and mechanical ventilation, and as the rib cage heals, function is restored. If respiratory failure ensues, not only will mechanical ventilation enhance gas exchange, but also the positive pleural pressure provided by the ventilator during inspiration will stabilize the flail segment. Ventilation delivered by a nasal or face mask to patients who are spontaneously breathing improves gas exchange and may allow for early mobilization and access to physical therapy.

Surgical techniques, none of which is supported by randomized clinical trial evidence, include open thoracotomy with stabilization of the fractured ribs. The indications for operative fixation are not fully defined, but patients who are unable to wean from mechanical ventilation owing to chest wall instability or patients who are undergoing thoracotomy for concomitant injuries may be candidates for surgical fixation.

PROGNOSIS

The overall mortality from chest wall trauma is high, ranging from 7 to 14%. If concomitant lung contusion is present, the mortality rate increases further and may be as high as 70%. The associated high mortality rate is also partly due to the coexistence of other injuries, such as fractures of the long bones, head trauma, or rupture of major vascular structures (Chapter 112). Older age is another poor prognostic factor.

In patients with flail chest without lung contusion, the restrictive impairment can resolve, and the VC can return to baseline values within 6 months after the acute injury. By contrast, individuals with flail chest and concomitant lung contusion often have persistent impairment of pulmonary function, which may persist for up to 4 years after injury. Operative fixation of the chest wall may reduce long-term respiratory dysfunction in these individuals.

ANKYLOSING SPONDYLITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Ankylosing spondylitis (Chapter 273) is an inflammatory disease that involves the ligamentous structures of the spine, sacroiliac, and large peripheral joints. It affects men more than women, with the most common age of onset between 15 and 25 years. There is a genetic predisposition, with the HLA-B27 antigen present in 95% of whites with ankylosing spondylitis. Chronic inflammation of the spine and peripheral joints may cause fibrosis and ossification of structures adjacent to the spine. Fusion of the costovertebral and sternoclavicular joints produces relative fixation of the rib cage in an inspiratory position, with limited motion of the rib cage during inspiration and a mild restrictive respiratory impairment. The degree of restriction is proportional to disease activity and duration as well as to the degree of spinal and rib cage immobility. Concomitant kyphosis, which may occur in advanced disease or be secondary to osteoporosis, will further impair respiratory function. Because the rib cage is less distensible, the diaphragm shortens to a greater degree for a given tidal volume, thereby increasing the work performed by the diaphragm. Intercostal muscle atrophy secondary to decreased rib cage mobility may cause inspiratory muscle weakness.

About 1 to 4% of patients with ankylosing spondylitis develop fibrobullous upper lobe disease. The cause of this apical disease is unknown, but its presence may impair gas exchange. Occasionally, individuals with ankylosing spondylitis develop nonapical interstitial lung disease (Chapter 92).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Ankylosing spondylitis is diagnosed when there is a history of low back pain and stiffness for more than 3 months, limited chest wall expansion, limited lumbar spine motion in the sagittal and frontal planes, and radiographic evidence of sacroiliitis. Radiographic findings include calcifications and ossifications of the vertebrae and paravertebral tissues.

Low back pain and spinal stiffness are the most common presenting symptoms. Dyspnea may be present as the disease progresses and chest wall expansion becomes more restricted. Physical examination may reveal loss of lateral flexion of the lumbar spine, tenderness over the sacroiliac joints, and kyphosis.

TREATMENT AND PROGNOSIS

Rx

Exercise and physiotherapy programs can enhance cardiorespiratory fitness and spinal mobility. Ankylosing spondylitis is treated with nonsteroidal anti-inflammatory agents and biological agents, such as tumor necrosis factor antagonists that relieve symptoms, reduce spinal inflammation, and improve quality of life. These agents also are associated with improvements in rib cage expansion. Corticosteroids do not prevent the progression of fibrobullous disease, which can be complicated by major hemoptysis. Thoracic surgery may be indicated for hemoptysis, but surgical intervention carries major risk, with 50 to 60% of patients developing bronchopleural fistulas. Ankylosing spondylitis rarely leads to disability unless individuals develop fibrobullous disease.

OBESITY

PATHOBIOLOGY

The degree of obesity (Chapter 227) can be assessed by measuring the body mass index (BMI), which is the ratio of body weight (BW) in kilograms to the square of the height (Ht) in meters (BW/Ht^2). Individuals with a BMI between 18.5 and 24.9 kg/m^2 are normal, whereas those with a BMI greater than 40 kg/m^2 are considered morbidly obese.

Obesity can be accompanied by changes in pulmonary function or alterations in respiratory control. Obesity characteristically reduces end-expiratory lung volume or functional reserve capacity (FRC) and expiratory reserve volume (ERV). TLC and VC may be normal or only mildly reduced except in the most severe cases. Obesity can be accompanied by alterations in respiratory control resulting in elevated levels of $Paco_2$ (Chapter 86).

Dyspnea and exercise intolerance, which are the most frequent respiratory complaints of obese individuals, may be related to disordered chest wall mechanics, restrictive pulmonary dysfunction, altered respiratory control, or the presence of inflammatory mediators, such as those linking obesity to airway hyper-responsiveness. Weight loss (Chapter 227) is the optimal therapy, and it improves lung volumes, respiratory muscle performance, gas exchange, dyspnea, and sleep apnea. In individuals with obesity-hypoventilation syndrome (Chapter 100), nocturnal positive-pressure ventilation can reverse gas exchange abnormalities.

PLEURA

The pleura, which is a thin membrane that covers the inner surfaces of the thoracic cavity, consists of a layer of mesothelial cells supported by a network of connective and fibroelastic tissue. The visceral pleura lines the lung, whereas the parietal pleura lines the rib cage, diaphragm, and mediastinal structures. The closed space between the visceral and parietal pleura is referred to as the pleural space. The vascular supply of the parietal pleural surface is from the systemic circulation, and it contains sensory nerves and lymphatics. By contrast, the visceral pleura is supplied with blood vessels from the pulmonary circulation and has no sensory nerves.

PLEURAL EFFUSION

EPIDEMIOLOGY AND PATHOBIOLOGY

The overall frequency of pleural effusion on a chest radiograph ranges from 0.3 to 1% but varies widely depending on the underlying disease. Pleural effusions occur most frequently in patients with pneumonia (Chapter 97) or heart failure (Chapter 58).

Normally, a small amount of fluid in the pleural space forms a thin layer between the visceral and parietal pleural surfaces and acts as a lubricant to minimize friction between the chest wall and lung as they move against each other during inspiration and expiration. There is continual movement of fluid into and out of the pleural space. This flux of fluid depends on the oncotic and hydrostatic pressures within the parietal and visceral pleura as well as the pressure within the pleural space itself. Hydrostatic pressure in the parietal pleura is similar to systemic circulation (30 cm H_2O), whereas that of the visceral pleura is similar to the pulmonary circulation (10 cm H_2O). Accordingly, most fluid in the pleural space is filtered from the higher-pressure vascular structures in the parietal pleura. Because the pressure within the pleural space itself is more subatmospheric at the apex than at the base, most of the fluid filters in from the less dependent upper lung zones. Fluid is drained out primarily through lymphatics in the parietal pleura. The fluid enters through lymphatic stomas on the surface of the parietal pleura, which are located beneath the mesothelial monolayer. The normal turnover of fluid within the pleural space is 10 to 20 mL/day, with only 0.2 to 1 mL remaining in the pleural space.

Under abnormal circumstances, fluid can accumulate within the pleural space. An increase in hydrostatic pressure, a decrease in oncotic pressure, decreased pressure in the pleural space, increased pleural membrane permeability, or obstruction of pleural lymphatics will promote pleural fluid accumulation (Table 99-3).

An increase in hydrostatic pressure or decrease in oncotic pressure will result in a low-protein collection of pleural fluid characterized as *transudates* (Table 99-4). For example, heart failure (Chapter 58) can produce transudates by increasing hydrostatic pressure in the pulmonary venous system, atelectasis (Chapter 90) can promote transudates by making pleural pressure more subatmospheric, and occasionally, oncotic pressure may be sufficiently reduced to cause transudates (e.g., with hypoalbuminemia). Changes in pleural membrane permeability can produce high-protein effusions, which are characterized as *exudates* and can be seen in inflammatory states such as pneumonia, tuberculosis, or rheumatoid arthritis. Tumors can disrupt the

integrity of the mesothelial layer or the integrity of the capillary epithelium, thereby resulting in exudative effusions, or they may block lymphatic drainage either through interference with stomal openings into the pleural space or obstruction of lymphatic channels.

CLINICAL MANIFESTATIONS

Patients with pleural effusions may be asymptomatic or may experience dyspnea. When the parietal pleura is actively inflamed, pain can be present, and it is generally unilateral, sharp, and worsens with inspiration. At times, effusions may be sufficiently large to contribute to respiratory failure. Physical findings include dullness to percussion in the area of the effusion, along with diminished breath sounds and absent tactile fremitus.

DIAGNOSIS

Chest radiography is often the first imaging method used to detect an effusion (Fig. 99-2). The volume of fluid in the pleural space needs to exceed 250 mL to be visualized on the chest radiograph. When an effusion is present, there is blunting of the costophrenic angle on the posteroanterior chest radiograph (Fig. 99-3), and a meniscus can be seen posteriorly on the lateral chest radiograph (see Fig. 99-2B). Fluid may also collect in either the minor or major fissures. Occasionally, pleural fluid collections in the major or minor fissures may appear as a pulmonary mass and are referred to as *pseudotumors*. A lateral decubitus chest radiograph can be obtained to determine whether fluid is free flowing or loculated. Chest CT provides much better characterization of pleural and parenchymal abnormalities by better defining loculated effusions, distinguishing between atelectasis and effusion, and distinguishing loculated effusion from lung abscess (Fig. 99-4).

Cholesterol	>45 mg/dL
Protein	>2.9 g/dL

LDH = lactate dehydrogenase.

TABLE 99-6 CORRELATION OF THE CHARACTERISTICS OF PLEURAL EXUDATES WITH SPECIFIC DISEASE

TEST	DISEASE
pH < 7.2	Empyema, malignancy, esophageal rupture; rheumatoid, lupus, and tuberculous pleuritis
Glucose (<60 mg/dL)	Infection, rheumatoid pleurisy, tuberculous and lupus effusions, esophageal rupture
Amylase (>200 µg/dL)	Pancreatic disease, esophageal rupture, malignancy, ruptured ectopic pregnancy
RF, ANA, LE cells	Collagen vascular disease
↓ Complement	SLE, RA
RBCs (>5000/µL)	Trauma, malignancy, pulmonary embolus
Chylous effusion (triglycerides > 110 mg/dL)	Tuberculosis, disruption of thoracic duct (trauma, malignancy)
Cytology or biopsy (+)	Malignancy
ADA (>50 µg/L)	Tuberculosis

ADA = adenosine deaminase; ANA = antinuclear antibody; RA = rheumatoid arthritis; RBC = red blood cell; RF, rheumatoid factor; SLE = systemic lupus erythematosus.

A sample of fluid from the pleural space by thoracentesis is the key to determining the etiology of a pleural effusion. The tests needed to make a diagnosis require a relatively small amount of fluid (30 to 50 mL). Larger volumes of fluid can be removed (1 to 1.5 L) in an attempt to alleviate symptoms. Removing volumes greater than 1.5 L may result in re-expansion pulmonary edema. Most thoracenteses can be performed at the bedside, using ultrasound guidance to enhance the procedure's safety. In instances when the effusion is small or fluid is loculated, a CT scan can help direct the thoracentesis catheter into fluid that would otherwise be difficult to drain. Relative contraindications to a diagnostic thoracentesis include a bleeding diathesis, a very small volume of pleural fluid, and a low benefit-to-risk ratio.

Once fluid is obtained, a definitive diagnosis may be achieved, and the fluid can be classified as either a transudate or exudate (Table 99-5). To differentiate an exudate from a transudate, the pleural fluid needs to be analyzed for protein and lactate dehydrogenase (LDH). Simultaneous serum values of protein and LDH also need to be obtained. A pleural fluid exudate is characterized by a pleural fluid–to–serum protein ratio greater than 0.5, a pleural fluid–to–serum LDH ratio greater than 0.6, and a pleural fluid LDH greater than two thirds the normal serum value for LDH. An exudate can also be defined if the pleural fluid cholesterol is higher than 45 mg/dL, protein higher than 2.9 g/dL, or LDH higher than 0.45 upper limit of normal serum value.

Transudates

Effusions that accumulate owing to changes in osmotic and hydrostatic forces usually form transudates. Transudative effusions are most commonly due to heart failure, in which the effusions are often bilateral or, if unilateral, preferentially involve the right hemithorax. Transudates may also be seen in cirrhosis (Chapter 156), nephrotic syndrome (Chapter 123), myxedema (Chapter 233), pulmonary embolism (Chapter 98), superior vena caval obstruction, and peritoneal dialysis (Chapter 133). With cirrhosis, ascites may cross from the peritoneum into the pleural space through small defects in the diaphragm (hepatic hydrothorax) (see Table 99-4). Unusual causes of transudates include peritoneal dialysis and atelectasis. Although malignancy typically causes an exudate, it can occasionally produce a transudate. Urinothorax, which is a rare cause of transudate, results from obstruction of the urinary system.

Exudates

An effusion is characterized as an exudate if it meets one of the following criteria: pleural fluid–to–serum protein ratio higher than 0.5, pleural fluid–to–serum LDH ratio higher than 0.6, or a pleural fluid LDH concentration higher than two thirds the normal serum value. Cholesterol levels also may be increased in exudates (>45 mg/dL). The pleural fluid analysis helps distinguish among the causes of pleural exudates (Table 99-6).

Parapneumonic Effusions

Parapneumonic effusions, which are the most common type of exudative pleural effusion, occur in up to 40% of patients with pneumonia. They typically occur in patients with bacterial pneumonia (Chapter 97) and can be classified as uncomplicated or complicated. With uncomplicated parapneumonic effusion, the pH is generally greater than 7.3, the glucose content more than 60 mg/dL, and the pleural fluid LDH less than 1000 IU/L. Uncomplicated parapneumonic effusions are usually free flowing, do not require drainage, and will respond to the same antibiotic therapy as the pneumonia itself. However, uncomplicated parapneumonic effusions can, at times, transition to complicated effusions. Complicated effusions are characterized by a pH of less than 7.2 and often have a low glucose content. These effusions generally will not respond to antibiotic therapy alone but require drainage to prevent formation of an empyema or a thick pleural peal.

Empyema

An empyema is present when frank pus is aspirated from the pleural space or when the Gram stain of the fluid is positive for bacteria. Pneumonia due to *Streptococcus pneumoniae* (Chapter 297) or *Staphylococcus aureus* (Chapter 296) infection can cause empyema. Individuals who aspirate are at high risk for empyema caused by anaerobic organisms, and patients with tuberculosis (Chapter 332) can develop a tuberculous empyema. Methicillin-resistant staphylococci, *Klebsiella* species pneumonia, and *Pseudomonas* species infections may cause an empyema that is difficult to treat. Uncommon infectious causes of effusions include *Actinomyces* species (Chapter 337), *Nocardia* species (Chapter 338), amebiasis (Chapter 360), *Echinococcus* species (Chapter 362), and paragonimiasis (Chapter 364).

Individuals with empyema often complain of pleuritic chest pain and have refractory fevers several days or more into the course of their pneumonia, but immunocompromised patients may develop empyema sooner and more rapidly. When an empyema is present, it requires prompt chest tube drainage. If chest tube drainage is unsuccessful in resolving the empyema,

video-assisted thoracic surgery (Chapter 101) is preferred, with intrapleural streptokinase reserved for patients who are poor candidates for video-assisted thoracic surgery or are in situations in which it is not available.■

Tuberculous Effusions

Tuberculosis (Chapter 332) can cause pleural effusion in up to 30% of patients who reside in endemic locations for tuberculosis. The pleural effusion typically is not due to direct mycobacterial infection itself, but rather to increased vascular permeability of the pleural membrane because of a hypersensitivity reaction to mycobacterial proteins. The pleural fluid is generally lymphocyte predominant and culture negative for acid-fast bacilli. Adenosine deaminase levels higher than 50 U/L may be helpful in identifying tuberculous pleural effusions. A tuberculous empyema, which is distinct from a tuberculous effusion, is characterized by direct extension of the infection from thoracic lymph nodes or hematogenous spread of tuberculosis into the pleural space.

Malignancy

Malignant effusions are the second most common cause of exudative pleural effusions. Rarely, a malignant effusion may be transudative. Lung cancer (Chapter 197) is the most frequent cause of malignant pleural effusion, and other malignancies that can involve the pleural space include breast cancer (Chapter 204), ovarian cancer (Chapter 205), gastric cancer (Chapter 198), and lymphoma (Chapters 191 and 192). When malignancy involves the pleural space, the prognosis is poor. However, the finding of a pleural effusion in an individual with underlying malignancy does not necessarily imply that there is a metastatic malignant process involving the pleural space. Benign effusions in patients with underlying malignancy may be due to atelectasis, postobstructive pneumonia, hypoalbuminemia, pulmonary emboli (Chapter 98), lymphatic obstruction, and complications from radiation (Chapter 19) or chemotherapy. For this reason, it is important to obtain a sample of pleural fluid in these individuals. The diagnosis of malignant pleural effusion is established by demonstrating malignant cells in the pleural fluid. Approximately 60% of malignant pleural effusions can be diagnosed with one thoracentesis, and the yield increases to 80% with repeat thoracenteses. If needed, a biopsy of the pleura may be useful in identifying the malignancy. Pleural biopsies are optimally obtained either by medical or surgical thoracoscopy (Chapter 101) rather than in a blind fashion (e.g., using a Cope or Abrams needle).

Systemic Inflammatory Disorders

Effusions may be seen in as many as 15% of patients with rheumatoid arthritis (Chapter 272), with a male preponderance to the development of effusions. Effusions typically appear within 5 years after the onset of disease but occasionally occur before the onset of joint disease. Rheumatoid factor in the pleural fluid is often greater than 1:320, and pleural fluid glucose is low (<60 mg/dL, or the pleural fluid–to–serum glucose ratio is <0.5). Other causes of low pleural fluid glucose include complicated parapneumonic effusions or empyema, malignant effusions, tuberculous pleurisy, lupus pleuritis, and esophageal rupture. Pleural effusions can be seen in 15 to 50% of patients with systemic lupus erythematosus (SLE). Lupus erythematosus cells and low levels of complement (C3 and C4) can be seen in effusions due to SLE. Wegener's granulomatosis, Sjögren's syndrome, and sarcoidosis are less common causes of pleural effusions.

Pancreatitis

Patients with pancreatitis or pancreatic pseudocysts (Chapter 146) may develop exudative pleural effusions that often involve the left hemithorax. A pleural fluid amylase concentration that is greater than the upper limits of normal for serum amylase is consistent with acute or chronic pancreatitis as a cause of the effusion. Amylase also may be seen in the pleural fluid with an esophageal rupture or malignancy. Pancreatic disease is associated with pancreatic isoenzyme amylase, whereas malignancy and esophageal rupture are characterized by a predominance of salivary amylase isoenzymes.

Chylothorax

A chylothorax has a milky-white appearance and is characterized by high levels of triglycerides (>110 mg/dL) and chylomicrons. A chylothorax is caused by leakage of lymph from the thoracic duct into the pleural space, most commonly related to mediastinal malignancy but also occurring after trauma to the thoracic duct. Major complications from a chylothorax are malnutrition and immunologic compromise when fat, protein, and lymphocytes are depleted by repeated thoracentesis or chest tube drainage. Chylous effusions must be distinguished from pseudochylous effusions, which have a white appearance but are devoid of chylomicrons, and are indicative of a chronic long-standing effusion.

Hemothorax

Blood in the thorax is easily recognized during a thoracentesis. A hemothorax has a pleural fluid hematocrit that is at least half that of the circulating hematocrit. By contrast, a bloody pleural effusion will appear red but have a lower hematocrit. A bloody effusion often suggests a malignant process. Other causes include trauma, pulmonary infarction (Chapter 98), tuberculosis (Chapter 332), collagen vascular disease (Chapters 272 and 274), and hematologic disorders. Generally, blood removed from the pleural space does not clot, whereas blood due to the trauma of the thoracentesis itself will clot when collected. Because blood in the pleural space does not clot, it can be removed by lymphatics if the volume is small. Larger hemothoraces may require chest tube drainage.

Asbestos Exposure

Pleural effusion may occur following exposure to asbestos. The effusion is often small, unilateral, and serosanguineous, with fewer than 6000 cells/mL. The effusion tends to resolve within a year, resulting in pleural plaques that may calcify over time. Malignant mesothelioma should be excluded in these individuals.

Other Causes of Pleural Exudates

Meigs' syndrome is the triad of ovarian tumor (Chapter 205), ascites, and pleural effusion. The effusion, which is usually large and on the right side, is formed when fluid moves from the abdomen to the pleural space through diaphragmatic defects. Meigs' syndrome usually occurs in postmenopausal women and resolves following removal of the tumor.

Dressler's syndrome may occur from 3 to 30 days following open heart surgery or myocardial infarction. The patient usually experiences pleuritic pain and has a small to moderate left-sided effusion. Treatment is as for the accompanying pericardial effusion (Chapter 77).

Uremia (Chapter 132), which can cause a polyserositis with effusion, must be distinguished from the transudate that commonly is seen in the nephrotic syndrome (Chapter 123). Subdiaphragmatic processes, such as hepatic or splenic abscesses (Chapter 154), may cause effusions. Trapped lung occurs when a lobe or segment is unable to re-expand owing to a restrictive visceral pleural peel or an endobronchial mass. Increased negative intrapleural pressures associated with trapped lung promote the formation of an effusion. A number of drugs, including amiodarone, bleomycin, dantrolene, hydralazine, isoniazid, methotrexate, methysergide, mitomycin, procainamide, and procarbazine, can cause pleural effusions. Treatment consists of discontinuing the offending agent, although treatment with oral corticosteroids may be needed (Chapter 262).

TREATMENT AND PROGNOSIS

Rx

Empyemas and complicated parapneumonic effusions require drainage by tube thoracostomy in concert with appropriate antibiotic therapy. Treatment options for malignant pleural effusion include observation, chemical pleurodesis with talc or tetracycline derivatives, ambulatory drainage catheter, and treatment of underlying malignancy. A complete response occurs in perhaps 50% of patients. A low pleural fluid pH (<7.2) tends to impart a poor response to chemical pleurodesis. Malignant effusions with a tendency to respond to generalized chemotherapy include those related to breast cancer (Chapter 204) and small cell carcinoma of the lung (Chapter 197). Malignant effusions related to lymphomas and obstruction of lymphatic drainage of the pleural space may also respond to treatment of the underlying disease. Treatment of inflammatory effusions centers on the use of anti-inflammatory agents and corticosteroids (Chapters 272 and 274). Treatment of chylous effusions may involve chest tube drainage, although fat malnutrition may ensue. Attempts to decrease chyle formation can be accomplished by intravenous hyperalimentation, decreased oral fat intake, and the intake of medium- and light-chain fatty acids, which are absorbed directly into the portal circulation. Ligation of the thoracic duct should be considered for traumatic chylous effusions.

MESOTHELIOMA

EPIDEMIOLOGY AND PATHOBIOLOGY

Malignant mesotheliomas are neoplasms arising from the serosal membrane of body cavities. Eighty percent of mesotheliomas originate in the pleural

space, and most others arise from the peritoneum. Individuals are usually older than 55 years and often have a history of asbestos exposure in the distant past (frequently, 30 to 40 years ago). Smoking is not a risk factor for developing mesothelioma, but smoking in concert with asbestos exposure increases the risk of lung cancer. Approximately 3000 cases of mesothelioma occur in the United States each year. The annual incidence is decreasing in the United States owing to better control of occupational exposure, but it may still be increasing in other countries where there are fewer regulations.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with mesothelioma often complain of dyspnea, weight loss, and pain. Malignant mesothelioma may present as an extremely large mass or pleural effusion occupying the entire hemithorax at times. Chest CT may demonstrate either localized or circumferential pleural thickening associated with various amounts of calcified pleural plaque (see Fig. 99-4). Thoracoscopy is the most efficient means of obtaining the diagnosis. Elevated levels of hyaluronic acid in the pleural fluid, as well as special stains and electron microscopy of biopsy tissue, may help to make the difficult distinction between metastatic adenocarcinoma and mesothelioma.

A fraction of mesotheliomas are benign. Benign mesotheliomas are usually large and often pedunculated at the time of diagnosis.

TREATMENT AND PROGNOSIS Rx

Unfortunately, no particular therapy, surgical or chemotherapy, has met with great success in malignant mesothelioma, and median survival is only 8 to 12 months after diagnosis. Pleurodesis with talc or pleurectomy is usually performed for palliation and control of symptoms related to any pleural effusion. In highly selected patients with localized disease and no comorbid illnesses, surgical resection or radical extrapleural pneumonectomy may be attempted. Radiation therapy can provide symptom palliation and has been used following attempts at curative surgery. Treatment of benign mesothelioma involves surgical resection.

PNEUMOTHORAX

Pneumothorax refers to the accumulation of air in the pleural space. Normally, the pressure within the pleural space is slightly subatmospheric. However, when more than a very small amount of air accumulates within the pleural space, pressure within it becomes positive, and there is compression of underlying lung.

EPIDEMIOLOGY AND PATHOBIOLOGY

Pneumothorax is often associated with blunt or penetrating trauma. With penetrating trauma, air may leak into the pleural space through the injured chest wall or into the pleural space from the injured lung. Patients with underlying lung disease undergoing mechanical ventilation may acutely develop a pneumothorax when high local pressures disrupt lung tissue, thereby leading to a leak (Chapter 105).

Pneumothorax also may occur spontaneously or be secondary to underlying lung disease. Typically, spontaneous pneumothorax occurs in tall, young, thin men, presumably as a result of rupture of preexisting apical blebs. Diseases that are associated with pneumothorax include emphysema (Chapter 88), cystic fibrosis (Chapter 89), granulomatous inflammation, necrotizing pneumonia, pulmonary fibrosis (Chapter 92), eosinophilic granulomatous disease, sarcoidosis (Chapter 95), and endometriosis (Chapter 244).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms typically include acute shortness of breath and sharp chest pain. Physical examination is characterized by tachycardia, decreased breath sounds, decreased tactile fremitus, a pleural friction rub, subcutaneous emphysema, hyper-resonance to percussion, and a tracheal shift toward the uninvolved hemithorax.

Air within the pleural space will separate the visceral from parietal pleura and appears as an area of lucency on the chest radiograph (Fig. 99-5). With a small pneumothorax, the lucency is best appreciated at the lung apex when the patient is upright (see Fig. 84-11 in Chapter 84). An end-expiratory radiograph is particularly helpful in diagnosing a small pneumothorax. During expiration, the density of the lung will increase because of a reduction in volume, thereby highlighting the difference between lung parenchymal and pleural gas. When a portable chest radiograph is obtained with the patient in the supine position, such as a patient in an intensive care unit, the lucent area may be most noticeable over the lower rib cage (superior sulcus sign).

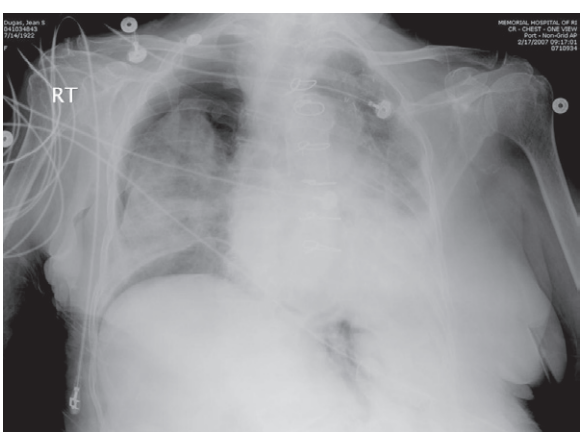

FIGURE 99-5. A portable anteroposterior chest radiograph demonstrating a right-sided pneumothorax. Note that the right lung has collapsed to less than half the size of the right hemithorax. In addition, there is a pneumoperitoneum best seen as a collection of air under the right hemidiaphragm.

A tension pneumothorax is defined as a pneumothorax associated with a mediastinal shift and hemodynamic compromise, usually because high intrathoracic pressures compress the vena cava and atrium. This physiology implies an ongoing leak of air into the pleural space.

TREATMENT AND PROGNOSIS Rx

If the pneumothorax is small and the patient is not in distress, tube thoracostomy is not needed, and observation alone may be sufficient. If a pneumothorax occupies more than 50% of the hemithorax, the patient develops symptoms, or a tension pneumothorax develops, tube thoracostomy and suction followed by water-seal drainage are indicated. If there is a continuing leak despite tube thoracostomy, a bronchopleural fistula may be suspected. In this instance, chemical pleurodesis or surgical correction, usually by video-assisted thoracoscopic surgery, may be necessary (Chapter 101).

MEDIASTINUM

The mediastinum, which is the central part of the thoracic cavity, lies between the right and left lung. It contains the heart and aorta, esophagus, trachea, lymph nodes, thymus, and great vessels. It is bordered by the two pleural cavities laterally, the diaphragm inferiorly, and the thoracic inlet superiorly.

MEDIASTINAL MASSES

PATHOBIOLOGY

For clinical purposes, the mediastinum has been divided into three compartments: anterior, middle, and posterior (E-Fig. 99-2). The anterior compartment contains the thymus, substernal extensions of the thyroid, blood vessels, pericardium, and lymph nodes. The middle compartment contains the heart, great vessels, trachea, main bronchi, lymph nodes, and the phrenic and vagal nerves. The posterior compartment contains the vertebrae, descending aorta, esophagus, thoracic duct, azygous and hemizygous veins, lower portion of the vagus, sympathetic chain, and lymph nodes.

CLINICAL MANIFESTATIONS

Mediastinal masses usually are not accompanied by symptoms, and most masses are incidentally found on either a chest radiograph or a chest CT scan. If present, however, symptoms include chest pain, cough, hoarseness, stridor, dysphasia, and dyspnea. One third of patients with a mediastinal thymoma have symptoms or weakness owing to myasthenia gravis (Chapter 430), and individuals with mediastinal lymphoma (Chapters 191 and 192) may have systemic symptoms such as fever, night sweats, and weight loss. Occasionally, a mass may produce superior vena cava obstruction with resultant facial edema and dilated neck and chest veins (Fig. 99-6).

DIAGNOSIS

Once a mass is identified by chest radiography or chest CT, further evaluation is mandatory. If a benign process is suspected, a follow-up CT may be

Lymphoma	Lymphoma	Lymphoma
Parathyroid tumor		Meningocele
Lipoma		Enteric cyst
Morgagni's diaphragm hernia		Esophageal diverticula
		Bochdalek's diaphragm hernia

indicated. If a malignant process is suspected, radiologic evaluation may include angiography, positron emission tomography, or magnetic resonance imaging. Biopsies can be obtained either with mediastinoscopy, mediastinotomy, or ultrasound-guided transbronchial needle aspiration biopsy. Direct sampling by transthoracic CT-guided needle aspiration may be useful in evaluating anterior or posterior mediastinal masses. The evaluation and differential diagnosis of mediastinal masses are guided by the compartment in which they arise (Table 99-7). The *anterior mediastinal compartment* includes lesions such as thymomas, germ cell tumors (teratomas), lymphomas, and intrathoracic thyroid tissue. Thymomas make up about 20% of mediastinal neoplasms in adults, in whom they are the most common anterior mediastinal primary neoplasm. Patients with systemic lymphoma often have involvement of the mediastinum, but only 5 to 10% of patients with lymphoma present with primary mediastinal lesions. Teratomas, which account for 10% of mediastinal tumors, may contain squamous cells, hair follicles, sweat glands, cartilage, and linear calcifications; about one third are malignant. Intrathoracic goiters (Chapter 233) (Fig. 99-7) may compress the trachea and cause stridor, cough, dyspnea, and, occasionally, superior vena cava obstruction. Anterior masses in the right cardiophrenic angle, which are rare and may be associated with pericardial defects or obesity, may be due to herniation of liver or intestinal contents through the foramina of Morgagni.

In the posterior mediastinum, neurogenic tumors are the most common lesions. Many of these tumors are benign and originate in the nerve sheath or sympathetic ganglion cells (ganglioneuroma). Posterior mediastinal masses also include cysts, meningocele, lymphoma (Chapter 191 and 192), aortic aneurysm (Chapter 78), and esophageal disorders (Chapter 140) such as diverticula and neoplasm. Herniation of abdominal contents into the thorax can result in posterior mediastinal masses. Herniation of abdominal contents through the foramina of Bochdalek results in a mass in the posterolateral area of the diaphragm, usually on the left side; it is the most common congenital hernia and may contain spleen or kidney. Herniation of the stomach through the esophageal hiatus (Chapter 140), which is the most common type of diaphragmatic herniation, produces a mass posterior to the heart, often with an air-fluid level.

Benign cysts can occur in the anterior, middle, or posterior compartments. Pericardial cysts, which are often located in the cardiophrenic angle, contain clear liquid. Bronchogenic cysts occur in the middle or posterior compartments and are filled with liquid and lined with respiratory epithelium; they often develop around the paratracheal area or carina and do not communicate with the tracheal bronchial tree.

TREATMENT Rx

The treatment of a mediastinal mass depends on the underlying pathology. Some lesions, such as thymomas, teratomas, cysts, neurogenic tumors, and hernias, require surgical resection. Others, such as lymphoma, are treated with radiation or chemotherapy. Some can be monitored over time.

MEDIASTINITIS

Acute mediastinitis is most commonly caused by bacterial infection. Mediastinal infections may be iatrogenic after sternotomy or invasive procedures involving the esophagus or tracheobronchial tree. Rupture of the esophagus or trachea from trauma or tissue necrosis can cause mediastinitis. Treatment of acute mediastinitis requires antibiotics, pleural drainage, and evacuation of necrotic tissue. Chronic mediastinitis (fibrosing mediastinitis) is a progressive illness that may be idiopathic or can be caused by granulomatous infection, neoplasm, radiotherapy, or drugs (such as methysergide). Patients with chronic mediastinitis remain asymptomatic until vascular or neurologic structures are affected, and the diagnosis and treatment often require surgical exploration.

PNEUMOMEDIASTINUM

Pneumomediastinum occurs when air infiltrates the mediastinal structures after a rupture of the esophagus, trachea, or lung dissects into the mediastinum. Loss of esophageal or tracheal integrity often results from trauma, whereas leaks from alveoli may result from trauma, occur spontaneously, or be a complication of mechanical ventilation. The diagnosis can be made by seeing thin columns of hyperlucency between mediastinal structures on chest radiography or CT scan. Pneumomediastinum may present as a sore throat, neck pain, or shortness of breath. Often, the mediastinal air dissects into the subcutaneous tissues of the neck and chest wall, where it results in subcutaneous emphysema. A characteristic crepitus is palpable when subcutaneous emphysema is present. Spontaneous pneumomediastinum generally resolves without treatment. When more severe collections of subcutaneous air occur, surgical decompression is often warranted.

OBSTRUCTIVE SLEEP APNEA

ROBERT C. BASNER

DEFINITION

Obstructive sleep apnea (OSA) is a chronic condition of cyclic obstruction of the upper airway during sleep, combined with associated symptoms or signs of disturbed sleep (Chapter 412), the most common being excessive daytime sleepiness and loud snoring. A frequency of at least five obstructive events per hour of sleep is a minimal criterion for diagnosing OSA in adults, although a higher frequency of obstructive events is more consistently correlated with an increased risk of cardiovascular and neurocognitive disorders.

EPIDEMIOLOGY

OSA is underrecognized by clinicians and underreported by patients. It is estimated that most adults with moderate to severe OSA remain undiagnosed. In adults, OSA is characteristically found in overweight persons, although other anatomic (primarily upper airway and craniofacial) and ventilatory abnormalities may also predispose to development of the syndrome. The presence of at least five obstructive events per hour of sleep has been found in 9 to 28% of persons without specific risk factors for, or symptoms of, OSA. Its overall prevalence appears to be much greater in men than in women, but postmenopausal and obese women are at increased risk. Populations with a particularly high prevalence of OSA include those older than 60 years; patients with systemic hypertension, particularly those with poorly controlled hypertension (Chapter 67); patients who have had strokes (Chapter 414); patients with heart failure (Chapter 58); and patients with medically refractory epilepsy (Chapter 410). African Americans, particularly those younger than 25 and older than 65 years; adult Hispanics; and Asians have a higher incidence and/or greater severity of OSA than whites. There is a strong familial disposition to OSA, such that the presence of OSA in a given patient more than doubles the chance of family members having the disorder when compared with controls. Mean annual medical costs for patients with untreated OSA are almost double those of otherwise normal people, and the costs increase in proportion to the severity of the OSA.

PATHOBIOLOGY

Genetics

Most identified candidate genes linked to OSA share linkages to body mass index (BMI). Similarly, most polymorphic DNA sequences related to expression of OSA appear to be linked to characteristics that predispose to the disorder, including obesity, serotonin transport, and craniofacial structure, or to correlates of the disorder, such as elevated blood pressure. Thus, no specific genes or genetic loci for OSA have been identified to date.

Pathogenesis

OSA involves complete or partial closure of the collapsible segments of the pharynx, including the velopharynx, oropharynx, and hypopharynx. *Obstructive apnea* is defined by absent airflow for at least 10 seconds associated with continued ventilatory effort. Partial obstruction is referred to as *hypopnea* and is recognized functionally by a discrete decrease in rather than cessation of airflow for at least 10 seconds, associated with either a pathologic decrease in the oxygen saturation of hemoglobin (Sao_2) or an abrupt arousal from sleep, typically with progressive ventilatory effort and/or crescendo snoring. Respiratory effort–related arousal occurs when such limitations of airflow and decrease in Sao_2 are not severe enough to cause hypopnea but the progressive ventilatory effort is nevertheless associated with abrupt arousal from sleep.

Both excess weight and increasing weight are closely linked to the development of OSA and the worsening of existing OSA in adults. Conversely, weight loss, both surgical and nonsurgical, has been associated with improvement in OSA (see Treatment). Anatomic and physiologic explanations of how excess weight contributes to OSA include restriction of chest wall movement, with resultant mechanical and reflex upper airway narrowing; increased compliance and narrowing of the upper airway; ventilatory instability; and impaired ability to compensate for increased upper airway resistance at sleep onset.

The final common pathway in each obstructive event is attainment of a critical pharyngeal closing pressure. Once collapsed, the pharynx is more difficult to expand during the next inspiratory effort, resulting in the characteristic generation of progressively more forceful inspiratory efforts against the obstructed upper airway and increasingly negative intrathoracic pressure excursions. The subsequent arousal is usually associated with reopening of the airway. After several hyperpneic breaths, re-transition into sleep generally occurs. The cycling of blood gases and the recurrent awake-to-asleep transitions interfere with the respiratory controllers' need to find a set point during sleep. Hypopnea or outright apnea followed by hyperpnea is the hallmark of OSA.

The pathogenic importance of respiratory periodicity in OSA varies by sleep stage (Chapter 412). The transition into "light" stages of sleep, termed *stages N1* and *N2 non–rapid eye movement* (NREM) *sleep*, is characterized by a tendency for arousal and sleep-wake cycling. These stages are most likely to demonstrate the periodic obstructive events characteristic of OSA. In contrast, "deep" NREM sleep, termed *stage N3* or *slow-wave sleep*, is characteristically a time of relatively regular central nervous system output, with a decreased tendency for arousal, a regularization of breathing, and a relative paucity of obstructive events, even with generally increased upper airway resistance when compared with N1 and N2 sleep. During rapid eye movement (REM) sleep, descending neural inhibition of accessory respiratory muscles may lead to severe alveolar hypoventilation. Severe hypoxemia, caused by a combination of obstructive events and ventilation-perfusion mismatch, is characteristic of REM sleep in patients with OSA.

Pathophysiology

With each obstructive event, the combination of progressive asphyxia, increasingly negative intrathoracic pressure, and sudden autonomic and behavioral arousal leads to acute cardiac and cerebrovascular perturbations, including increased afterload of both the left and right ventricles, decreased left ventricular compliance, increased pulmonary artery pressure, decreased coronary artery blood flow, and increased myocardial oxygen demand (Chapter 52). The abrupt arousal at the termination of the majority of obstructive events is associated with sympathetic discharge, leading to peripheral vasoconstriction and an abrupt increase in the heart rate and in systolic and diastolic blood pressure, even as cardiac output continues to fall when ventilation resumes with the airway reopened. Accordingly, systemic blood pressure characteristically fluctuates; it is relatively low during apnea and acutely elevated at termination of the obstructive event (Chapter 67). Electrocardiographic abnormalities include sinus bradycardia during obstructive events and acceleration at arousal; in REM sleep, which is a time of increased vagal tone, sinoatrial and atrioventricular block may be seen. Ventricular and supraventricular ectopy and atrial fibrillation occur with OSA. At the termination of obstructive apnea, cerebral blood flow and oxygenation are decreased. The recurrent abrupt, transient arousal from sleep at the termination of each obstructive event is associated with fragmented sleep and a decreased ability to consolidate restorative sleep.

CLINICAL MANIFESTATIONS

Symptoms and Signs

The cardinal manifestations of OSA include loud, chronic snoring; excessive daytime somnolence; and apneas witnessed by third parties. Snoring in OSA reflects vibratory noise from partially occluded pharyngeal soft tissue, usually

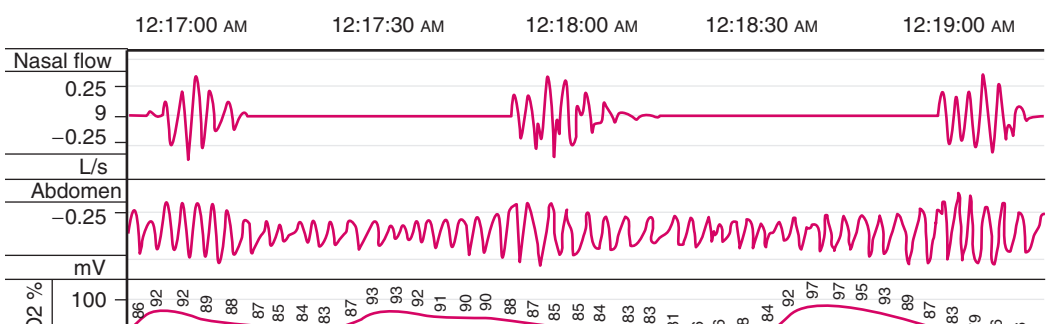

FIGURE 100-1. Polysomnographic tracing of a patient with obstructive sleep apnea during 2 minutes of non–rapid eye movement sleep. Displayed are airflow in the upper airway ("nasal flow"), recorded with a nasal pressure transducer; respiratory effort ("abdomen"), recorded by inductance plethysmography; and oxygen saturation of hemoglobin (Spo_2), recorded with pulse oximetry.

with the mouth open, and it typically occurs in a crescendo pattern, with a burst of louder noise at resolution of the event. Loud snoring without OSA may progress to OSA, particularly if the patient gains weight.

In the hospital setting, OSA may be detected because of apnea or refractory decreases in Sao_2 during surgical or endoscopic procedures that require sedation or anesthesia. In other cases, the diagnosis may be suspected when hospital staff note nocturnal heart block or dysrhythmias during sleep.

Excessive Daytime Somnolence

Patients with excessive daytime somnolence (Chapter 412) fall asleep unexpectedly; this is typically microsleep rather than sustained sleep episodes. Excessive daytime somnolence may be quantified by laboratory tests that monitor the propensity to fall asleep during the day or by questionnaires or subjective scales that assess sleepiness or decrements in quality of life. Resolution of OSA does not necessarily resolve excessive daytime somnolence, suggesting the possibility of sustained neurologic perturbation from chronic intermittent hypoxemia. However, many patients with significant OSA do not complain of excessive daytime somnolence, nor are patients typically aware of their degree of sleep fragmentation. Mood disorders, including depression and irritability, as well as perturbations in visual memory and working memory appear to be related to the severity of sleep fragmentation and hypoxemia.

Obstructed Breathing

The bed partners of OSA patients often describe breathing cessation rather than obstructed breathing; close questioning usually elicits the obstructive nature of the breathing. Patients may be aware of their own snoring or complain of choking or dyspnea, particularly in relation to an inability to sleep supine. Morning dry mouth is a common symptom, as is morning headache.

Insomnia and Parasomnia

Insomnia, which is the subjective complaint of difficulty falling asleep or staying asleep (Chapter 412), is associated with the consistent sleep interruption characteristic of OSA. Transient arousals during N3 sleep may result in confusional parasomnias, such as sleep walking and sleep talking. Arousals and increased work of breathing may result in restless sleep and night sweats. Nocturia, possibly mediated via atrial natriuretic receptors, may resolve with treatment of OSA.

Upper Airway Abnormalities

Nasal congestion, rhinitis, chronic sinusitis, and nasopharyngeal anatomic abnormalities are often associated with OSA, as are craniofacial abnormalities such as micrognathia and retrognathia. Large tonsils, redundant soft palate tissue, and a large tongue may all be associated with a "crowded" oropharynx, but the precise role of these upper airway abnormalities in the pathogenesis of adult OSA is unclear.

DIAGNOSIS

The spectrum of sleep-related breathing disorders other than OSA includes hypoventilation and gas exchange disorders that may worsen with sleep, including nocturnal asthma (Chapter 87), chronic obstructive pulmonary disease (Chapter 88), neuromuscular and chest wall disorders (Chapter 99), and obesity-hypoventilation syndrome (Chapter 227), as well as other disorders in which central apnea (Chapter 412) is prominent, such as idiopathic central apnea, Cheyne-Stokes breathing, and central alveolar hypoventilation (Chapter 86). Patients with OSA alone characteristically do not hypoventilate while awake, unlike patients with other disorders of hypoventilation. Disorders associated with hypersomnia, such as narcolepsy, insufficient sleep, poor sleep hygiene, periodic limb movement disorder, and circadian rhythm disorders such as shift work sleep disorder, must also be considered in patients with suspected OSA (Chapter 412).

Polysomnography

The definitive diagnostic study is polysomnography (Fig. 100-1), which generally involves all-night monitoring in a sleep laboratory via electroencephalography, electro-oculography (primarily to determine rapid eye movements characteristic of REM sleep), electrocardiography, leg and chin electromyography, and measures of respiratory effort, airflow, Sao_2, and alveolar or arterial carbon dioxide (usually end-tidal or transcutaneous CO_2). Audiovisual recordings can identify crescendo snoring and thoracoabdominal paradoxical breathing efforts to help differentiate obstructive from nonobstructive hypopnea.

The severity of OSA is usually described by the apnea-hypopnea index (AHI), which is the number of obstructive apneas plus hypopneas per hour of sleep (Fig. 100-2). The term *respiratory disturbance index* includes obstructive apneas and hypopneas, as well as obstructive events that do not meet the threshold for hypopnea but nevertheless result in a discrete arousal that appears to be associated with abnormal indices of oxygen desaturation. Oxygen desaturation more directly reflects the chronic intermittent hypoxia that has been increasingly linked to adverse cardiovascular effects and outcomes.

It is possible to diagnose OSA by means of unattended home studies that include cardiorespiratory monitoring and/or use of an autotitrating positive airway pressure (PAP) machine, which continuously self-adjusts the level of positive pressure delivered to the airway on a breath-to-breath basis in response to upper airway impedance changes. Such autotitration allows the immediate diagnosis and treatment of a patient suspected of having severe OSA.

TREATMENT Rx

The goal of treatment is to decrease sleep fragmentation and repetitive asphyxia, the resultant cardiovascular and cerebrovascular stress, and the increased work of breathing associated with OSA.

Mechanical Therapy

Positive Airway Pressure

PAP, which is the current first-line therapy for OSA, consistently lowers the AHI, decreases oxygen desaturation, decreases diurnal and nocturnal blood pressure, and improves sleep efficiency, daytime sleepiness, and quality of life at a reasonable cost compared with oral appliances or no treatment, especially in patients with an AHI greater than 30/hour. For patients with less severe OSA, continuous positive airway pressure (CPAP) is generally recommended in those with prominent oxygen desaturation, daytime sleepiness, or concurrent respiratory, cardiovascular, or cerebrovascular disease. CPAP improves cognitive function, improves left ventricular function in patients with heart failure and decreases the risk of motor vehicle accidents.

The major equipment required to administer PAP includes an interface with appropriate headgear, anchoring straps, and hosing and a compact airflow generator (Fig. 100-3). With CPAP, the fixed level of positive pressure delivered to the upper airway acts as a physiologic splint throughout the respiratory cycle, allowing the patient to achieve normal ventilation as well as more continuous and deeper sleep. CPAP does not supply ventilation above this

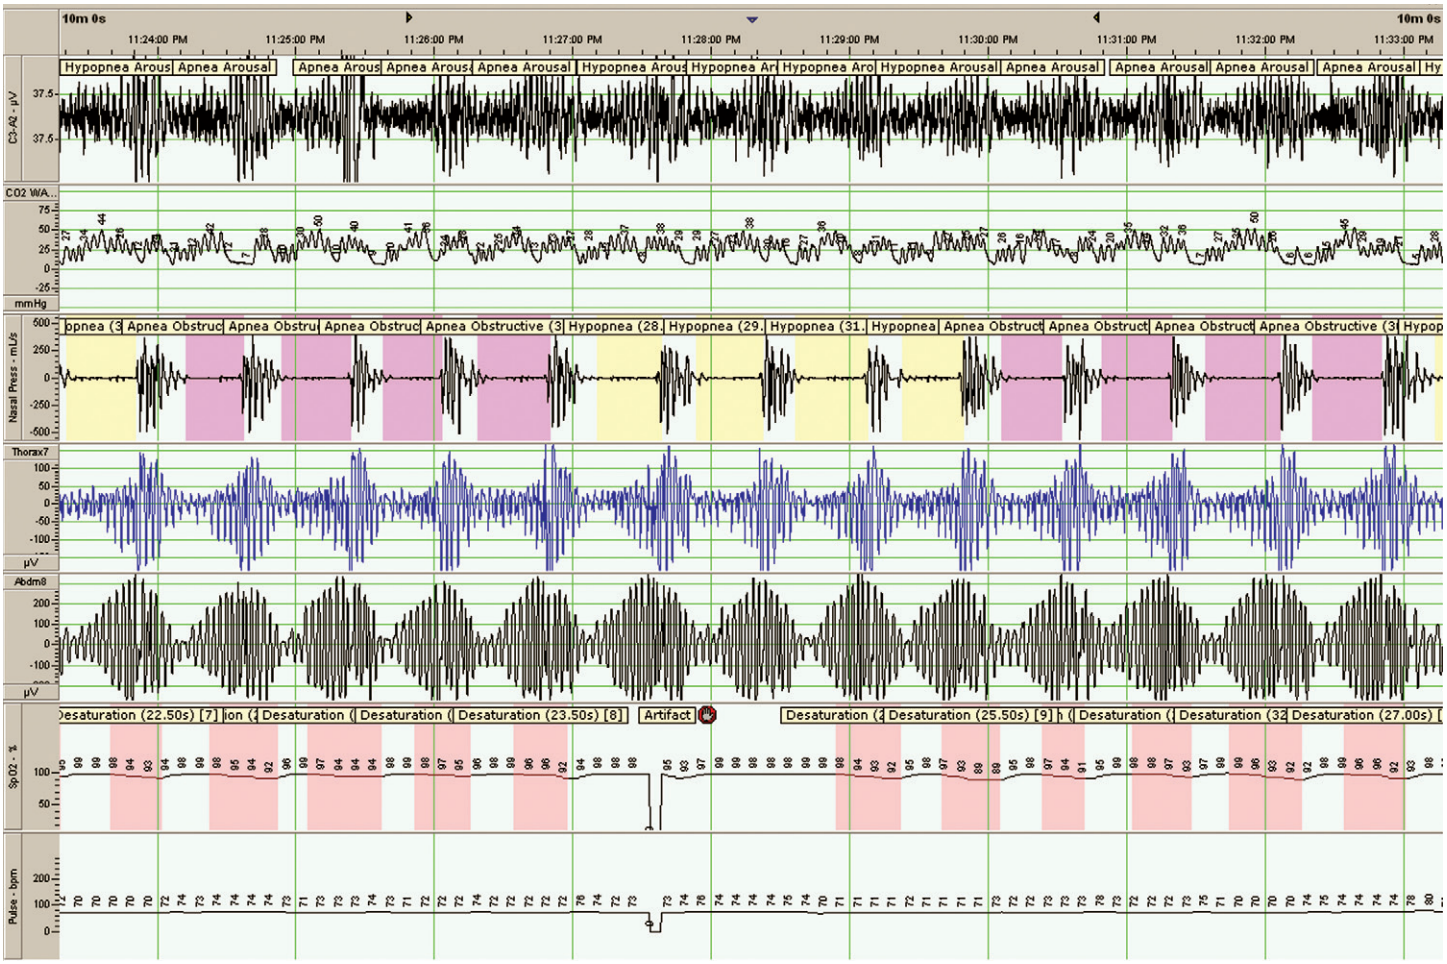

FIGURE 100-2. Continuous 10-minute polysomnographic tracing in a patient with severe obstructive sleep apnea. The 14 repetitive obstructive apneas constitute an apnea-hypopnea index of 84/hour. Each obstructive event is associated with a cyclic waxing-waning respiratory effort (seen in the thoracic and abdominal effort tracings), absent airflow (in the nasal pressure transducer), electroencephalographic arousal (C3-A2, top tracing), oxygen desaturation, and increased end-tidal P_{CO_2}.

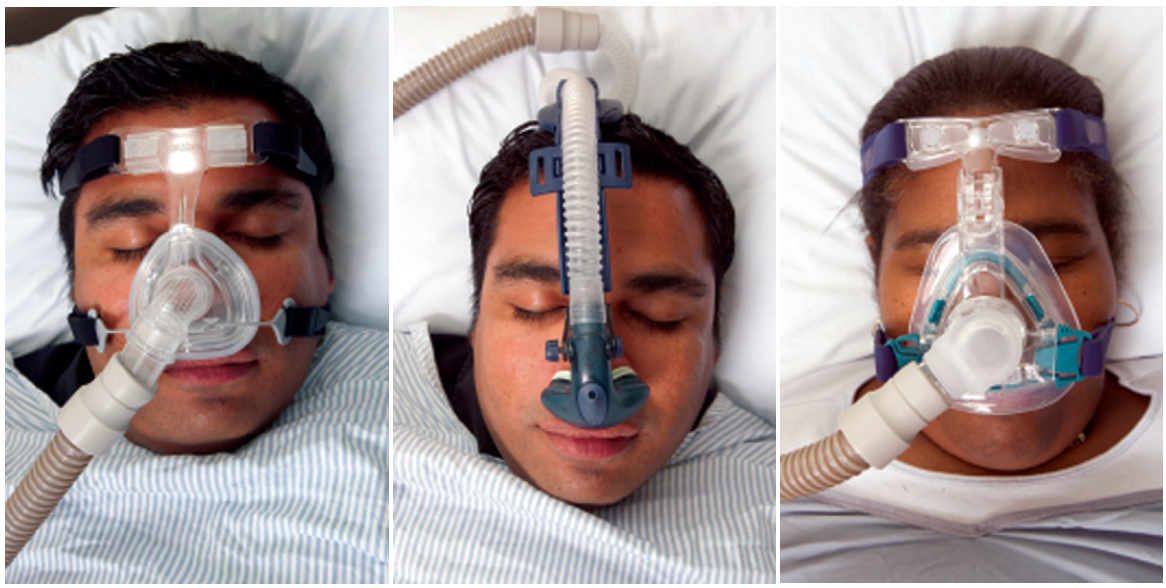

A B C

FIGURE 100-3. Positive airway pressure–patient interfaces. A, Subject wearing a nasal mask and headgear with positive airway pressure being delivered. Positive pressure is delivered only to the nasal airway; opening of the mouth may cause air to leak and decrease the efficacy of the positive-pressure regimen. **B**, Subject wearing nasal pillows. Positive pressure is delivered directly into the nares rather than covering the nose or mouth; only minimal headgear is necessary to anchor the interface in place. **C**, Subject wearing a full face mask. Positive pressure is delivered to both the nose and the mouth based on the subject's own breath-to-breath partitioning of nasal and oral airflow.

splinting; the positive end-expiratory pressure may, however, result in improved oxygenation.

Prescribing PAP

PAP is typically prescribed after therapeutic titration in the sleep laboratory, beginning with CPAP of 2 to 4 cm H_2O and increasing by 1- to 2-cm H_2O increments to the minimum level that eliminates obstructive events in all sleep stages. Such a level should reduce other evidence of increased upper airway resistance and increased work of breathing (e.g., snoring, use of accessory inspiratory muscles, thoracoabdominal paradoxical respiration), while improving sleep. Although CPAP is typically prescribed in the 8- to 12-cm H_2O range, it is not uncommon for patients with severe OSA to need pressures up to 20 cm H_2O. However, as pressures increase above 12 to 14 cm H_2O, the likelihood of air leak and discomfort rises. When laboratory titration is not available, starting CPAP at a level of 10 cm H_2O is reasonable. Short-term outcomes, including AHI, symptomatic sleepiness, and quality of life, are similar, regardless of whether CPAP is guided by titration at a sleep center or use of an autotitrating machine at home to determine a fixed pressure.[2,3] Adding a feature that decreases expiratory pressure ("pressure relief") does not improve outcomes or adherence or reduce side effects.[4]

The first night of CPAP is generally associated with a "rebound" of slow-wave NREM sleep and REM sleep, along with amelioration of acute fluctuations in heart rate and blood pressure. Daytime sleepiness and vigilance consistently improve with chronic use of CPAP; diurnal and nocturnal blood pressure and catecholamine levels decrease, and left ventricular ejection fraction and diastolic function improve. However, OSA returns when CPAP is removed, so CPAP must be used nightly throughout sleep. The term *complex sleep apnea* refers to the commonly noted emergence of central apneas during initial CPAP titration; the significance of this phenomenon remains to be elucidated.

Bilevel PAP

In some cases, a more ventilatory mode of pressure delivery—generally, bilevel PAP, wherein inspiratory pressure is set higher than expiratory pressure—may be helpful after the degree of expiratory positive pressure necessary to prevent closure of the airway during expiration is established. Bilevel PAP may be delivered with a backup rate, similar to assist/control mode ventilation. Bilevel PAP should be considered in those with hypoventilation syndromes that overlap OSA, such as obese patients who continue to have significant hypoventilation or ventilation-perfusion mismatch–related hypoxemia despite CPAP. For most OSA patients beginning treatment, however, no high-quality data show improved outcomes or cost-effectiveness of bilevel PAP compared with CPAP, even when bilevel PAP is used as secondary therapy when CPAP is unsuccessful; numerous randomized controlled trials have demonstrated similar adherence with CPAP and bilevel PAP.[5]

Autotitrating PAP

Both CPAP and bilevel PAP can be delivered so that the pressure automatically adjusts to the patient's breathing, based on either breath-to-breath detection of changes in airway resistance or the pattern of breathing. However, autotitrating PAP does not improve adherence or outcomes compared with fixed-pressure CPAP.[6]

PAP-Patient Interface

The choice of interface is important for achieving optimal efficacy and adherence. Aside from many different shapes, sizes, and consistencies of nasal masks (Fig. 100-3A), flexible nasal "pillows" or "prongs" (Fig. 100-3B) can fit directly into the nares, avoiding the discomfort of a mask over the nose and pain and pressure at the bridge of the nose and over the upper teeth. Although nasal PAP is most commonly used, nasal delivery is often ineffective because of nasal congestion, nasopharyngeal anatomic abnormalities, or inability to keep the mouth closed, allowing air to leak from the mouth so that ineffective pressure is delivered to the collapsible airway. Soft "hybrid" interfaces, which have a mouthpiece and nasal prongs to permit both mouth and nose breathing, are often used in such settings. Full face masks (Fig. 100-3C) may also improve CPAP efficacy in such situations, but gastrointestinal bloating secondary to air swallowing is a common side effect, and the risks of vomiting and aspiration are a concern. Regardless of the interface used, the patient must be vigilant to maintain the interface throughout sleep, particularly after changes in position. Cold or heated humidification may be added directly to the circuit to improve comfort and adherence, but contamination of the humidifier with pathogenic organisms must be avoided.

Adherence and Outcome

Adherence to PAP is generally similar to that for treatments of other chronic medical disorders, although most studies suggest that CPAP is not used optimally for maximizing restorative sleep. Adherence may be improved by systematic cognitive behavioral and educational strategies, as well as strategies that address the specific issues of individual patients.[7] Treatment with PAP should be objectively monitored by tracking the amount of time that physiologically successful PAP levels are delivered.

Oxygen

Although supplemental oxygen alone during sleep may ameliorate hypoxemia and improve sleep quality in OSA, such treatment alone may lengthen apneas, cause paradoxical worsening of Sa_{O_2}, and fail to improve sleep fragmentation. Therefore, oxygen alone should not be used as first-line treatment for suspected or proven OSA without nocturnal monitoring.

When sleep Sa_{O_2} remains low despite otherwise optimal levels of CPAP or bilevel PAP, oxygen can be added directly to the mask, to an adapter near the mask, or beneath the mask via nasal cannulae. Higher flow rates of oxygen may be necessary as PAP levels increase, particularly if bilevel PAP is used.

Other Ways to Relieve or Bypass Obstruction

Oral appliances, usually in the form of mandibular advancement devices fitted by an expert, improve symptoms in patients with mild to moderate OSA, particularly with predominantly supine OSA. However, such devices are generally less effective than CPAP in improving AHI and oxygen desaturation during sleep,[8] and they are currently recommended only for patients with mild or moderate OSA who do not benefit from CPAP or who prefer such an appliance over CPAP.

General Measures

Sleep Positioning and Nasal Treatments

Sleep positioning may benefit many patients who have OSA predominantly in the supine position, although such positioning does not appear to be as effective as CPAP in decreasing the AHI.[9] Treatment of chronic nasal congestion and inflammation with nasal steroids, saline washes, and systemic antihistamine-decongestant regimens may ameliorate OSA in many cases. Otolaryngologic consultation can be useful to identify treatable nasopharyngeal disorders, including the rare nasopharyngeal neoplasm.

Weight Loss

Weight loss is a primary treatment in an overweight patient with OSA. It not only affects the severity of the breathing disorder during sleep but also may contribute to regression of the deleterious metabolic and cardiovascular perturbations associated with OSA. In obese diabetic patients with a mean BMI greater than 35 kg/m^2, an intensive lifestyle intervention resulting in a mean weight loss of 10.8 kg produced a significantly greater decrease in the number of apneic-hypopneic events per hour, less oxygen desaturation during sleep, and a better resolution rate of OSA than was achieved in a control group with a mean weight loss of 0.6 kg.[9] Non–morbidly obese patients who achieve nonsurgical weight loss also have significantly greater improvements in OSA than do controls without such weight loss. In severely obese patients with marked OSA, weight loss achieved with bariatric surgery significantly ameliorates but usually does not resolve OSA.[10]

Treatment of Other Underlying Conditions

It is important to treat underlying conditions such as diabetes (Chapter 237) and heart failure (Chapter 59) in patients with OSA, but such treatment does not substitute for treating the OSA itself. For example, in patients with OSA and heart failure, cardiac atrial overdrive pacing provides small improvements in the AHI and sleep-related oxygen desaturation, but it is not as effective as CPAP.

Surgery

Tracheostomy

Tracheostomy, which bypasses the site of upper airway obstruction, decreases morbidity and mortality and improves blood gas abnormalities in OSA. However, tracheostomy makes speech difficult and is reserved for only the most severe cases and for patients with concomitant hypoventilation syndromes that do not respond to noninvasive forms of PAP.

Uvulopalatopharyngoplasty

Procedures to reduce uvular or palatal tissue, which were once widely recommended, have not shown a consistent benefit in high-quality studies.[11] As a result, surgical uvulopalatopharyngoplasty, radio frequency volumetric tissue reduction of the palate or tongue (or both), and laser-assisted uvuloplasty are not recommended as first-line therapy to treat symptomatic OSA patients.

Medical Therapy

At this time, there is no acceptably efficacious pharmacologic therapy for OSA. Respiratory stimulants, including medroxyprogesterone and acetazolamide, have not proved effective in patients with normal Pa_{CO_2} levels. Selective serotonin re-uptake inhibitors, including fluoxetine and paroxetine, have been associated with a decreased apnea index during NREM but not REM sleep in a small number of patients. Tricyclic antidepressants have shown some utility in predominantly REM sleep–associated OSA by decreasing REM volume, although side effects have hindered the use of such agents. Hormone replacement therapy may ameliorate the breathing disorder in postmenopausal women.

PROGNOSIS

Population studies show an increased risk of all-cause and cerebrovascular and coronary mortality in patients with untreated severe OSA and in patients with AHIs of 30 or more per hour, independent of other major risk factors. When patients with severe OSA are prescribed CPAP, 5-year survival rates are significantly higher in those with good CPAP adherence (>6 hours/day) than in those with poor adherence. Like other patients with sleep disorders (Chapter 412), patients with OSA are at greater risk for morbidity and mortality from motor vehicle accidents compared with drivers without OSA.

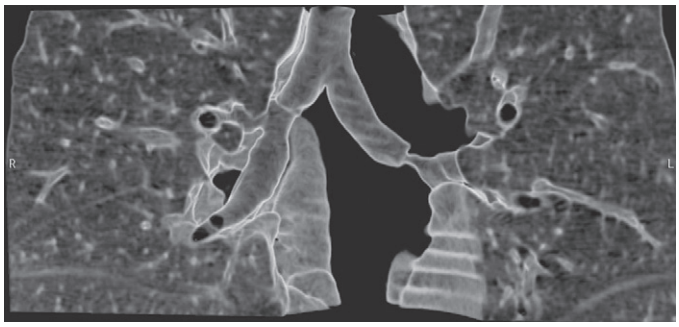

FIGURE 101-1. Three-dimensional reconstruction of a computed tomographic scan in a 20-year-old woman status after bilateral lung transplantation. The image clearly shows the high-grade stenosis at the level of the left mainstem anastomosis. The right-sided airways are normal.

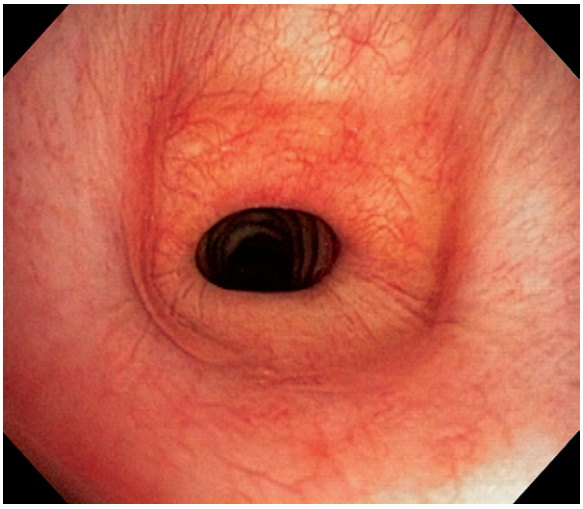

FIGURE 101-2. Bronchoscopic view of the proximal trachea in a 54-year-old man with shortness of breath and stridor. Significant circumferential narrowing is noted in the subglottic space, consistent with gastric reflux–induced subglottic stenosis.

101 INTERVENTIONAL AND SURGICAL APPROACHES TO LUNG DISEASE

ARMIN ERNST AND MALCOLM M. DECAMP

Currently available interventional and surgical procedures can provide diagnostic and staging information and sometimes definitively treat or effectively palliate patients with benign, infectious, and malignant lung diseases.

BRONCHOSCOPY

Bronchoscopy affords a direct view of the major airways and access to lung parenchyma for blind biopsy. Endobronchial therapy has conventionally been used for the management of central airway obstruction, but newer technologic developments permit minimally invasive diagnosis and staging of lung cancer with endobronchial ultrasound (US) and endoscopic approaches to diseases such as emphysema.

Bronchoscopy for Central Airway Obstruction

Airway disorders that cause central airway obstruction of the trachea, mainstem bronchi, and bronchus intermedius are a common indication for therapeutic bronchoscopy. The airway obstruction may be caused by malignant conditions (e.g., bronchogenic carcinoma or metastatic malignancy to the bronchi) and benign disorders (e.g., sarcoidosis, amyloidosis, goiters). The reduction in the airway lumen may remain asymptomatic until a critical airway diameter (5 to 8 mm) is reached or a new event (infection, bleeding, or mucous plugging) exacerbates the underlying narrowing.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A high index of suspicion is mandatory because patients with central airway obstruction often do not have specific symptoms. Stridor is usually a sign of impending respiratory failure that requires urgent intervention.

Hemoptysis may be prominent in patients with malignancies. Some patients may present with a postobstructive pneumonia that responds poorly to antibiotic treatment or recurs. Most patients, however, present with nonspecific symptoms, including dyspnea and cough.

Patients who have risk factors for chronic airway obstruction and present with symptoms consistent with obstruction unresponsive to conventional therapy should undergo airway imaging by computed tomography (CT) scanning (Fig. 101-1) and flexible bronchoscopy (Fig. 101-2). Because loss of airway patency can be lethal, evaluation of these patients must be performed by individuals experienced in the management of critical airway disorders.

TREATMENT

Rx

Removal of obstructing tissue is a key objective in the relief of airway obstruction. Mechanical débridement, which is accomplished by "coring-out" the tissue with the barrel of the rigid bronchoscope, is the safest approach to patients with chronic airway obstruction. Although laser and electrocautery can be used to vaporize tumor tissue, the preferred technique is to use electrocautery or argon plasma coagulation before mechanical débridement, in a fashion known as *heat-assisted mechanical debulking.*

Airway stenting is the primary treatment for airway obstruction caused by extrinsic compression, as may be seen by patients with large malignant mediastinal masses. However, airway stenting is associated with long-term complications, including stent and airway fractures, secondary airway occlusion, infection, and migration, so it should be considered primarily as a palliative procedure for malignant diseases.

For malignant disease, local débridement may temporize the clinical situation while extirpative options are considered. If the lesion or patient is deemed inoperable, such procedures, with or without stenting, are usually a complement to definitive radiation therapy. Patients with endoscopically relieved malignant airway obstruction usually experience a significant improvement in their of quality of life and are more likely to succumb to distant disease than to a local recurrence.

Endobronchial Ultrasound

Bronchoscopy is a standard component of the evaluation and staging of patients with thoracic tumors. Endobronchial US incorporated into the tip of special endoscopes provides ultrasonographic visualization of peri-airway abnormalities and allows transbronchial needle biopsies to be targeted at abnormal areas instead of being taken blindly. Endobronchial ultrasound with biopsy of enlarged nodes has largely obviated the need for mediastinoscopy for the biopsy of mediastinal lymph nodes for staging or diagnosis of cancer and can be useful for the diagnosis of sarcoidosis (Chapter 95). For example, adding endobronchial ultrasound to surgical staging improves the sensitivity for finding nodal metastases and can reduce the unnecessary thoracotomy rate from 18 to 7%.[1]

Surgical Approaches

Open Approaches

Thoracotomy has been the standard approach to evaluate the contents of the pleural space, lung parenchyma, pulmonary hilum, and ipsilateral mediastinum and diaphragm. Selective lung ventilation, achieved by use of a double-lumen endotracheal tube or mainstem bronchial blocker, allows one lung to be collapsed and visualized. Given the precision and accuracy of contemporary preprocedure CT and magnetic resonance imaging (MRI), many procedures can be performed using smaller targeted incisions, with a muscle-sparing technique that allows specific access to regional pathology. Many lung processes can also be approached through a median sternotomy, which affords access to both lungs, although access to the left lower lobe through this approach can be challenging.

Video-Assisted Thoracoscopic Surgery

Thoracoscopy, or video-assisted thoracoscopic surgery (VATS), requires two or three incisions, termed *ports,* to place instruments in any intercostal space. A common configuration is to place one port for the video thoracoscope and two ports for endoscopic instrumentation. With the VATS approach, recovery is shorter than following an open thoracotomy because little if any muscle is divided and no mechanical rib spreading retractors are used.

The size of the surgical incisions depends on the goals of the procedure and the anatomic findings at the time of exploration. Unexpected pleural symphysis or incomplete lobar fissures may require extension of the incision to facilitate visualization. In patients undergoing anatomic resection, such as segmentectomy or lobectomy, at least one of the port incisions is extended to 4 to 8 cm in length to permit extraction of the resected lung from the hemithorax.

SURGERY FOR BENIGN LUNG DISEASE

A variety of benign lung diseases present as focal parenchymal lesions that require a tissue biopsy for diagnosis. Thoracoscopy has essentially replaced a limited thoracotomy and wedge resection for this purpose. VATS provides a more complete view of the ipsilateral hemithorax, including the visceral, parietal, and mediastinal pleura. In addition, subpleural nodules that are too small to be visualized by preoperative radiography can be identified so that representative biopsy samples can be obtained.

Spontaneous Pneumothorax

Although most spontaneous pneumothoraces (Chapter 99) are uncomplicated, up to 20% of patients with pneumothoraces experience complications such as tension pneumothorax, persistent air leak despite tube drainage, or recurrent pneumothoraces either ipsilaterally or contralaterally. Patients in whom a second pneumothorax develops have a 70 to 80% chance of a third recurrence within 2 years. The current surgical approach to the treatment of recurrent pneumothoraces is VATS resection of the subpleural blebs responsible for the pneumothorax, usually combined with mechanical abrasion of the parietal pleura or chemical pleurodesis with insufflated talc to cause an inflammatory reaction that will allow the lung to adhere to the chest wall.

Giant Bullae

Most patients with chronic obstructive pulmonary disease (COPD) have diffuse parenchymal disease, but a small number of patients with COPD have dominant or giant bullae that may occupy 50% or more of the volume of the hemithorax and that compress relatively preserved lung parenchyma. The indications for bullectomy include progressive symptoms with demonstrated disability, obstructive spirometry (Chapter 85), and a single or dominant bullous lesion with radiographic demonstration of compression of the surrounding preserved lung parenchyma. Either excision or plication can remove the bullous lesion.

Malignant Lung Disease

Solitary Pulmonary Nodules

Most small pulmonary nodules (see Fig. 197-5 in Chapter 197) present in the periphery of the lung beyond the reach of diagnostic bronchoscopy. For such lesions, VATS excisional biopsy of a small pulmonary nodule leads to a definitive diagnosis in almost all cases and is generally preferred over transthoracic needle biopsy. Furthermore, thoracoscopy can allow concurrent nodal staging should a primary malignancy (Chapter 197) be confirmed. In the absence of regional adenopathy, patients with primary malignant lesions can undergo definitive resection at the same time.

Primary Lung Cancer

In patients with node-negative primary lung cancer and adequate pulmonary reserve, lobectomy or pneumonectomy is indicated to obtain optimal survival and to decrease the risk of local recurrence. Lobectomy can be achieved by thoracotomy or VATS with similar outcomes. Although VATS wedge resection of primary lung cancer has not been specifically studied in randomized trials, available evidence suggests that an open wedge resection may not be as good as lobectomy for staging or for tumor-free prognosis.

Metastatic Cancer

The lung is a frequent site of metastatic recurrence. Common histologies include colorectal cancer (Chapter 199), renal cell carcinoma (Chapter 203), sarcoma (Chapter 209), melanoma (Chapter 210), breast cancer (Chapter 204), and head and neck cancer (Chapter 196). VATS is often the diagnostic procedure of choice to detect and locate nodules too small for reliable percutaneous biopsy.

The role of pulmonary metastectomy as therapy for advanced disease remains controversial. Five-year survival rates of 20 to 30% have been reported for selected patients, especially if the disease-free interval from original diagnosis to lung metastasis is greater than 3 years. These cases often require resection of bilateral lung nodules, which in turn mandate either a median sternotomy, clamshell incision, or staged, bilateral VATS.

SURGERY FOR ADVANCED LUNG DISEASES: LUNG VOLUME REDUCTION SURGERY

Emphysema (Chapter 88) is the most common chronic progressive disabling lung disease treated by pulmonologists and thoracic surgeons. In eligible patients (Table 101-1), lung volume reduction surgery confers durable symptomatic, physiologic, and survival benefits compared with medical therapy (Fig. 101-3) for patients who have severe emphysema but who do not have a forced expiratory volume in 1 second (FEV_1) measure of less than 20% of predicted with either a homogeneous distribution of emphysema on CT or a diffusing capacity of less than 20% of predicted.[2] However, subgroup analyses suggest that the benefit is mainly in patients with upper lobe predominant disease.

For eligible patients, most programs require a 6- to 10-week preoperative pulmonary rehabilitation followed by a cardiopulmonary exercise test to assess the risks and benefits of surgery. Patients with upper lobe predominant emphysema and a low preoperative exercise capacity have a nearly 50% lower risk of death after lung volume reduction surgery compared with continued

TABLE 101-1 INCLUSION AND EXCLUSION CRITERIA FOR LUNG VOLUME REDUCTION SURGERY

INCLUSION CRITERIA
Radiographic evidence of emphysema, especially involving upper lobes
Hyperinflation evidenced by TLC > 100% predicted and RV > 150% predicted
FEV_1 > 20 and < 45% predicted (after bronchodilator)
DLCO > 20% predicted
Severe dyspnea
Restricted activities of daily living
Decreased quality of life
Abstinence from tobacco
EXCLUSION CRITERIA
Active smoking
Bronchiectasis
Pulmonary nodule requiring evaluation
Excessive daily sputum production
Previous thoracotomy
Obvious pleural disease
Active or inducible coronary ischemia
Pulmonary hypertension
Depressed LVEF (<45%)
Obesity (BMI > 32)
Unable or unwilling to participate in pulmonary rehabilitation
Systemic steroids, ≥20 mg prednisone/day

BMI = body mass index; DLCO = diffusion capacity for carbon monoxide; FEV_1 = first second forced expiratory volume; LVEF = left ventricular ejection fraction; RV = residual capacity; TLC = total lung capacity.

Lung volume reduction surgery: technique, operative mortality and morbidity. *Proc Am Thorac Soc.* 2008;5:442-446; and DeCamp MM Jr, Lipson D, Krasna M, et al. The evaluation and preparation of the patient for lung volume reduction surgery. *Proc Am Thorac Soc.* 2008;5:427-431.

TABLE 101-2 DECISION GUIDE FOR SELECTION OF LUNG VOLUME REDUCTION SURGERY VERSUS TRANSPLANTATION FOR SEVERE CHRONIC OBSTRUCTIVE PULMONARY DISEASE

FACTORS FAVORING LVRS	FACTORS FAVORING TRANSPLANTATION
Age > 65 yr	FEV_1 ≤ 20% predicted
Upper lobe predominant disease	DLCO ≤ 20% predicted
Chronic medical conditions	Homogeneous or lower lobe distribution of disease
Hepatitis B and/or C	TLC < 100% predicted
HIV infection	RV < 150% predicted
Renal insufficiency	$PaCO_2$ > 60 mm Hg
Cirrhosis	PaO_2 < 45 mm Hg
Neuropathy	6 MWD < 140 m or
Poorly controlled diabetes	< 3 min unloaded pedaling cycle ergometer
Osteoporosis	Pulmonary hypertension
Severe GERD	Bronchiectasis
Poor esophageal motility	Recurrent pulmonary infections
Malignancy	
Unable to maintain long-term follow-up	
Psychiatric issues limiting compliance	
Insufficient social support	

6 MWD = six-minute walk distance; DLCO = diffusion capacity of carbon monoxide; FEV_1 = first second forced expired volume; GERD = gastroesophageal reflux disease; HIV = human immunodeficiency virus; LVRS = lung volume reduction surgery; RV = residual volume; TLC = total lung capacity.
Adapted from Patel N, DeCamp M, Criner GJ. Lung transplantation and lung volume reduction surgery versus transplantation in chronic obstructive pulmonary disease. *Proc Am Thorac Soc.* 2008;5:447-453.

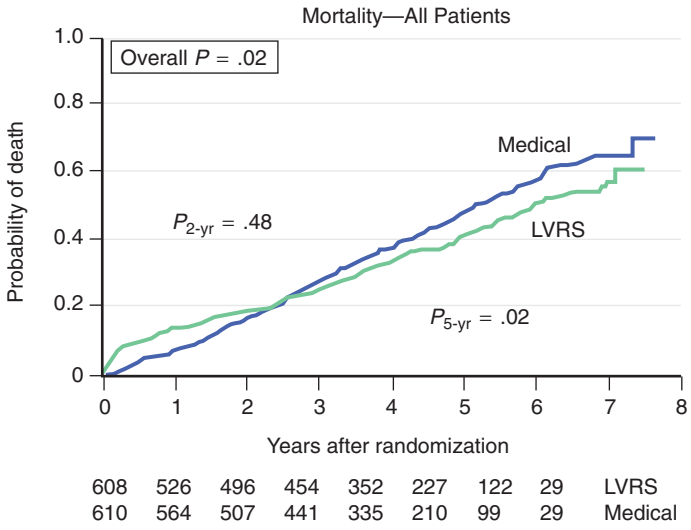

FIGURE 101-3. Long-term mortality of all patients treated with lung volume reduction surgery (LVRS) versus maximal medical therapy in the National Emphysema Treatment Trial. Note the statistically significant (*P* = .02) reduction in relative risk of death (RR = 0.85) for the surgical cohort. (Adapted from Naunheim KS, Wood DE, Mohsenifar Z, et al, for the National Emphysema Treatment Trial Research Group. Long-term follow-up of patients receiving lung-volume-reduction surgery versus medical therapy for severe emphysema in the National Emphysema Treatment Trial. *Ann Thorac Surg.* 2006;82:431-443.)

medical therapy. High-risk patients with severe airflow obstruction (FEV_1 < 20%) should be assessed for lung transplantation evaluation unless their disease is localized to the upper lobes and their gas exchange as defined by diffusing capacity is preserved (Table 101-2).

In experienced centers, bilateral stapled resection approaches yield nearly twice the physiologic benefit of unilateral lung volume reduction surgery without adversely affecting operative morbidity or mortality. Bilateral lung volume reduction surgery using the VATS approach reduces hospital length of stay and increases the likelihood of living independently 60 days after surgery.■

ENDOSCOPIC MANAGEMENT OF EMPHYSEMA

Endoscopic approaches to lung volume reduction include airway valves, blockers, stents, sealants, and implants. Unlike lung volume reduction surgery, which causes peridiaphragmatic pleural scarring and can restrict diaphragmatic movement when lower lobe emphysema is treated, endobronchial lung volume reduction does not cause such scarring and may result in better postoperative functional outcomes. Endobronchial lung volume reduction may permit stepwise and gradual therapy that may facilitate weaning of COPD patients from ventilators. Furthermore, some endobronchial lung volume reduction modalities, such as endobronchial valves, are reversible and can be removed if they are not beneficial or if complications arise.

Endobronchial valves are designed to exclude the most affected emphysematous regions from ventilation and reduce dynamic air trapping. If segmental or lobar atelectasis can be induced, a physiologic effect similar to lung volume reduction surgery can be obtained. In a randomized trial, bronchoscopic implantation of endobronchial valves to allow air to escape from but not enter emphysematous lung areas resulted in a 7% relative improvement in FEV_1 but at the expense of more hemoptysis, pneumonia, and exacerbations of COPD.■ Endobronchial valve therapy for emphysema is safer than lung volume reduction surgery, with a reported mortality rate of approximately 1% and with most patients being discharged within 2 to 4 days. Postobstructive pneumonia has not been a commonly reported complication.

The bronchoscopic creation of extra-anatomic bronchial fenestrations allows trapped air to escape by bypassing obstructed airways, thereby partially deflating emphysematous lung segments through enhanced collateral ventilation.

Biological sealants induce localized irreversible atelectasis by sealing off highly damaged areas of lung. Unlike endobronchial valves or bypass, sealants work at the alveolar level, where air space inflammation and remodeling leads to scarring and contraction of lung parenchyma. Within 6 to 8 weeks, a mature scar and functional lung volume reduction reduce dead space and residual volume to a degree similar to what can be achieved with lung volume reduction surgery.

LUNG TRANSPLANTATION

About 150 worldwide lung transplant centers perform more than 2700 transplantations per year. Lung transplantation is now an accepted therapy for all forms of advanced lung disease.

TABLE 101-3 INDICATIONS AND CONTRAINDICATIONS FOR LUNG TRANSPLANTATION

SINGLE-LUNG TRANSPLANT	PATIENTS (%)	DOUBLE-LUNG TRANSPLANT	PATIENTS (%)
INDICATIONS			
COPD	49	CF, bronchiectasis	31
Pulmonary fibrosis, sarcoid	31	Emphysema	26
α_1-Antitrypsin deficiency	6	α_1-Antitrypsin deficiency	8
PPH, Eisenmenger's	1.2	PPH, Eisenmenger's	6
CF, bronchiectasis	2.4	Pulmonary fibrosis, sarcoid	17
Retransplantation	3	Retransplantation	2
Other*	7	Other*	10
ABSOLUTE CONTRAINDICATIONS			
Untreatable advanced extrapulmonary organ dysfunction (e.g., heart, liver, kidney)			
CAD not amenable to PCI or bypass			
Poor LV function (could consider heart-lung transplantation)			
Malignancy within 2 years (excludes cutaneous squamous or basal cell carcinoma)			
5-year disease-free interval preferred			
Noncurable extrapulmonary infection			
Infection with human immunodeficiency virus			
Hepatitis B antigen positivity			
Hepatitis C with histologic evidence of active liver disease			
Active substance abuse (including cigarettes)			
Severe musculoskeletal disease affecting the thorax			
Documented noncompliance			
Untreatable psychiatric condition which impairs compliance			
Absence of consistent and reliable social support			
RELATIVE CONTRAINDICATIONS			
Physiologic age > 65 years			
Poor nutritional status (<70% ideal body weight)			
Severe obesity (BMI > 30 kg/m)			
Symptomatic osteoporosis			
Colonization with highly virulent and/or highly resistant fungi, mycobacteria, or bacteria			
Requirement for invasive ventilation and/or circulatory support			
Uncontrolled chronic medical conditions (e.g., diabetes, hypertension, GERD)			
Severely limited functional status with poor rehabilitation potential			
Psychosocial problems likely to affect the outcome adversely			
High-dose (>20 mg of prednisone daily) corticosteroid use			

*Other includes lymphangioleiomatosis, non-retransplantation-related obliterative bronchiolitis, and miscellaneous indications.
BMI = body mass index; CAD = coronary artery disease; CF = cystic fibrosis; COPD = chronic obstructive pulmonary disease; GERD = gastroesophageal reflux disease; LV = left ventricle; PCI = percutaneous coronary intervention; PPH = primary pulmonary hypertension.
Adapted from Registry of the International Society for Heart and Lung Transplantation. Twenty-second official adult lung and heart-lung transplant report—2009. *J Heart Lung Transplant.* 2009;28:989-1049; and Orens JB, Estenne M, Arcasoy S, et al. International guidelines for the selection of lung transplant candidates: 2006 update. A consensus report from the Pulmonary Scientific Council of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant.* 2006;25:745-755.

The most common indications for transplantation (Table 101-3) are diseases or conditions that share the following features: they produce extreme disability in affected patients, they are unresponsive to medical therapy, and they are responsible for limited life expectancy in affected patients. With the exception of a small number of cases of sarcoidosis and lymphangioleiomyomatosis, the original lung disease does not usually recur after lung transplantation.

Types of Procedures

Currently, four types of lung transplantation procedures are performed. *Single-lung transplantation*, which is typically performed through a posterolateral thoracotomy incision, requires three anastomoses: the mainstem bronchus, pulmonary artery, and pulmonary veins and left atrium. The contralateral lung is not removed, so single-lung transplantation is not performed in patients with bilaterally infected lungs (e.g., patients with cystic fibrosis or bronchiectasis) (see Table 101-3).

Bilateral lung transplantation is performed in a sequential fashion that is functionally equivalent to two single-lung transplantations completed during a single operation, most commonly through a transverse sternotomy ("clamshell") incision. It requires six anastomoses: both mainstem bronchi, both pulmonary arteries, and both sets of pulmonary veins. It is the procedure of choice for patients with bilaterally infected lungs and is also performed in certain patients with emphysema, primary pulmonary hypertension, and other diseases (see Table 101-3). Bilateral transplantations are preferred for nearly all indications because a double-lung recipient can expect a half-life of 6.6 years compared with 4.6 years for a single-lung recipient.

Heart-lung transplantation is now performed in only about 75 cases per year. It is an en bloc procedure with right atrial, aortic, and distal tracheal anastomoses. It is performed in patients with advanced lung disease and coexistent irreparable cardiac disease, usually associated with fixed pulmonary hypertension, and Eisenmenger's syndrome (Chapter 69).

Living donor lobar transplantation involves the removal of a lower lobe from each of two living donors. One is implanted into each hemithorax of the recipient in a manner similar to bilateral lung transplantation.

Evaluation of Potential Transplant Recipients

The ideal candidate for lung transplantation has lung disease unresponsive to medical therapy but is in otherwise good health. Patients who experience critical illness as a result of lung disease often have poor nutritional status, coexistent major organ dysfunction, refractory infection, or other contraindications to transplantation. The specific evidence-based recommendations for referral for transplant evaluation vary with the underlying disease.

In the United States, the lung allocation system is based on expected disease-specific and patient-specific survival during the waiting period and following engraftment, thereby reflecting net transplant benefit. Early evaluations of the system, which was introduced in 2005, indicate shorter waiting times, an increase in the total number of transplantations performed, a decreased waitlist mortality, and an unchanged overall survival after transplantation.

Post-transplantation Issues

Most of the medical issues that patients and physicians face after lung transplantation are the consequence of the transplantation and post-transplantation medication rather than the underlying disease for which the transplantation was performed. Examples include immunosuppression, infections and their prophylaxis, acute allograft rejection, chronic allograft rejection, and nonpulmonary complications of transplantation.

Immunosuppression

The standard chemotherapeutic regimen for immunosuppression after lung transplantation consists of a calcineurin inhibitor such as cyclosporine or tacrolimus, azathioprine or mycophenolate mofetil, and corticosteroids. Some centers add an antilymphocyte antibody preparation in the first days after transplantation, although this addition has not been demonstrated to improve outcome.

Infections and Prophylaxis after Lung Transplantation

Lung transplant recipients are at high risk for bacterial, viral, fungal, and protozoal infections; infections are the leading causes of death during the early post-transplantation period. In the first 3 months after transplantation, bacterial infections are responsible for most deaths. In approximately one third of patients, pneumonia is diagnosed in the first weeks after transplantation, with gram-negative organisms as the cause in 75% of cases. Colonization and recurrent infections, usually with *Pseudomonas* species, often develop in patients with chronic rejection.

Among potential viral pathogens, *cytomegalovirus* (CMV; Chapter 384) is the most important in lung transplant recipients. Seronegative patients who receive an allograft from a seropositive donor are at particularly high risk for the development of a clinically significant CMV infection. Seronegative patients who have a seronegative donor are at low risk for infection if they are treated with seronegative blood products. Epstein-Barr virus (EBV) has been associated with the development of post-transplantation lymphoproliferative disorder.

Aspergillus species are the most common cause of invasive fungal infection (Chapter 347). Colonized patients and those deemed at risk may receive prophylactic inhaled amphotericin B.

Because of the nature of the immunosuppressive chemotherapeutic regimen used, patients are at high risk for infection by the protozoan *Pneumocystis jirovecii* (Chapter 349). The use of trimethoprim-sulfamethoxazole prophylaxis (typically 1 double-strength tablet three times weekly indefinitely) has virtually eliminated *Pneumocystis* pneumonia.

Acute Rejection

Histologically, the initial manifestation of acute rejection is a lymphocyte-predominant inflammatory response, usually centered around blood vessels, airways, or both. By convention, acute rejection is graded histologically from 0 (normal) to 4 (severe), with subclasses defined by the presence or absence of airway inflammation.

The risk for acute allograft rejection is highest in the early months after transplantation and declines with time. Multiple episodes of acute rejection are the major risk factor for the subsequent development of chronic rejection.

Clinically, patients may have fever, cough, and exertional dyspnea. Evaluation may demonstrate rales or rhonchi on chest examination, a decline in pulmonary function by spirometry, leukocytosis, opacities on chest radiography, and exertional desaturation. The clinical manifestation is often indistinguishable from infectious pneumonia, and the clinical impression is accurate in only 50% of cases.

Treatment of acute rejection most often consists of high-dose corticosteroids (typically, 1 g/day of methylprednisolone administered intravenously for 3 days).

Chronic Rejection

PATHOBIOLOGY

The bronchiolitis obliterans syndrome is thought to be a manifestation of chronic rejection. Risk factors for development of the syndrome include the number of acute rejection episodes and, in some series, previous symptomatic CMV infection. Pathologically, "early" lesions demonstrate inflammation and disruption of the epithelium of small airways, followed by growth of granulation tissue into the airway lumen and subsequent complete or partial obstruction. The granulation tissue then organizes in a stereotypical pattern with resultant fibrosis that obliterates the lumen of the airway.

CLINICAL MANIFESTATIONS

Clinically, bronchiolitis obliterans is accompanied by nonspecific symptoms. Progressive exertional breathlessness typically develops, and pulmonary function testing usually demonstrates evidence of progressive airflow obstruction (Chapter 85). Bronchiolitis obliterans is classified according to the FEV_1: 0 (no significant abnormality) if FEV_1 is greater than 80% of baseline; 1 (mild) if FEV_1 is 65 to 80% of baseline; 2 (moderate) if FEV_1 is 50 to 65% of baseline; and 3 (severe) if FEV_1 is 50% or less of baseline. In early stages, chest radiography is notable only for hyperinflation, but it may show bronchiectasis as the syndrome progresses. Later stages of bronchiolitis obliterans may include a syndrome of bronchiectasis with chronic productive cough and airway colonization with *Pseudomonas* species.

DIAGNOSIS

The diagnosis of bronchiolitis obliterans is made on both clinical and pathologic grounds. Transbronchial biopsy has a low yield for demonstrating histologic evidence of bronchiolitis obliterans, but when such evidence is seen, it is diagnostic. In patients with a compatible clinical syndrome, exclusion of anastomotic stenosis and occult pulmonary infection is sufficient to establish the diagnosis.

TREATMENT

Rx

A variety of therapies have been tried, including pulse corticosteroids, antilymphocyte antibodies, total lymphoid irradiation, photopheresis, and nebulized cyclosporine, but none has been clearly established as effective. Most patients with bronchiolitis obliterans experience a progressive decline in pulmonary function despite immunosuppression.

PROGNOSIS

Bronchiolitis obliterans is the leading cause of late mortality after lung transplantation. Half of lung transplant recipients surviving to 5 years will have either biopsy-proven bronchiolitis obliterans or the clinical diagnosis of bronchiolitis obliterans syndrome.

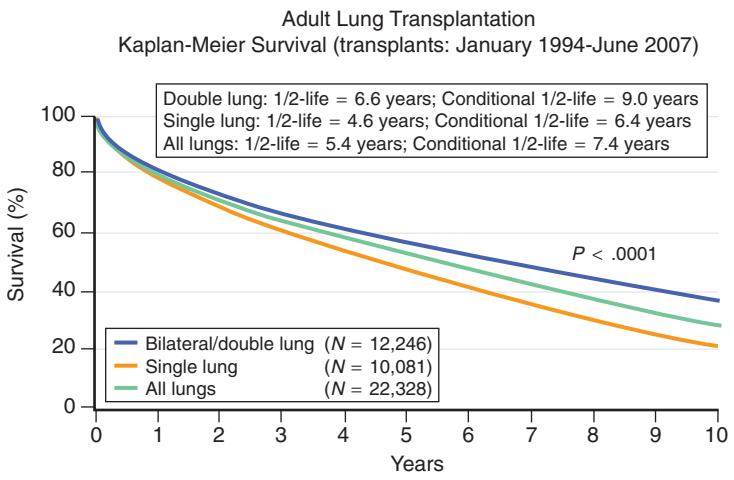

FIGURE 101-4. Kaplan-Meier survival estimates for all lung transplantations reported to the International Registry for Heart and Lung Transplantation from 1994 to 2007. Note the highly statistically significant survival advantage conferred by double lung grafts. (Adapted from Registry of the International Society for Heart and Lung Transplantation. Twenty-second official adult lung and heart-lung transplant report—2009. *J Heart Lung Transplant.* 2009;28:989-1049.)

Nonpulmonary Medical Complications of Lung Transplantation

Most of the nonpulmonary medical complications that arise in patients after lung transplantation are the result of immunosuppressive therapy. One or more of these complications develop in virtually all lung transplant recipients.

Osteoporosis (Chapter 251) is common because of the long-term use of corticosteroids and cyclosporine. Bone density should be monitored periodically, and pharmacologic therapy should be instituted if excessive bone loss is identified.

Chronic renal insufficiency (Chapter 132) is common and is the result of therapy with the calcineurin inhibitors cyclosporine or tacrolimus, both of which affect afferent vascular tone in the kidneys and result in an average 50% drop in the glomerular filtration rate in the first 12 months after lung transplantation. Systemic arterial hypertension is also common and is caused by corticosteroids and cyclosporine. Calcium-channel blockers, which are often used to treat hypertension, raise serum cyclosporine levels; appropriate monitoring and dose adjustment are needed when starting such therapy. Both corticosteroids and tacrolimus contribute to the development of diabetes mellitus and hyperlipidemia.

Solid organ transplantation is associated with an increased incidence of malignancy, thought to be due to pharmacologic immunosuppression and alteration in immune surveillance. Patients are at increased risk for lymphoproliferative malignancies and other types of cancers. Post-transplantation lymphoproliferative disorders occur in about 4% of patients after organ transplantation; most are associated with EBV. These syndromes can be polyclonal or monoclonal. Reduction in immunosuppression is sometimes therapeutic in those with polyclonal disease. The prognosis in patients with monoclonal disease is poor, with little response to modification of immunosuppression or antineoplastic chemotherapy. Patients are also at increased risk for skin, cervical, anogenital, and hepatobiliary malignancy after solid organ transplantation.

Outcomes after Lung Transplantation

Currently, the annual mortality following lung transplantation is 8 to 10% per year, largely owing to bronchiolitis obliterans syndrome. The median survival after lung transplantation is about 5.4 years (Fig. 101-4).

102 APPROACH TO THE PATIENT IN A CRITICAL CARE SETTING

DEBORAH J. COOK

THE INTENSIVIST-LED MULTIDISCIPLINARY TEAM

Patients with critical illness in the intensive care unit (ICU) usually require advanced life support such as mechanical ventilation, inotropic agents, or dialysis. Morbidity associated with critical illness includes complications of both acute and chronic diseases, nosocomial and iatrogenic consequences, and impaired quality of life among survivors. Critically ill patients are at a higher risk of death than any other hospital population. Accordingly, the goals of critical care are to reduce morbidity and mortality, maintain organ function, and restore health. Unlike many other specialties, critical care medicine is not limited to a particular population, disease, diagnosis, or organ system.

Staffing of ICUs with critical care physicians, often referred to as *intensivists*, who provide mandatory consultations or principal ongoing care is associated with a significantly reduced ICU and hospital mortality and reduced ICU and hospital lengths of stay. These findings emphasize the value of the on-site availability of trained physicians who are dedicated to appropriate triaging, prevention, diagnosis, monitoring, treatment, and palliation of critically ill patients.

In addition, daily rounds by an ICU physician who leads a multidisciplinary team appear to improve outcomes. Emerging evidence suggests that leadership, communication, and organizational culture can streamline the process of critical care. These favorable findings may be due to the intensivist-coordinated teamwork of physicians, nurses, respiratory therapists, dieticians, and pastoral care workers to meet the needs of patients and families.

FLUID RESUSCITATION

Intravenous fluids to maintain or restore intravascular volume are an important component of ICU therapy. Both crystalloid and colloid solutions are in widespread use. Crystalloids are readily available and inexpensive, whereas colloids generally require less volume to achieve a specific physiologic goal. Albumin is a naturally occurring protein colloid that increases intravascular oncotic pressure, but its use also carries a small risk of transmitting infection.

In a large randomized trial of fluid replacement with either normal saline or 4% albumin, mortality was the same (21%) in both groups, and there were no differences in organ failure, duration of mechanical ventilation, renal replacement therapy, or length of ICU or hospital stay[1]; however, crystalloid resulted in lower mortality for the pre-specified subgroup of patients with traumatic brain injury. Based on these data, either crystalloid- or albumin-based fluid resuscitation is recommended for most critically ill patients, but crystalloids are recommended for head-injured patients.

Intravenous hydroxyethyl starch, which, like albumin, draws extravascular fluid into the intravascular space, appears to be associated with an increased risk of adverse outcomes, especially the need for renal replacement therapy in the setting of severe sepsis and septic shock.[2] Although starch has not been shown to increase overall mortality, it should be avoided in patients with severe sepsis and septic shock pending ongoing randomized trials.

SEDATION, ANALGESIA, AND SPONTANEOUS BREATHING TRIALS

Endotracheal intubation, central venous catheterization, postoperative pain management, and other ICU procedures require that most patients receive sedation, analgesia, or both. Continuous infusion of sedatives and analgesics is preferable to intermittent boluses, because infusions ensure ongoing tolerance to mechanical ventilation and provide consistent relief of pain and anxiety.

Daily interruption of the infusion of sedatives and analgesics, using protocols that provide an opportunity for the patient to be observed in a less sedated state, is associated with a shorter duration of mechanical ventilation and ICU length of stay.[3] A standardized approach to sedation and analgesia, combining a drug titration protocol with a sedation scale, can favorably impact ICU outcomes and resource consumption.

Discontinuation of ventilatory support is affected by sedation and analgesic infusions, and vice versa. A daily sedation vacation followed by a spontaneous breathing test increases the days of breathing without assistance and shortens ICU stay and hospital stay compared with usual sedation management plus a daily spontaneous breathing test.[4] Although sedation vacations may theoretically increase the risk of self-extubation, the number of patients requiring reintubation does not appear to be increased. In the year after enrollment, patients who were treated with a "wake up and breathe" protocol, which linked daily sedation vacation periods with daily spontaneous breathing trials, had a 32% better survival rate. Based on these data, a nurse-implemented sedation and analgesic management scale with daily drug interruption and daily spontaneous breathing trials are recommended for mechanically ventilated critically ill patients.

LONG-TERM OUTCOMES FOR SURVIVORS

For survivors of critical illness, triggers for ICU discharge are restoration of hemodynamic stability, ability to protect the airway, and spontaneous breathing. However, biomarkers of inflammation, residual organ dysfunction, and functional disabilities persist in most ICU survivors. Treatments administered in the ICU also have serious sequelae. For example, neuromuscular blockers and corticosteroids may contribute to critical illness polyneuropathy. These problems have particularly serious adverse consequences for elderly critically ill patients who are deconditioned before hospitalization.

In addition, anxiety, post-traumatic stress, and major mood disorders are common among patients and their caregivers during recovery. Therefore, although ICU discharge and hospital discharge are milestones in a patient's trajectory, sequelae of critical illness have rarely resolved completely when patients are on the regular hospital floor or at home. Accordingly, multidimensional rehabilitation may optimize the long-term outcomes of survivors of critical illness and their families.

Sedative-induced immobility is now understood to be a preventable contributor to ICU-acquired weakness and functional impairment in the recovery phase of critical illness. This concept has prompted multifaceted interventions to improve long-term outcomes. In a randomized trial of previously independent patients who received mechanical ventilation for 72 hours or less, the addition of graduated, individualized, early physical therapy and occupational therapy during daily sedation vacation periods improved functional capacity at hospital discharge, reduced the duration of delirium, and reduced the number of ventilator days during the 28-day follow-up.[5] Discontinuation of therapy as a result of patient instability, usually patient-ventilator asynchrony, occurred in only 4% of all sessions. This trial highlights how the recovery of critically ill patients can be improved by coordinated multidisciplinary care, including the interruption of sedation, physical therapy, and occupational therapy in the early days of critical illness.

APPLYING EVIDENCE TO PREVENT COMPLICATIONS OF CRITICAL ILLNESS

Considerable evidence of effective preventive and therapeutic ICU interventions has emerged in randomized trials over the past decade. However, barriers to applying this evidence in fast-paced ICUs can lead to a lack of responsibility and decisional authority and to errors of omission.

Analysis of most clinical practices has shown that passive dissemination of information, whether written or verbal, is generally ineffective in modifying physicians' behavior. More effective strategies to encourage the implementation of evidence-based recommendations are interactive education, audit and feedback, reminders (written or computerized), involvement of local opinion leaders, and multifaceted approaches. In the high-acuity ICU setting, preprinted physician orders may help guide (but never dictate) management (Table 102-1). Highlights of evidence-based management include low tidal volume ventilation, high positive end-expiratory pressure,[6] inotrope or vasopressor infusion, low-dose corticosteroids, early enteral small bowel nutrition, head of bed elevation, oral antisepsis, stress ulcer prophylaxis, thromboprophylaxis, and insulin therapy aimed at avoiding marked hyperglycemia but not achieving normoglycemia (Chapters 104 and 105).[7,8] Another useful management strategy is oral decontamination with nonabsorbable antiseptic agents such as chlorhexidine, which decreases the risk of pneumonia. This antiseptic approach is favored over using antibiotics

TABLE 102-1 ICU ADMISSION ORDERS: EXAMPLE FOR A PATIENT WITH UROSEPSIS AND ARDS

MANAGEMENT STRATEGY	ORDERS	REEVALUATE
ACUTE PHASE		
Mechanical ventilation	Target TV 5-7 mL/kg of ideal body weight, PC 16 cm, rate 12, F_{IO_2} 0.7, PEEP 18 cm, plateau pressure <30 cm	PRN
Maintenance fluid	Ringer's lactate 75 mL/hr IV	PRN
Norepinephrine	Titrate to mean arterial pressure >65 mm Hg	PRN
Corticosteroids	Hydrocortisone 50 mg IV q6h while vasopressor dependent	Daily
Sedation	Midazolam 2-8 mg/hr IV, bolus 2-4 mg PRN	PRN
Analgesia	Morphine 1-4 mg IV PRN	PRN
Antibiotics	Ampicillin 2 g IV q6h	Daily
Head of bed	45-degree elevation from horizontal	PRN
Oral antisepsis	Chlorhexidine 15 mL q6h	Daily
Small bowel enteral nutrition	10 mL/hr of a commercial balanced feed containing about 1 kcal/mL; increase by 10 mL q6h to 70 mL/hr	Daily
Stress ulcer prophylaxis	Ranitidine 50 mg IV q8h	Daily
Thromboprophylaxis	Unfractionated heparin 5000 U SC q12h	Daily
Intensive insulin therapy if glucose >180 mg/dL	50 U insulin in 50 mL NS; start at 0.5 U/hr, repeat glucose q1h for 4 hr, and reassess; target 110-150 mg/dL	Daily
Glucometer calibration	Calibrate glucose from glucometer and central laboratory every morning	Daily
Tests	Glucose q4h when stable, ABG with each ventilator change, other tests as per ICU team	PRN
Monitoring	Arterial catheter for systolic blood pressure, central venous catheter for central venous pressure and mixed venous oxygen saturation, ECG, oximetry, ABGs, sedation scale, Foley catheter, others as per ICU monitoring protocols	PRN
RECOVERY PHASE		
Sedation vacation	Daily interruption of sedation from 0700 h until 0900 h; restart at half prior infusion at 0900 h as tolerated	Daily
Spontaneous breathing trials	Spontaneous breathing trial when weaning readiness criteria met	Daily
Early mobility	Physiotherapy and occupational therapy when able	Daily

ABG = arterial blood gas; ARDS = acute respiratory distress syndrome; ECG = electrocardiogram; F_{IO_2} = fraction of inspired oxygen; ICU = intensive care unit; IV = intravenous; NS = normal saline; PC = pressure control; PEEP = positive end-expiratory pressure; PRN = as needed; SC = subcutaneous; TV = tidal volume.

for conventional selective digestive tract decontamination, given concerns about global microbial antibiotic resistance.[9] In mechanically ventilated adults, chest radiographs on demand provide equivalent clinical outcomes as do routine radiographs, despite about one-third fewer radiographs.[10] Later during the recovery phase of critical illness, evidence-based management includes daily interruption of sedation infusions, daily spontaneous breathing trials, and early mobilization.

For example, in a statewide study, the creation and coaching of local safety teams to lead multidisciplinary education, central venous catheter carts stocked with necessary equipment, a five-step procedural checklist to decrease blood stream infections (handwashing, full barrier precautions for catheter insertion, chlorhexidine skin cleansing, avoidance of the femoral site, and removal of unnecessary catheters), and periodic site-specific feedback on infection rates decreased catheter-related blood stream infections from 7.7 per 1000 catheter-days at baseline to 1.4 at 18 months' follow-up.[11]

PREDICTIONS, PREFERENCES, AND END-OF-LIFE CARE

As the population ages and new technologies are developed, the use of basic and advanced life support will increase. Since demand for ICU beds is outstripping supply, the selection of patients to receive critical care is challenging. Three common but not mutually exclusive approaches to rationing ICU beds are admitting the sickest patients; admitting on a first-come, first-served basis; and triaging on the grounds of likely relative benefit. When ICU beds are rationed, patients who are refused ICU admission owing to a perceived minimal potential to benefit have a three-fold higher hospital mortality than those admitted. However, when ICU beds are reduced because of bed closures, admitted patients are sicker, are less frequently admitted for monitoring, and have shorter stays without adverse effects.

Once in the ICU, the prognosis of many critically ill patients improves. For others, treatment responsiveness is delayed or not realized, organ dysfunction evolves but does not resolve, and complications arise. Despite best efforts of the multidisciplinary ICU team, critical illness proves fatal to between 5 and 40% of adults. When a therapeutic trial of critical care is started, and particularly when it is failing, it is crucial to discuss prognosis openly with families. Families bring key information about the patients' prior function and preferences. In the shared decision-making model that dominates today, these exchanges often result in plans to withhold or withdraw basic or advanced life support.

Mechanical ventilation is the most frequent life support administered to, and withdrawn from, critically ill patients. Ventilator withdrawal very often precedes death in the ICU. Patients undergoing ventilator withdrawal or who die while mechanically ventilated have a shorter ICU stay than patients successfully weaned from the ventilator. Such withdrawal may be guided by the severity of the illness and other physiologic characteristics, but it is more heavily influenced by the contemporary life support model that is attentive to a patient's values and the physician's predictions about future quality of life. This complexity underscores the need for ICU teams to be expert communicators, sensitive in eliciting patients' preferences, timely in relieving suffering, and compassionate in providing dignity to the dying while administering culturally competent, family-centered end-of-life care.

103 RESPIRATORY MONITORING IN CRITICAL CARE

JAMES K. STOLLER AND NICHOLAS S. HILL

Monitoring the respiratory system involves a broad array of assessment techniques, ranging from low-technology approaches like a careful physical examination to using very sophisticated technologies to monitor oxygenation and ventilation.

PHYSICAL EXAMINATION

The physical examination can provide important information regarding the patient's ventilation and oxygenation. Ventilation can be assessed by recording the respiratory rate (normally 12 to 20 breaths/minute in adults) as well as by closely inspecting the pattern of chest wall movement during inspiration and by noting the use of accessory inspiratory muscles (e.g., the scalene, trapezius, and sternocleidomastoid muscles). Hypopnea (shallow or slow breathing) or a slowed respiratory rate (bradypnea) can indicate decreased ventilation. Shallow breathing may relate to muscle weakness (Chapter 429) or increased lung stiffness, which is commonly accompanied by a compensatory increase in the ratio of the respiratory rate to maintain ventilation. Bradypnea may relate to a suppressed respiratory drive (e.g., excessive use of narcotics, slowing the respiratory rate). Conversely, sustained tachypnea (e.g., >35 breaths/minute in an adult) can indicate ongoing increased work of breathing, impending respiratory failure, and the need for mechanical assistance, such as noninvasive ventilation or intubation and mechanical ventilation, depending on the etiology of the respiratory failure.

Contraction of the sternocleidomastoid muscles or scalene muscles, often with a seated, bent posture, is called the *tripod sign* (E-Fig. 103-1). This response indicates inadequate diaphragmatic function, most commonly in the setting of emphysema with associated diaphragmatic flattening, which causes a mechanical disadvantage of diaphragmatic contraction. In this circumstance, patients may demonstrate Hoover's sign, which is inspiratory retraction of the rib cage at the level of the zone of apposition, where the diaphragm inserts on the chest wall.

The physical examination of the nail beds and lips may also reveal cyanosis, which suggests hypoxemia. Cyanosis occurs when saturation falls, but it requires the presence of 5 g of desaturated hemoglobin. As such, polycythemic patients may show cyanosis with relatively high oxyhemoglobin saturation values, whereas patients with profound anemia may not demonstrate cyanosis even in the face of low values of oxyhemoglobin saturation.

SYSTEMIC ARTERIAL BLOOD GAS ANALYSIS

Sampling arterial blood, either through a percutaneous arterial puncture or by withdrawing blood from an indwelling arterial catheter, provides important information about the patient's oxygenation and ventilation status as well as the acuity of and compensation for derangements. The partial pressure of carbon dioxide ($Paco_2$) reflects ventilation, the elimination of carbon dioxide. In many but not all cases, $Paco_2$ is close to the mixed alveolar Pco_2.

The $Paco_2$ in the arterial blood is closely related to the ratio of metabolic CO_2 production to alveolar ventilation:

$$Paco_2 = (K)(CO_2 \text{ production rate})/(\text{alveolar ventilation}[V_A]) \quad (1)$$

The partial pressure of oxygen (Pao_2) reflects the level of oxygenation, with normal levels of oxygenation defined by the alveolar-arterial oxygen gradient, $P(A\text{-}a)o_2$, which is calculated as:

$$P(A\text{-}a)o_2 = Fio_2(P_B - P_{H_2O \text{ at standard pressure and body temperature}}) - (Pao_2 + Paco_2/\text{respiratory quotient}) \quad (2)$$

where the respiratory quotient equals the number of moles of CO_2 produced for each mole of oxygen consumed (generally ~0.8 under normal metabolic conditions at rest, but variable with dietary intake and metabolic rate). The normal value of the alveolar-arterial oxygen gradient varies with age and position and can be approximated by the simple equation:

$$P(A\text{-}a)o_2 = (\text{age}/4) + 4 \quad (3)$$

Normal age-related values of Pao_2 in the sitting position can be determined by the equation:

$$Pao_2 \text{ sitting} = 104.2 - (0.27 \times \text{age in years}) \quad (4)$$

Normal values of Pao_2 are generally in the range of 70 to 95 mm Hg, depending on the patient's age.

The $Paco_2$ helps assess the adequacy of the patient's ventilation. At sea level, normal values of $Paco_2$ range from 35 to 45 mm Hg. Values of $Paco_2$ below 35 mm Hg indicate hyperventilation, either as a primary respiratory event (e.g., with anxiety) or in response to another insult (e.g., hypoxemia, sepsis, liver disease). Similarly, values of $Paco_2$ exceeding 45 mm Hg indicate hypoventilation, hypercapnia, and respiratory acidosis, which may result either from suppression of the ventilatory drive (Chapter 86) (e.g., excess narcotics; Chapter 33) or from respiratory insufficiency (e.g., respiratory muscle weakness; Chapter 429).

Assessment of the patient's bicarbonate level (HCO_3^-) helps define the chronicity of changes in the patient's Pco_2, where the value of bicarbonate is defined by the Henderson-Hasselbalch equation:

$$pH = 6.1 + \log_{10}[HCO_3^-]/0.003\, Paco_2 \quad (5)$$

Acute increases in $Paco_2$ drive the normal kidney to retain bicarbonate (Chapter 120), whereas acute decreases in $Paco_2$, as in hyperventilation from anxiety or liver disease, would be expected to cause the normal kidney to waste bicarbonate in order to preserve the body's pH (normally 7.35 to 7.45).

The clinician can also assess whether the patient's ventilatory response to metabolic acidosis is appropriate or inadequate by using the Winter equation, which predicts the expected $Paco_2$ in the face of a decreased bicarbonate from a metabolic acidosis (Equation 6). Specifically, a measured $Paco_2$ above the expected value indicates an inadequate ventilatory response, whereas a value of $Paco_2$ that falls within the expected range indicates an expected, appropriate ventilatory response to the metabolic derangement (i.e., the acidosis).

$$Paco_2 = (1.5[HCO_3^-] + 8) \pm 2 \quad (6)$$

When the patient is hypercapnic and hypoxemic, a useful step is to calculate the ambient air $P(A\text{-}a)o_2$ and to determine whether it is normal or increased for the patient's age. Of the six mechanisms of hypoxemia, only two (hypoventilation and breathing decreased ambient oxygen, as at altitude or from a hypoxic gas mixture) are associated with a preserved $P(A\text{-}a)o_2$ (Table 103-1). Under clinical circumstances at sea level, hypoxemia in the face of a normal $P(A\text{-}a)o_2$ indicates that the patient's hypoxemia is caused by hypoventilation and should prompt the clinician to consider the various etiologies of suppressed respiratory drive (Chapter 86) or respiratory insufficiency that interferes with a normal ventilatory response (e.g., respiratory muscle weakness; Chapter 429).

PULSE OXIMETRY

Pulse oximetry is a noninvasive method to assess arterial blood oxygenation. The percentage of hemoglobin that is oxygenated is measured by passing light of two different wavelengths (660 nm [for deoxyhemoglobin] and 940 nm [for oxyhemoglobin]) through a blood-carrying tissue (e.g., finger, earlobe, forehead), identifying the pulsatile component (which contains arterial blood and background tissue elements), and subtracting the nonpulsatile component to isolate the arterial component. The device can

estimate the percent of oxygenated hemoglobin over the range of 100% to about 75%. Most clinicians regard the output of pulse oximeters to be inaccurate for percent saturation values of less than 70%, although the probability of a low saturation should not be discounted (Fig. 103-1). Pulse oximetry measurements may help identify significant drops in Pa_{O_2} below 60 to 65 mm Hg but are relatively insensitive to changes in Pa_{O_2} from 90 to 65 mm Hg.

CARBON DIOXIDE MONITORING: CAPNOMETRY AND TRANSCUTANEOUS CARBON DIOXIDE MEASUREMENT

The fraction of CO_2 in exhaled air can be measured in real time by infrared capnometry. Partial pressures can then be calculated based on knowledge of atmospheric pressure. The expiratory capnogram (see Fig. 103-1) represents a continuous plot of exhaled P_{CO_2} versus time or exhaled volume and reflects the sequential appearance of gas from various compartments (e.g., the endotracheal tube, central airways, and finally the alveoli, where the P_{CO_2} is in equilibrium with end-capillary blood). The shape of the capnogram provides clues to the presence of chronic obstructive pulmonary disease, in that emptying of areas of lung with increased dead space (see later) can cause the capnogram to have a rising contour (see Fig. 103-1A), whereas the attainment of a so-called alveolar plateau on the normal capnogram (see Fig. 103-1B) indicates that alveolar gas is composed of a mix with a relatively small contribution from areas of increased dead space. The value of $P_{E}CO_2$ measured at the end of expiration on the capnometer (i.e., the highest value recorded) represents the end-tidal $P_{ET}CO_2$. Notably, the value of $P_{ET}CO_2$ is always below the $PaCO_2$ because there is a normal component of dead space ventilation (V_D/V_T) related to the anatomic dead space of the conducting airways (i.e., the trachea and airways to the level of gas-exchanging alveolar ducts and alveoli). The numerical difference between the $PaCO_2$ and the mixed exhaled CO_2 tension ($P_{E}CO_2$, defined as the partial pressure of carbon dioxide that would be measured in a balloon in which the entire exhaled volume is gathered) is related to the magnitude of dead space ventilation (i.e., areas of the lung that are ventilated without accompanying blood flow, normally ~0.3 to 0.4) as defined by the Bohr equation:

$$V_D/V_T = (PaCO_2 - P_ECO_2)/PaCO_2 \quad (7)$$

The difference between $PaCO_2$ and P_ECO_2 may be as low as several millimeters of mercury, but changing conditions of ventilation-perfusion matching (e.g., with pulmonary embolism [Chapter 98], atelectasis [Chapter 90]) may change the gradient over time. Measurement of the $P_{ET}CO_2$ can be clinically useful to assess trends, to help detect esophageal intubation, to detect disconnection from the ventilator, and to detect perfusion during cardiopulmonary resuscitation, but it is not a reliable surrogate for $PaCO_2$. Furthermore, measurement of the dead space fraction has prognostic value in patients with early acute respiratory distress syndrome (Chapter 104), in whom rising dead space is linearly related to increased mortality risk.

Measurement of transcutaneous P_{CO_2} using heated probes applied to the skin represents an alternative noninvasive method for estimating $PaCO_2$. This approach is less widely used clinically, at least in adults, because of technical requirements, such as site rotation for the probes and repetitive calibration, and its generally lower accuracy in estimating $PaCO_2$.

TABLE 103-1 PHYSIOLOGIC MECHANISMS OF HYPOXEMIA AND ACCOMPANYING VALUES OF THE ALVEOLAR-ARTERIAL OXYGEN GRADIENT BREATHING ROOM AIR

MECHANISM/ PHYSIOLOGIC PROCESS	EXAMPLE	ALVEOLAR-ARTERIAL OXYGEN GRADIENT ON ROOM AIR
Ventilation-perfusion mismatch	Pneumonia	Increased
Diffusion impairment	Interstitial lung disease	Increased
Anatomic right-to-left shunt	Pulmonary arteriovenous malformation	Increased
Hypoventilation	Neuromuscular weakness	Normal
Breathing decreased ambient oxygen (from either hypobaric conditions [e.g., altitude] or breathing a gas mixture with decreased inspired oxygen fraction)	Altitude exposure	Normal
Diffusion-perfusion impairment	Hepatopulmonary syndrome	Increased

ARTERIAL OXYGEN CONTENT AND SYSTEMIC OXYGEN DELIVERY

Arterial (Ca_{O_2}) and venous oxygen content (Cv_{O_2}) are used to calculate cardiac output using the Fick equation (Equation 8), which is an alternative to determining cardiac output by the thermodilution method using a flow-directed pulmonary artery (Swan-Ganz) catheter (Chapter 57). The Fick equation is:

$$\text{Oxygen consumption}\,(\text{mL O}_2/\text{min}) = \text{cardiac output} \times (Ca_{O_2} - Cv_{O_2}) \quad (8)$$

where oxygen content has the units of mL O_2/100 mL of blood and is calculated as:

$$\text{Oxygen content} = 1.34(\text{hemoglobin})(\%\,\text{saturation}) + 0.0031(Pa_{O_2}) \quad (9)$$

Under normal conditions (with, for example, an arterial percent saturation of 95% and a hemoglobin of 15 g/100 mL and an oxygen consumption of 250 mL/minute), arterial oxygen content is about 20 mL/100 mL and, because mixed venous oxygen saturation is about 75%, central venous oxygen content is about 15 mL/100 mL, making the normal arteriovenous oxygen content difference with a normal cardiac output about 5 mL/100 mL.

Systemic oxygen transport defines the amount of oxygen delivered to the tissues and multiplies the arterial oxygen content by the cardiac output:

$$\text{Systemic oxygen transport}\,(\text{mL/min}) = \text{cardiac output} \times Ca_{O_2} \quad (10)$$

where the normal value is about 1000 mL/minute.

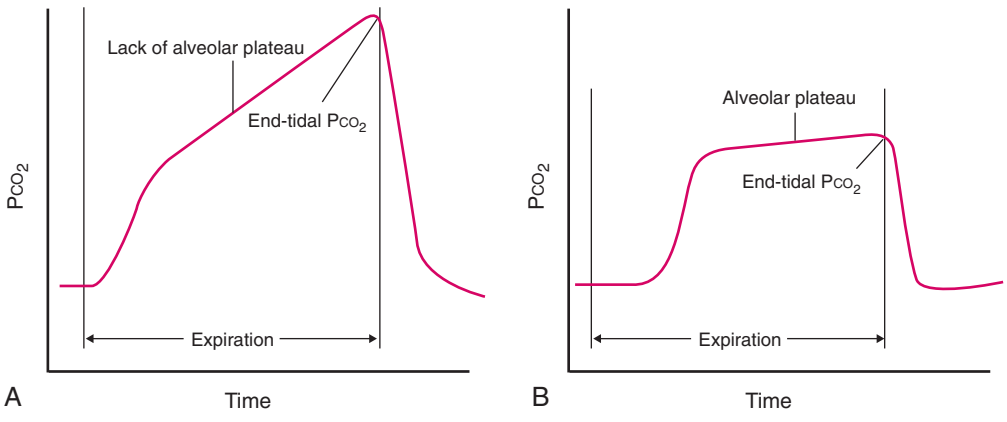

FIGURE 103-1. Abnormal and normal end-tidal capnograms. A, Illustration of a capnogram from a patient with chronic obstructive pulmonary disease in which the end-tidal P_{CO_2} rises throughout expiration as CO_2 excretion varies from different parts of the lung. **B,** Illustration of a normal capnogram in which the end-tidal P_{CO_2} reaches a plateau with more uniform CO_2 excretion. The end-tidal P_{CO_2} ($P_{ET}CO_2$) is the highest point of the alveolar plateau.

MEASURING VENTILATION: MINUTE VENTILATION AND ALVEOLAR VENTILATION

Minute ventilation (V_E), which is the amount of gas exhaled from the airway per minute, is the product of the respiratory rate times the exhaled tidal volume, measured at body temperature and standardized to barometric pressure at sea level, saturated with water vapor (BTPS). The BTPS is a standard condition under which many measurements for most pulmonary function equipment and mechanical ventilators are made. These devices use an airflow meter to measure exhaled airflow and integrate the signal to derive tidal volume. An alternative way to measure tidal volume in an intensive care setting is respiratory impedance plethysmography, which uses calibrated magnetic coils in belts strapped around the chest and abdomen to monitor respiratory frequency and changes in thoracic volume.

Alveolar ventilation is the rate of gas delivery in liters per minute to gas-exchanging areas of the lung (i.e., the alveoli and alveolar ducts). The portion of minute ventilation that fails to undergo gas exchange is dead space ventilation (V_D) and is determined by Equation 7 above. Minute, alveolar (V_A), and dead space ventilation are related as follows:

$$V_E = V_A + V_D \quad (11)$$

It follows that conditions such as acute lung injury or acute respiratory distress syndrome (ARDS; Chapter 104) that are associated with very high dead space ratios require high V_E to achieve a sufficient V_A. Conversely, conditions that cause neuromuscular weakness (Chapter 429) are associated with small tidal volumes and have a high V_D/V_T ratio because the anatomic dead space is fixed and constitutes a higher fraction of the diminished tidal volume.

MEASURING CARBON DIOXIDE PRODUCTION

Measurement of CO_2 production is sometimes referred to as *indirect calorimetry* because it provides an index of metabolic rate and permits estimation of caloric requirements. Metabolic "carts" that simultaneously measure not only CO_2 production but also O_2 consumption and respiratory quotient are commonly used clinically to estimate metabolic needs in order to prescribe nutritional repletion (Chapter 223). The normal baseline CO_2 production is in the range of 200 mL/minute but is subject to wide variation because of hypermetabolic states commonly encountered in critically ill patients, such as sepsis or the systemic inflammatory response syndrome. A high CO_2 production might be used as an indication to increase caloric delivery.

The respiratory quotient also gives insight into the composition of feedings because carbohydrates yield a respiratory quotient of 1, whereas fatty acids yield a ratio of 0.8 and amino acids a ratio of 0.7. Thus, balanced nutrition should yield a respiratory quotient of approximately 0.85. A respiratory quotient of 1 in combination with a high CO_2 production suggests that the dietary proportion of carbohydrates is excessive.

MEASURING RESPIRATORY COMPLIANCE

Respiratory compliance is the change in respiratory system volume induced by a change in applied pressure (i.e., inspiratory pressure) and is the inverse of elastance. Compliance diminishes in conditions like lung injury and ARDS (Chapter 104) or pulmonary fibrosis (Chapter 92), in which diffuse inflammation and scarring alter lung structure and contribute to increased lung "stiffness." Static respiratory compliance is measured in patients receiving volume-limited mechanical ventilation by imposing a brief inspiratory hold at end inspiration. Assuming the patient has no spontaneous breathing effort, the airway pressure measured when airflow ceases is referred to as the plateau pressure ($P_{plateau}$). The difference between this pressure and the positive end-expiratory pressure (PEEP) is taken as the driving pressure required to deliver the tidal volume (Fig. 103-2). Static respiratory system compliance (C_{RS}) is then calculated as:

$$C_{RS} = \Delta V(\text{exhaled tidal volume})/\Delta P(P_{plateau} - \text{PEEP}) \quad (12)$$

This compliance not only reflects the status of the lung but also includes contributions of the chest wall and abdomen. Thus, patients with chest wall deformities or morbid obesity have lower values of respiratory compliance even in the absence of lung abnormalities (Chapter 99). The normal respiratory compliance is in the range of 50 to 70 mL/cm H_2O, and patients with ARDS usually have values of C_{RS} of less than 30 cm H_2O. If respiratory compliance is below 20 to 25 cm H_2O, weaning from mechanical ventilation (Chapter 105) is unlikely because of the high work of breathing requirements (see later).

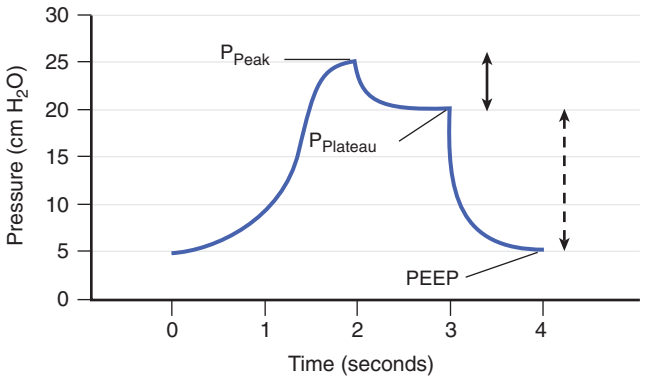

FIGURE 103-2. Illustration of inspiratory hold maneuver to determine plateau pressure ($P_{plateau}$). Airway pressure during volume-targeted mechanical ventilation rises as the tidal volume is delivered and reaches a peak. An inspiratory hold is initiated at peak pressure that prevents exhalation, so pressure falls to a "plateau" of about 20 cm H_2O. The drop in pressure reflects the pressure needed to overcome airway resistance. After slightly more than 1 second, the inspiratory hold is released, and airway pressure falls to positive end-expiratory pressure (PEEP). The difference between ($P_{plateau}$) and PEEP is used to calculate static compliance by dividing the difference into the tidal volume.

MEASURING RESPIRATORY DRIVE

The respiratory center, located in the pons and medulla, regulates respiratory drive. Hypercapnia is a strong stimulus to ventilation (Chapter 86). This response may be blunted by chronic CO_2 retention or by drugs like narcotics. Hypoxemia is a weaker ventilatory stimulus that is potentiated by hypercapnia and blunted by hypocapnia.

Thus, respiratory drive can be assessed as the response to CO_2 in the blood in the hypercapnic ventilatory response. In one technique to measure respiratory drive, the patient rebreathes his or her exhaled air while minute ventilation and $P_{ET}CO_2$ are monitored; a graph relating $P_{ET}CO_2$ with minute ventilation is used to measure respiratory drive. However, this technique is impractical in an intensive care unit (ICU) setting. Another technique is to measure the negative swing in airway pressure during the first 100 msec of inspiration (P_{100}). This technique avoids the problem of diminished ventilatory response due to airway obstruction, but it is still subject to blunting by some drugs and still underestimates drive in patients with respiratory muscle weakness, a very common problem in the ICU. In patients who are failing to wean from mechanical ventilation, a practical way to assess the integrity of respiratory drive is to determine whether the respiratory rate increases, usually into the 30s or 40s, as $PaCO_2$ rises after the patient is removed from ventilatory support.

MEASURING RESPIRATORY MUSCLE STRENGTH

Respiratory muscle weakness has long been recognized as a contributor to respiratory failure and failure to wean from mechanical ventilation in the ICU (Chapter 105). This recognition has intensified in recent years with the increased awareness of ICU-acquired weakness following critical illness. However, measurement of respiratory muscle strength remains challenging because of the need to differentiate between actual weakness and reduced muscle performance owing to inability to cooperate or to exert a full inspiratory effort.

The most commonly used measures of respiratory muscle strength are the maximal inspiratory and expiratory pressures ($P_{I_{max}}$ or MIP and $P_{E_{max}}$ or MEP). These values are obtained by measuring the pressure change with a manometer when the patient inhales with maximal force from residual volume and exhales with maximal force from total lung capacity. Normal MIP is usually more negative than −75 cm H_2O, and normal MEP is usually more positive than 125 cm H_2O. When the value for MIP is less negative than −20 or −30 cm H_2O, weaning may be difficult, and values less positive than 60 cm H_2O suggest cough insufficiency. However, these values have poor predictive value in mechanically ventilated patients because many of these patients are unable to cooperate. This problem may be addressed by attaching a one-way valve to the end of endotracheal tube that permits exhalation but not inhalation and then measuring the inspiratory pressure efforts for 20 to 25 seconds.

MEASURING WORK OF BREATHING

Work of breathing is the product of pressure and volume for each breath (Fig. 103-3). The components include work needed to overcome elastic recoil of

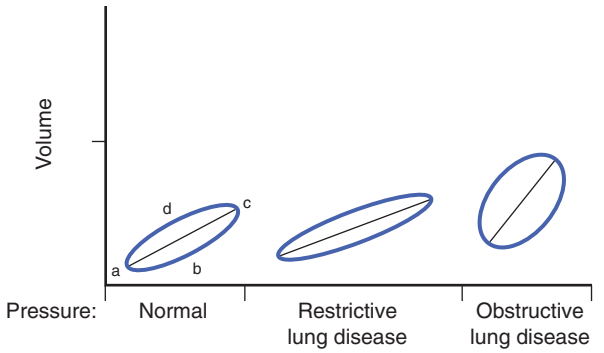

FIGURE 103-3. Pressure-volume curves illustrating components of work in a normal subject and in patients with restrictive or obstructive disease. The line between **a** and **c** represents elastic work as the lung expands, but this work is a net zero because static forces return the lung to its neutral position. The restrictive curve is flatter than normal because the lung is stiffer and volume changes less for a given unit change in pressure. The obstructive curve has a greater slope because (e.g., in emphysema) the lung is more compliant and starts inhalation from a higher volume. The **abc** curve represents resistive work during inspiration, and **cda** represents resistive work during exhalation. Resistive work during exhalation is greater in patients with obstructive lung disease.

the lung and to displace the chest wall and abdomen as well as work needed to overcome airway resistance and lung viscosity and work needed to overcome inertia. With restrictive lung diseases, the inspiratory work of breathing is increased because of the decreased lung elasticity. With obstructive diseases, the work of breathing is increased because of increased airway resistance.

In clinical settings, a more practical way to assess the inspiratory work of breathing is to calculate the pressure-time product (PTP) in cm H_2O-seconds. The PTP can be calculated using the decrease in airway pressure during inspiration, esophageal pressure (measured using an esophageal balloon manometer), or transdiaphragmatic pressure (measured using esophageal and gastric balloon manometers)—as an index of diaphragmatic work. The work can be calculated as work of breathing per breath or as work of breathing per minute by multiplying the work per breath by the respiratory frequency. Commercially available devices using esophageal manometry automatically calculate the inspiratory work of breathing, which may be of some value in assessing the likelihood of weaning from mechanical ventilation. If the drop in inspiratory pressure necessary to achieve an adequate tidal volume is too large, the calculated work of breathing will be high, and the likelihood of successful weaning will be reduced.

104 ACUTE RESPIRATORY FAILURE

LEONARD D. HUDSON AND ARTHUR S. SLUTSKY

ACUTE RESPIRATORY FAILURE

DEFINITION

Acute respiratory failure occurs when dysfunction of the respiratory system results in abnormal gas exchange that is potentially life-threatening. Each element of this definition is important to understand. The term *acute* implies a relatively sudden onset (from hours to days) and a substantial change from the patient's baseline condition. Dysfunction of the respiratory system indicates that the abnormal gas exchange may be caused by abnormalities in any element of the respiratory system (e.g., a central nervous system abnormality affecting the regulation of breathing or a musculoskeletal thoracic abnormality affecting ventilation; Chapter 83), in addition to abnormalities of the lung itself. The term *respiration* refers, in a broad sense, to the delivery of oxygen (O_2) to metabolically active tissues for energy usage and the removal of carbon dioxide (CO_2) from these tissues (Table 104-1). Respiratory failure is a failure of the process of delivering O_2 to the tissues and/or removing CO_2 from the tissues. Abnormalities in the periphery (e.g., cyanide poisoning, pathologic distribution of organ blood flow in sepsis) can also lead to tissue

TABLE 104-1 ABBREVIATIONS COMMONLY USED IN ACUTE RESPIRATORY FUNCTION

ABG	Arterial blood gas or arterial blood gas analysis
ALI	Acute lung injury
ARDS	Acute respiratory distress syndrome
ARF	Acute respiratory failure
cm H_2O	Centimeters of water
Ca_{O_2}	Content of oxygen in arterial blood
Cc_{O_2}	Content of oxygen in end-capillary blood
CO_2	Carbon dioxide
COPD	Chronic obstructive pulmonary disease
CPAP	Continuous positive airway pressure (used when positive pressure during exhalation is applied with spontaneous ventilation)
Cv_{O_2}	Content of oxygen in mixed venous blood
F_{IO_2}	Fraction of inspired oxygen
g/dL	Grams per deciliter
HbO_2	Saturation of hemoglobin by oxygen
L/min	Liters per minute
mL/kg	Milliliters per kilogram
mL/min	Milliliters per minute
mm Hg	Millimeters of mercury
NIPPV	Noninvasive positive-pressure ventilation
O_2	Oxygen
$P(A\text{-}a)O_2$	Difference of partial pressure of oxygen between mean alveolar gas and arterial blood (alveolar-to-arterial oxygen difference)
PAc_{O_2}	Partial pressure of carbon dioxide in alveolar gas
Pac_{O_2}	Partial pressure of carbon dioxide in arterial blood
PAO_2	Partial pressure of oxygen in alveolar gas
Pa_{O_2}	Partial pressure of oxygen in arterial blood
Pa_{O_2}/F_{IO_2}	Ratio of partial pressure of oxygen in arterial blood to fraction of inspired oxygen
PBW	Predicted body weight
Pcc_{O_2}	Partial pressure of carbon dioxide in end-capillary blood
Pc_{O_2}	Partial pressure of oxygen in end-capillary blood
PEEP	Positive end-expiratory pressure (used when positive pressure during exhalation is applied with mechanical ventilation)
P/F	Pa_{O_2}/F_{IO_2} ratio
P_{IO_2}	Partial pressure of oxygen in inspired gas
P_{O_2}	Partial pressure of oxygen
Pvc_{O_2}	Partial pressure of carbon dioxide in mixed venous blood
Pv_{O_2}	Partial pressure of oxygen in mixed venous blood
$\dot{Q}$	Blood flow or perfusion
RR	Respiratory rate
Sa_{O_2}	Percentage of saturation of hemoglobin by oxygen in arterial blood
$\dot{V}$	Ventilation
$\dot{V}/\dot{Q}$	Ventilation-to-perfusion ratio
V_T	Tidal volume

TABLE 104-2 SYSTEMS TO CLASSIFY ACUTE RESPIRATORY FAILURE

HYPOXIC VERSUS HYPERCAPNIC-HYPOXIC ARF
Causes of Hypoxic ARF
Acute lung injury/ARDS
Pneumonia
Pulmonary thromboembolism
Acute lobar atelectasis
Cardiogenic pulmonary edema
Lung contusion
Acute collagen vascular disease (Goodpasture's syndrome, systemic lupus erythematosus)
Causes of Hypercapnic-Hypoxic ARF
Pulmonary disease
COPD
Asthma: advanced, acute, severe asthma
Drugs causing respiratory depression
Neuromuscular
Guillain-Barré syndrome
Acute myasthenia gravis
Spinal cord tumors
Metabolic derangements causing weakness (including hypophosphatemia, hypomagnesemia)
Musculoskeletal
Kyphoscoliosis
Ankylosing spondylitis
Obesity hypoventilation syndrome (often with additional acute, superimposed abnormality as cause of ARF)
ETIOLOGIC MECHANISMS OF HYPOXEMIA
Normal P(A-a)O_2*
↓P_{IO_2}
High altitude; inadvertent administration of low F_{IO_2} gas mixture
Hypoventilation
See causes of hypercapnic-hypoxic ARF above
Increased P(A-a)O_2*
Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch
Airway disease
Vascular disease, including pulmonary thromboembolism
Shunt
Acute lung injury/ARDS
Pneumonia
Parenchymal lung disease
Cardiogenic pulmonary edema
Pulmonary infarction
Diffusion limitation†

ARF WITH AND WITHOUT CHRONIC LUNG DISEASE
With Chronic Lung Disease
COPD
Asthma
Parenchymal lung diseases
Restrictive lung/chest wall diseases
Without Chronic Lung Disease‡
Acute lung injury/ARDS
Pneumonia
Pulmonary thromboembolism
ARF BY ORGAN SYSTEM INVOLVED
Respiratory (Lungs and Thorax)
Airway/airflow obstruction
COPD
Asthma
Pulmonary parenchyma
Pneumonia
Acute lung injury/ARDS
Acute flare of chronic collagen vascular disease (e.g., Goodpasture's syndrome, systemic lupus erythematosus)
Central Nervous System
Respiratory depression
Increased sedatives, tranquilizers with respiratory effect; opiates; alcohol
Brain stem and spinal cord involvement
Tumors, trauma, vascular accidents
Neuromuscular
Guillain-Barré syndrome
Myasthenia gravis
Cardiovascular
Cardiogenic pulmonary edema
Pulmonary thromboembolism
Renal/Endocrine
Volume overload
Metabolic abnormalities

*Calculated using the alveolar-air equation; see text for description.
†See text for discussion.
‡These can also be superimposed on chronic disease.
ARDS = acute respiratory distress syndrome; ARF = acute respiratory failure; COPD = chronic obstructive pulmonary disease; F_{IO_2} = fraction of inspired oxygen; P(A-a)O_2 = alveolar-to-arterial oxygen difference; P_{IO_2} = partial pressure of inspired oxygen; $\dot{V}/\dot{Q}$ = ventilation-to-perfusion ratio.

hypoxia; although these conditions represent forms of respiratory failure in the broadest terms, this chapter focuses on respiratory failure resulting from dysfunction of the lungs, chest wall, and control of respiration.

PATHOBIOLOGY

Abnormal gas exchange is the physiologic hallmark of acute respiratory failure, which can be classified in several ways (Table 104-2). Although gas exchange can be abnormal for either oxygenation or CO_2 removal, significant hypoxemia is nearly always present when patients with acute respiratory failure breathe ambient air. If CO_2 is retained at a potentially life-threatening level, this is usually accompanied by significant hypoxemia (see later). The *life-threatening* aspect of the condition places the degree of abnormal gas exchange in a clinical context and calls for urgent treatment.

The diagnosis of acute respiratory failure requires a significant change in blood gases from baseline. Many patients with chronic respiratory problems can function with blood gas tensions that would be alarming in a physiologically normal individual. Over time, these patients with so-called chronic respiratory failure or chronic respiratory insufficiency develop mechanisms to compensate for inadequate gas exchange. Conversely, this chronic condition makes patients vulnerable to insults that could be easily tolerated by a previously healthy individual.

In acute respiratory failure, the O_2 content in the blood (available for tissue use) is reduced to a level at which the possibility of end-organ dysfunction increases markedly. The value of the partial pressure of O_2 in the arterial blood (Pa_{O_2}) that demarcates this vulnerable zone is the point of the oxyhemoglobin dissociation relationship at which any further decrease in the Pa_{O_2} results in sharp decreases in the amount of hemoglobin saturated with O_2 (Sa_{O_2}) and in the arterial blood O_2 content (Ca_{O_2}). Although arbitrary, acute respiratory failure is often defined in practice as occurring when the Pa_{O_2} is less than 55 mm Hg (Fig. 104-1). In general, the locus on the curve that indicates the partial pressure at which O_2 is being unloaded to the tissues is the most important determinant of how much O_2 is available for the cells and their mitochondria. Usually, the ability to unload O_2 at the tissue level more than compensates for small decreases in the amount of O_2 picked up in the lungs when the oxyhemoglobin dissociation curve is shifted rightward. With a leftward shift in the curve, O_2 is bound more tightly to hemoglobin, so less O_2 is available for tissue delivery.

These clinical considerations imply that any definition of acute respiratory failure based on an absolute level of Pa_{O_2} is arbitrary. A healthy, young, conditioned individual climbing at high altitude may have a Pa_{O_2} of less than 50 mm Hg because of the reduction in inspired O_2 pressure. This individual is not in acute respiratory failure, even though the Pa_{O_2} may be in the low 40s. A patient who has chronic obstructive pulmonary disease (COPD) and whose usual range of Pa_{O_2} is 50 to 55 mm Hg would not be considered to be in acute respiratory failure if the Pa_{O_2} was 50 mm Hg. However, if a patient's usual Pa_{O_2} was 60 to 70 mm Hg, a Pa_{O_2} of 50 mm Hg would be associated

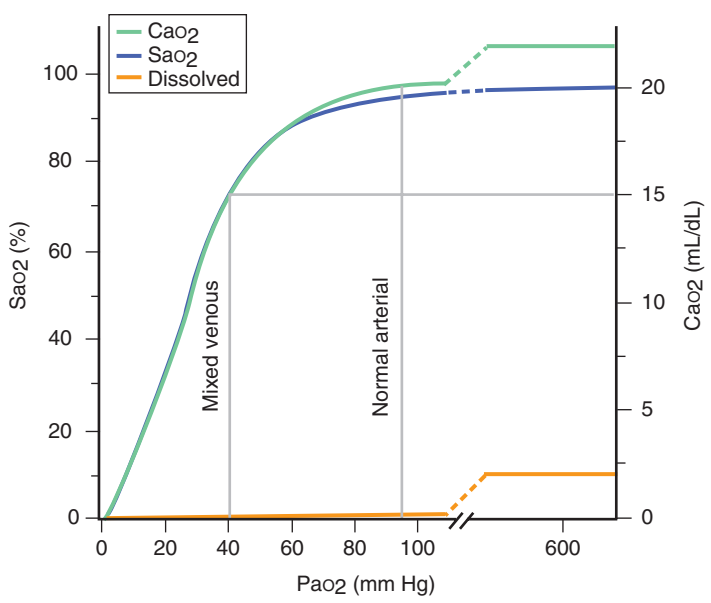

FIGURE 104-1. Oxyhemoglobin association-dissociation curve. The axis for oxygen saturation in the arterial blood (Sa_{O_2}) is on the left, and the axis for arterial content of oxygen (Ca_{O_2}) is on the right. Ca_{O_2} is the sum of the oxygen dissolved in plasma (denoted as "Dissolved" in the figure) plus the oxygen bound to hemoglobin. At a normal hemoglobin, most of the oxygen is carried in combination with hemoglobin, with only a relatively small amount of oxygen dissolved in plasma. When the value of the arterial partial pressure of oxygen (Pa_{O_2}) is on the "flat" portion of the curve (Pa_{O_2} ≥60 to 65 mm Hg, normal partial pressure of carbon dioxide [P_{CO_2}], and normal pH), raising the Pa_{O_2} further has relatively little effect on total oxygen content. Increases in temperature, P_{CO_2}, hydrogen ion concentration, or 2,3-diphosphoglycerate cause a rightward shift in the oxyhemoglobin association-dissociation curve.

with a substantial risk for a further life-threatening reduction in oxygenation; this patient should be considered to have acute respiratory failure.

Traditionally, the level of arterial CO_2 partial pressure (Pa_{CO_2}) that defines acute respiratory failure has been 50 mm Hg or greater, if accompanied by arterial acidosis with a pH of 7.30 or less. The Pa_{CO_2} is linked to pH because it is generally thought that acidosis leads to tissue dysfunction and symptoms. Patients with severe COPD may have chronic CO_2 retention, but renal compensation for the respiratory acidosis protects them against abnormalities related to the elevation in CO_2. A further acute rise in Pa_{CO_2} can precipitate symptoms and other organ dysfunction; however, even severe respiratory acidosis (pH 7.1) seems to be better tolerated than metabolic acidosis of the same pH in most previously healthy individuals if arterial and tissue oxygenation is adequate.

Pathophysiology

Five mechanisms can lead to a reduction in Pa_{O_2}: (1) decreased inspired partial pressure of O_2 (P_{IO_2}) (e.g., at high altitude or when breathing a reduced percentage O_2 mixture); (2) hypoventilation; (3) ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch; (4) shunting of blood from the pulmonary to systemic circulation, bypassing the alveoli anatomically or functionally; and (5) abnormal diffusion of O_2 from the alveoli into the capillary blood. In essence, a shunt is an extreme $\dot{V}/\dot{Q}$ mismatch in which blood perfuses alveoli with *no* ventilation; it is differentiated clinically from other $\dot{V}/\dot{Q}$ mismatching by the response to breathing supplemental O_2 (see later).

For clinical purposes, diffusion abnormalities are not an important cause of hypoxemia at sea level because there is sufficient time for adequate diffusion of O_2 during the transit of a red blood cell through the pulmonary capillary bed, even in the presence of severe lung disease. Even when diffusion abnormalities are present and contribute to hypoxemia, $\dot{V}/\dot{Q}$ mismatch and shunting nearly always coexist and are quantitatively more important causes of hypoxemia. Except at high altitude or when a subject is breathing a gas mixture low in O_2, hypoventilation, $\dot{V}/\dot{Q}$ mismatch, and shunting are the dominant causes of acute respiratory failure.

If only hypoventilation is present, the resulting hypoxemia is associated with a normal difference between the calculated alveolar and the measured arterial oxygenation levels ($P(A\text{-}a)_{O_2}$). In this setting, an elevated Pa_{CO_2} suggests disease processes that affect nonpulmonary respiratory function (e.g., central respiratory depression resulting from drug overdose, neuromuscular diseases such as Guillain-Barré syndrome, or chest wall disease such as flail chest; Chapter 86). In contrast, $\dot{V}/\dot{Q}$ mismatch and shunting are associated with an elevated $P(A\text{-}a)_{O_2}$, which may or may not coexist with hypoventilation. The normal value for $P(A\text{-}a)_{O_2}$ varies as a function of the fraction of inspired O_2 (F_{IO_2}), increasing as F_{IO_2} increases.

When $\dot{V}/\dot{Q}$ mismatch or shunting is the cause of hypoxemia, some alveolar regions have increased PA_{CO_2} and reduced PA_{O_2}; the blood in the vessels perfusing these alveoli reflects these abnormal gas tensions. The increased PA_{CO_2} usually can be reversed by increasing overall ventilation, but hyperventilation does not correct the decreased Pa_{O_2}.

$\dot{V}/\dot{Q}$ mismatch is distinguished from shunting by assessing the Pa_{O_2} response to enhanced O_2 administration. Hypoxemia caused by $\dot{V}/\dot{Q}$ mismatch can be corrected to a nearly complete O_2 saturation of the hemoglobin in most patients by a relatively small increase in F_{IO_2}, such as from 0.24 to 0.28 by face mask or 1 to 2 L/minute O_2 by nasal prongs, in patients with acute exacerbations of COPD. If the airways to poorly ventilated alveoli remain open and the enriched O_2 mixture is administered for an adequate length of time (ranging from a few minutes to 20 minutes, depending on the degree of $\dot{V}/\dot{Q}$ inequality), the increased P_{IO_2} is reflected by an increased PA_{O_2} and an increased Pa_{O_2}. When a shunt is present (no ventilation but continued perfusion), a relatively small increase in the F_{IO_2} has little or no effect on the Pa_{O_2}, and even large increases in F_{IO_2} up to 1.0 result in only modest increases in Pa_{O_2} (Fig. 104-2).

CLINICAL MANIFESTATIONS

The hallmark of acute respiratory failure is the inability to maintain adequate oxygenation or the inability to maintain an appropriate Pa_{CO_2}. Patients are typically dyspneic and tachypneic, unless progressive respiratory failure causes fatigue—sometimes leading to respiratory arrest—or a drug overdose or neuromuscular condition prevents an appropriate respiratory response to hypoxia and/or the hypercapnic acidosis. Neurologic function may deteriorate, and myocardial ischemia or even infarction may be precipitated by the hypoxemia. In addition, each cause has its own specific manifestations (see later).

DIAGNOSIS

As part of the diagnosis of acute respiratory failure, the physician has three objectives: (1) confirm the clinical suspicion that acute respiratory failure is present, (2) classify the type of acute respiratory failure (e.g., hypoxemia caused by hypoventilation vs. hypoxemia caused by $\dot{V}/\dot{Q}$ mismatch or shunting), and (3) determine the specific cause (e.g., acute lung injury secondary to sepsis or decompensated COPD because of acute bronchitis). Defining the type of acute respiratory failure and determining the specific cause are prerequisites to optimal management.

The initial approach to diagnosis consists of considering information from four sources: (1) clinical history and physical examination; (2) physiologic abnormalities, particularly arterial blood gas derangements, which help establish the pathophysiologic mechanisms of hypoxemia; (3) chest radiographic findings; and (4) other tests aimed at elucidating specific causes. In many cases, the clinical picture from the history is so clear that the presumptive type of acute respiratory failure (and sometimes the cause) is obvious, so treatment can be started while confirmatory laboratory studies are ordered. In other cases, a clinician may be asked to see a patient because of an abnormal chest radiograph or abnormal arterial blood gases ordered by someone else and may elicit the pertinent history based on these clues. When the degree of hypoxemia is life-threatening, therapeutic decisions must be made quickly, even if data are limited. The clinician must obtain updated information continually and should view most therapeutic decisions as therapeutic trials, with careful monitoring to assess desired benefits and possible detrimental effects.

Clinical Evaluation

The presentation often reflects one of three clinical scenarios: (1) the effects of hypoxemia and/or respiratory acidosis, (2) the effects of primary (e.g., pneumonia) or secondary (e.g., heart failure) diseases involving the lungs, and (3) the nonpulmonary effects of the underlying disease process. The clinical effects of hypoxemia and/or respiratory acidosis manifest mainly in the central nervous system (e.g., irritability, agitation, changes in personality, depressed level of consciousness, coma) and the cardiovascular system (e.g., arrhythmias, hypotension, hypertension) (Table 104-3). In patients with underlying COPD (Chapter 88) with a gradual onset of acute respiratory failure, central nervous system abnormalities may be the major presenting

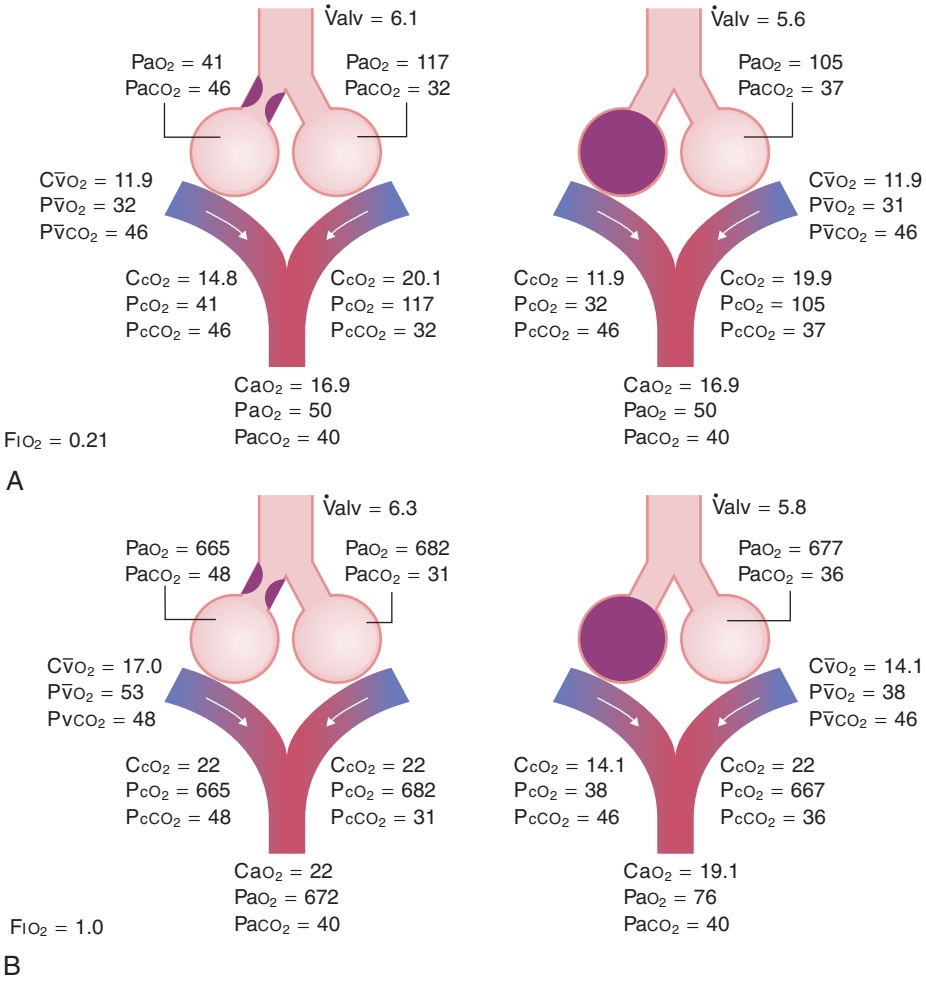

FIGURE 104-2. Arterial oxygenation. Comparison of the effect on arterial oxygenation of increasing the fraction of inspired oxygen (FIO_2) from breathing ambient air ($FIO_2 = 0.21$) (**A**) and breathing 100% oxygen ($FIO_2 = 1.0$) (**B**) with a low ventilation-to-perfusion ratio ($\dot{V}/\dot{Q}$) (left) and a shunt (right), using a two-compartment lung model. Shunting and decreased $\dot{V}/\dot{Q}$ can lead to identical arterial blood gases (partial pressure of oxygen in arterial blood [PaO_2] = 50 mm Hg; partial pressure of carbon dioxide in arterial blood [$PaCO_2$] = 40 mm Hg). The response to supplemental oxygen administration is markedly different. Hypoxemia is only partially corrected by breathing 100% oxygen when a shunt is present because arterial oxygenation represents an average of the end-capillary oxygen content (CcO_2) from various parts of the lung, not an average of the partial pressures of oxygen (partial pressure of carbon dioxide in the end-capillary blood [$PcCO_2$]). When the CcO_2 values are mixed, the PaO_2 is determined from the resultant content of oxygen in the arterial blood (CaO_2) by the oxyhemoglobin association-dissociation relationship (see Fig. 104-1). With low $\dot{V}/\dot{Q}$ (as is often the case in patients with chronic obstructive pulmonary disease), an increase in FIO_2 increases the alveolar partial pressure of oxygen (PO_2) of the low $\dot{V}/\dot{Q}$ unit and leads to a marked increase in arterial PO_2. The values in this figure were generated from modeling to result in the same $PaCO_2$ (40 mm Hg) for all four situations shown; this is the reason for slight changes in alveolar ventilation ($\dot{V}/\dot{Q}$ alv) for some of the conditions. Several assumptions are made: (1) no diffusion limitation is present; (2) oxygen consumption = 300 mL/minute, and CO_2 production = 240 mL/minute; (3) cardiac output = 6.0 L/minute; (4) the low $\dot{V}/\dot{Q}$ regions in the left panels represent 60% of the cardiac output perfusing alveoli with a $\dot{V}/\dot{Q}$ 25% of normal; and (5) the shunts in the right panels represent a 37% shunt (i.e., 37% of the cardiac output is perfusing alveoli with no ventilation).

TABLE 104-3 CLINICAL MANIFESTATIONS OF HYPOXEMIA AND HYPERCAPNIA

HYPOXEMIA	HYPERCAPNIA
Tachycardia	Somnolence
Tachypnea	Lethargy
Anxiety	Restlessness
Diaphoresis	Tremor
Altered mental status	Slurred speech
Confusion	Headache
Cyanosis	Asterixis
Hypertension	Papilledema
Hypotension	Coma
Bradycardia	Diaphoresis
Seizures	
Coma	
Lactic acidosis*	

*Usually requires additional reduction in oxygen delivery because of inadequate cardiac output, severe anemia, or redistribution of blood flow.

findings. Cyanosis, which requires at least 5 g/dL of unsaturated hemoglobin to be detectable, may not be seen before serious tissue hypoxia develops, especially in patients with underlying anemia.

Pulmonary symptoms and signs often reflect the respiratory disease causing the acute respiratory failure. Examples include cough and sputum with pneumonia (Chapter 97) or chest pain from pulmonary thromboembolism with infarction (Chapter 98). Dyspnea and respiratory distress are nonspecific reflections of the respiratory system's difficulty in meeting the increased demands from pulmonary and nonpulmonary diseases.

Physical findings may be associated with a particular pathologic lung process, such as pneumonia, causing bronchial breathing and crackles on auscultation, or the crackles (rales) of cardiogenic pulmonary edema (Chapter 58). Abnormal findings may be minimal or absent in patients with acute lung injury or pulmonary thromboembolism.

In some patients, the clinical picture is dominated by the underlying disease process, particularly with diseases that cause acute lung injury, such as sepsis (Chapter 108), severe pneumonia (Chapter 97), aspiration of gastric contents (Chapter 94), and trauma. In these conditions the physical examination is often nonspecific, with no obvious clues except, for example, fever with sepsis or pneumonia and hypotension with septic shock.

Assessment of Physiologic Abnormalities

The clinical suspicion of acute respiratory failure must be addressed by arterial blood gas analysis to answer several questions.

1. *Is hypoxemia present?* The answer is based largely on the value of the Pa_{O_2} or Sa_{O_2}, and the degree of the hypoxemia not only confirms the diagnosis of acute respiratory failure but also helps define its severity.
2. *Is hypoventilation present?* If the Pa_{CO_2} is elevated, alveolar hypoventilation is present.
3. *Does the degree of hypoventilation explain the hypoxemia?* If the $P(A\text{-}a)o_2$ is normal, hypoventilation explains the presence and degree of hypoxemia. In this case, the most likely causes of acute respiratory failure are central nervous system abnormalities and a chest wall abnormality. If the $P(A\text{-}a)o_2$ is increased but hypoventilation does not explain the hypoxemia, another condition must be present; common diagnoses include COPD, severe asthma, and early-stage acute respiratory distress syndrome (ARDS).
4. If hypoxemia exists without hypoventilation, an elevated $P(A\text{-}a)o_2$ should be confirmed, and the response to breathing an enhanced O_2 mixture would answer this question: *Is the increase in $P(A\text{-}a)o_2$ the result of a $\dot{V}/\dot{Q}$ abnormality or of shunting?* If hypoxemia is primarily the result of a $\dot{V}/\dot{Q}$ abnormality, the likely cause is an airway disease, either COPD or acute severe asthma, or a vascular disease, such as pulmonary

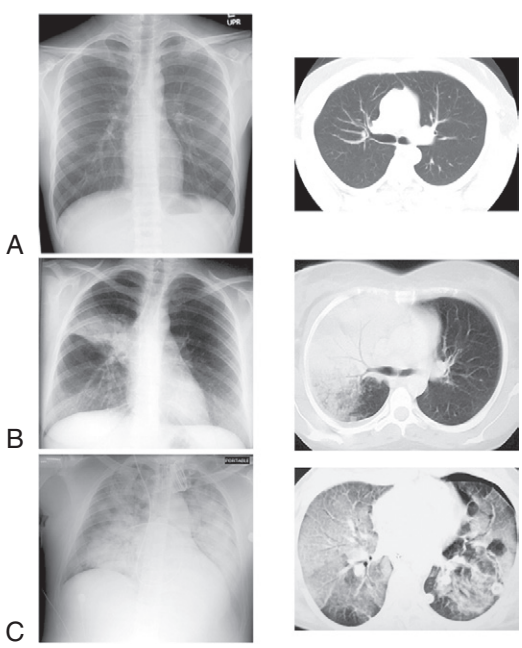

FIGURE 104-3. Chest radiographs (left) and computed tomography (CT) scans (right) of the three most common findings in diseases causing acute respiratory failure. A, Relatively clear chest, consistent with an acute exacerbation of airway disease (e.g., asthma, chronic obstructive pulmonary disease) or a central nervous system or neuromuscular disease as the cause of acute respiratory failure. **B**, Localized alveolar filling opacity, most commonly seen with acute pneumonia. **C**, Diffuse bilateral alveolar filling opacities consistent with acute lung injury and acute respiratory distress syndrome. The CT scan in **C** shows a small left pneumothorax and cavities or cysts that are not apparent on the anteroposterior chest radiograph.

thromboembolism. If shunting is the major explanation for the hypoxemia, processes that fill the air spaces (e.g., cardiogenic pulmonary edema, noncardiogenic pulmonary edema in acute lung injury or ARDS, or purulent pulmonary secretions in acute pneumonia) or, less commonly, an intracardiac or anatomic intrapulmonary shunt is the likely cause. Conditions that fill air spaces should be confirmed by an abnormal chest radiograph; if the radiograph is normal, an intracardiac shunt should be considered and confirmed by echocardiography.

Chest Radiography

The chest radiograph in acute respiratory failure is likely to show one of three patterns (Fig. 104-3): (1) normal (or relatively normal), (2) localized alveolar filling opacities, or (3) diffuse alveolar filling opacities. Diffuse interstitial opacities are also possible, but diseases that cause this pattern usually have a more gradual onset and are associated with chronic respiratory failure. If the chest radiograph is normal (i.e., it is clear or relatively clear), airway diseases, such as COPD and asthma, or pulmonary vascular diseases, such as thromboembolism, are more likely. If a localized alveolar filling abnormality is present, pneumonia is the major consideration, but pulmonary embolism and infarction should also be considered. When diffuse (bilateral) alveolar filling abnormalities are present, cardiogenic pulmonary edema, acute lung injury (e.g., as seen in sepsis, trauma, or aspiration of gastric contents), and diffuse pneumonia are the major considerations. The combination of the chest radiograph and the arterial blood gas interpretation can be helpful. The finding of a significant shunt may suggest acute lung injury in a patient in whom this diagnosis was not clinically obvious; the chest radiograph should help to confirm that possibility.

Other Evaluations

All patients with acute respiratory failure should have a complete blood count, including a platelet count; routine blood chemistry tests; prothrombin time; and urinalysis to screen for possible underlying causes and comorbid conditions. Other blood tests should be guided by the clinical picture. Examples include a serum amylase level if pancreatitis is a possible cause of ARDS and thyroid indices if severe hypothyroidism is a possible cause of hypoventilation. Blood cultures are recommended whenever sepsis is suspected.

Any abnormal fluid collections, especially pleural effusion (Chapter 99), should be aspirated for diagnostic purposes. Sputum Gram stain and culture are indicated when pneumonia is suspected.

Other specific tests should be directed by the history, physical examinations, arterial blood gas levels, and chest radiograph. An abdominal computed tomography (CT) scan may be indicated to search for the source of infection in a patient with sepsis and acute lung injury. A chest CT scan may help define pulmonary disease if the chest radiograph is not definitive. A CT arteriogram of the pulmonary circulation may diagnose pulmonary thromboembolism (Chapter 98). A head CT scan may be indicated if a stroke involving the respiratory center is suspected. Routine blood chemistry studies can detect diabetic ketoacidosis or renal failure as contributing causes.

TREATMENT Rx

General Measures

The management of acute respiratory failure depends on its cause, its clinical manifestations, and the patient's underlying status. Certain goals apply to all patients: (1) improvement of the hypoxemia to eliminate or markedly reduce the acute threat to life, (2) improvement of the acidosis if it is considered life-threatening, (3) maintenance of cardiac output or improvement if cardiac output is compromised, (4) treatment of the underlying disease process, and (5) avoidance of predictable complications.

The precise methods for improving hypoxemia depend on the cause of the acute respiratory failure. An increase in the inspired O_2 concentration is a cornerstone of treatment for nearly all patients, however.

The level of acidosis that requires treatment other than for the underlying disease process is not clear. Although normalization of the arterial pH was suggested in the past, respiratory acidosis is apparently well tolerated in many patients with severe ARDS, so a patient with a pH of 7.15 or greater may not require bicarbonate therapy. If the acidemia coexists with clinical complications, such as cardiac arrhythmias or a decreased level of consciousness, that have no other obvious cause, treatments to increase pH should be considered. The therapeutic goal is alleviation or reduction of the accompanying complications by improving the level of acidosis; it usually is not necessary to normalize the pH (Chapter 120).

The maintenance of cardiac output is crucial for O_2 delivery in acute respiratory failure, especially because mechanical ventilation and positive end-expiratory pressure (PEEP) may compromise cardiac output. Placement of a pulmonary artery catheter allows measurement of cardiac output and filling pressures, but patients who have these catheters do no better than similar patients managed without them.[1]

Many therapeutic interventions that improve short-term physiologic variables may worsen long-term, clinically important outcomes. Transfusing all patients to maintain a hemoglobin greater than 10 g/dL increases mortality in critically ill patients who have not had an acute myocardial infarction and do not have unstable angina, even though the O_2 carrying capacity of the blood is acutely increased. Use of a relatively large tidal volume (e.g., 12 mL/kg predicted body weight, which is equivalent to approximately 10 to 10.5 mL/kg measured body weight in patients who are somewhat overweight) increases mortality in patients with ARDS when compared with a lower tidal volume (6 mg/kg predicted body weight), even though it raises Pa_{O_2} more in the short term than does a lower tidal volume. Conservative use of fluids improves lung function and shortens the duration of mechanical ventilation and intensive care.[2]

Improvements in oxygenation, acid-base status, and cardiac output are of no more than temporary benefit unless the underlying disease processes are diagnosed and treated properly. In patients with acute lung injury, sepsis may worsen injury to the lung and other organs despite optimal supportive care. Similarly, if the precipitating cause of acute respiratory failure in a patient with COPD is not identified and treated, supportive care is likely to be futile. Complications may arise from the physiologic effects of the gas exchange abnormality, from the disease processes causing the acute respiratory failure, from being critically ill and its associated incursions on homeostasis (e.g., sleep deprivation), or from iatrogenic complications of therapy.

Mechanical Therapy to Improve Oxygenation

A Pa_{O_2} greater than 60 mm Hg is usually adequate to produce an Sa_{O_2} in the low to middle 90s. The Pa_{O_2} can be increased by the administration of supplemental O_2, by pharmacologic manipulations, by continuous positive airway pressure (CPAP), by mechanical ventilation with or without maneuvers such as PEEP, and by the prone position. PEEP, pharmacologic manipulations, and positioning are used primarily in patients with acute lung injury (see later).

The initial choice of the concentration and amount of supplemental O_2 is based on the severity of the hypoxemia, the clinical diagnosis, the likely mechanism causing the hypoxemia, and the O_2 delivery systems available. For the tracheal FI_{O_2} to be the same as the delivered FI_{O_2}, the O_2 delivery system must deliver a flow that matches the patient's peak inspiratory flow rate with gas of a known FI_{O_2}. High-flow O_2 blenders can achieve this goal by delivering gas at 80 L/minute or greater to a nonintubated patient. These systems require a large flow of O_2 (from a wall unit or tank), however, and are not universally available. Other systems for nonintubated patients (including nasal prongs, simple face masks, and non-rebreather and partial rebreather masks) use a

simple regulator that mixes room air with O_2 at 12 L/minute from a wall unit or tank, with resulting flows that are frequently unable to match the patient's peak inspiratory flow rate. The patient entrains more air from the environment, and the resulting tracheal F_{IO_2} or partial pressure of oxygen in inspired gas (P_{IO_2}) is unknown. The amount of air entrained depends on the patient's inspiratory pattern and minute ventilation. Although the resulting F_{IO_2} is unknown, these systems are satisfactory if the delivery is constant and if they result in adequate arterial O_2 saturation, as monitored by arterial blood gases or oximetry. Nasal prongs can deliver a tracheal F_{IO_2} of approximately 0.50, and nonrebreather masks can deliver 50 to 100% O_2; in both cases, this depends on the inspiratory pattern and flow rate. If only hypoventilation or $\dot{V}/\dot{Q}$ mismatch is present, only a small increment in F_{IO_2} (e.g., an F_{IO_2} of 0.24 or 0.28 delivered by a Venturi principle face mask or by mechanical ventilation; or 1 to 2 L/minute O_2 delivered by nasal prongs) is likely to be required. By comparison, if marked shunting or many lung units with low but not zero $\dot{V}/\dot{Q}$ are the cause of hypoxemia, a considerably higher F_{IO_2} (e.g., >0.7) may be required, and even this high F_{IO_2} may not reverse the hypoxemia. A common practice when a significant shunt is suspected is to give an F_{IO_2} of 1.0, then adjust the F_{IO_2} downward as guided by the resulting Pa_{O_2} or Sa_{O_2}.

The O_2 concentration that is toxic to the lungs in critically ill patients is not known, but prior injury may provide tolerance to O_2 toxicity, whereas other conditioning agents, such as bleomycin, may enhance oxidative injury. An F_{IO_2} of 0.7 or higher is generally considered injurious to the normal human lung. Because it is unknown what lower concentration is safe, however, patients should be given the lowest F_{IO_2} that provides an adequate Sa_{O_2} (≥90%). If an F_{IO_2} equal to or greater than 0.5 to 0.7 is required for adequate oxygenation, other measures, especially PEEP or CPAP, should be considered. Even a lower F_{IO_2} of about 0.5 may be associated with impaired ciliary action in the airways and impaired bacterial killing by alveolar macrophages, but the clinical importance of these effects is not known.

A low concentration of supplemental O_2 can be administered by nasal prongs or nasal cannula, which most patients find comfortable and allows them to cough, speak, eat, and drink while receiving O_2. When the nasal passages are open, the P_{IO_2} does not depend too much on whether the patient breathes through the nose or the mouth because O_2 is entrained from the posterior nasal pharynx during a breath taken through the mouth. The level of O_2 can be adjusted by the flow rate to the nasal prongs. In patients with COPD, flows as low as 0.5 to 2 L/minute are usually adequate unless an intrapulmonary shunt is contributing to the hypoxemia, as usually occurs in acute pneumonia. At flows greater than approximately 6 L/minute, only a small further augmentation in the P_{IO_2} can be achieved. Because gas flow through the nose has a drying and irritating effect, a face mask should be considered at high flow rates. O_2 face masks using the Venturi principle allow the regulation of F_{IO_2} and can be particularly useful when COPD is suspected, and it is important to avoid the CO_2 retention that can be associated with the unregulated administration of O_2. A higher F_{IO_2} of 0.5 to nearly 1.0 can be administered through a non-rebreathing face mask with an O_2 reservoir. If an F_{IO_2} equal to or greater than 0.70 is required for more than several hours, particularly in an unstable patient, endotracheal intubation should be considered so O_2 can be administered by a closed system with reliable maintenance of the patient's Sa_{O_2}. Indications for placing an artificial airway in a patient with acute respiratory failure include airway protection against massive aspiration of gastric contents, delivery of an increased F_{IO_2}, facilitation of prolonged mechanical ventilation, and to aid in the control of respiratory secretions (Chapter 105).

Ventilatory maneuvers that may increase arterial oxygenation include mechanical ventilation itself and the administration of PEEP or CPAP, all of which allow ventilation of areas of the lung that were previously poorly ventilated or unventilated. Although large tidal volumes with mechanical ventilation may open areas of atelectasis and may improve oxygenation initially, these higher tidal volumes can cause lung injury, particularly if the lung is already injured (Chapter 105).

CPAP refers to the maintenance of positive pressure during the respiratory cycle while breathing spontaneously. PEEP refers to the maintenance of positive pressure throughout the expiratory cycle when it is applied together with mechanical ventilation (Chapter 105). CPAP and PEEP can result in recruitment of microatelectatic regions of the lung that are perfused but were not previously ventilated, thus contributing substantially to hypoxemia. CPAP and PEEP have the theoretical advantage of keeping some of these regions open during exhalation, thus preventing cyclic closure and reopening of lung units, which can result in alveolar wall stress and injury.

Supportive Measures

Every patient with acute respiratory failure is at risk for deep vein thrombosis, pulmonary thromboembolism, and gastric stress ulceration. Prophylactic anticoagulation is recommended in patients who are not at high risk for bleeding complications; sequential leg compression therapy may be preferred for high-risk patients (Chapter 81).

The best means of preventing stress ulceration is not known, but current evidence indicates that the use of an H_2-blocker is superior to the gastric administration of sucralfate, based on a large randomized, controlled trial that found a higher incidence of significant bleeding in patients receiving sucralfate than in those receiving ranitidine. Evidence also indicates that proton pump inhibitors may be useful in the acute care setting. There is little firm evidence to guide nutritional management in patients with acute respiratory failure (Chapters 221 and 224).

Current evidence supports maintaining the head of the bed at a 45-degree angle to reduce aspiration in critically ill patients. Attempts should be made to ensure a normal day-night sleep pattern, including minimizing activity and reducing direct lighting at night. The patient should change position frequently, including sitting in a chair and walking short distances if possible, even while receiving mechanical ventilatory support. Mobilization can enhance the removal of secretions, help maintain musculoskeletal function, reduce the risk of deep vein thrombosis, and provide psychological benefits.

SPECIFIC ACUTE RESPIRATORY FAILURE SYNDROMES

Chronic Obstructive Pulmonary Disease

EPIDEMIOLOGY AND PATHOBIOLOGY

The epidemiology and pathobiology of COPD are discussed in Chapter 88.

CLINICAL MANIFESTATIONS

When COPD causes acute respiratory failure, patients commonly have a history of increasing dyspnea and sputum production. Acute respiratory failure may manifest in more cryptic ways, however, such as changes in mental status, arrhythmias, or other cardiovascular abnormalities. Acute respiratory failure must be considered whenever patients with COPD have significant nonspecific clinical changes.

DIAGNOSIS

The diagnosis can be confirmed or excluded by arterial blood gas analysis. The pH is helpful in assessing whether the hypoventilation is partly or exclusively acute: The pH drops by approximately 0.08 for each 10 mm Hg rise in the Pa_{CO_2} in acute respiratory acidosis without renal compensation. By comparison, in chronic respiratory acidosis with normal renal compensation, the pH drops only about 0.03 for each 10 mm Hg rise in the Pa_{CO_2}.

TREATMENT

General Care

As soon as acute respiratory failure is confirmed in a patient with COPD, attention must focus on detecting any precipitating events (Table 104-4), including decreased ventilatory drive, commonly because of oversedation; decreased muscle strength or function, often related to electrolyte abnormalities, including hypophosphatemia and hypomagnesemia; decreased chest wall elasticity, possibly related to rib fracture, pleural effusion, ileus, or ascites; atelectasis, pneumonia, or pulmonary edema; increased airway resistance, caused by bronchospasm or increased secretions; or increased metabolic O_2 requirements, such as with systemic infection. Many of these abnormalities can impair the cough mechanism, diminish the clearance of airway secretions, and precipitate acute respiratory failure.

Infection

The most common specific precipitating event is airway infection, especially acute bronchitis. The role played by viral agents, *Mycoplasma pneumoniae,* chronic contaminants of the lower airway such as *Haemophilus influenzae* and *Streptococcus pneumoniae,* and other acute pathogens is difficult to determine on a clinical or even microbiologic basis. Acute exacerbations of COPD commonly result from new infections rather than re-emergence of an infection from preexisting colonization. Antibiotics modestly shorten the duration of the exacerbation, with no significant increase in toxicity, compared with placebo; the impact of antibiotics on the subsequent emergence of resistant organisms is not known. It is standard practice to use antibiotics to treat a patient with COPD who has an exacerbation severe enough to cause acute respiratory failure and who has evidence consistent with acute tracheobronchitis (Chapters 88 and 96). Pneumonia may account for 20% of cases of acute respiratory failure in patients with COPD. Compared with the physiologically normal population, patients with COPD who have community-acquired pneumonia are more likely to have gram-negative enteric bacteria or *Legionella* infections and are more likely to have antibiotic-resistant organisms.

Other Precipitating Causes

Other common precipitating causes of acute respiratory failure include heart failure and worsening of the underlying COPD, often related to noncompliance with medications. Less common and often difficult to diagnose in this setting is pulmonary thromboembolism.

TABLE 104-4 KEY PRINCIPLES IN THE MANAGEMENT OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE PATIENTS WITH ACUTE RESPIRATORY FAILURE

1. Monitor and treat life-threatening hypoxemia (these measures should be performed virtually simultaneously).
   a. Assess the patient clinically, and measure oxygenation by arterial blood gases and/or oximetry.
      (1) If the patient is hypoxemic, initiate supplemental oxygen therapy with nasal prongs (low flows [0.5-2. L/min] are usually sufficient) or by Venturi face mask (24 or 28% oxygen delivered).
      (2) If the patient needs ventilatory support, consider noninvasive ventilation.
      (3) Determine whether the patient needs to be intubated; this is almost always a clinical decision. Immediate action is required if the patient is comatose or severely obtunded.
   b. A reasonable goal in most patients is Pa_{O_2} of 55-60 mm Hg or Sa_{O_2} of 88-90%.
   c. After changes in F_{IO_2}, check blood gases and check regularly for signs of carbon dioxide retention.
2. Start to correct life-threatening acidosis.
   a. The most effective approach is to correct the underlying cause of ARF (e.g., bronchospasm, infection, heart failure).
   b. Consider ventilatory support, based largely on clinical considerations.
   c. With severe acidosis, the use of bicarbonate can be considered, but it is often ineffective, and there is little evidence of a clinical benefit.
3. If ventilatory support is required, consider noninvasive mechanical ventilation.
   a. The patient must have intact upper airway reflexes and be alert, cooperative, and hemodynamically stable.
   b. Careful monitoring is required; if the patient does not tolerate the mask, becomes hemodynamically unstable, or has a deteriorating mental status, consider intubation.
4. Treat airway obstruction and the underlying disease process that triggered the episode of ARF.
   a. Treat airway obstruction with pharmacologic agents: systemic corticosteroids and bronchodilators (ipratropium and/or β-adrenergic agents).
   b. Improve secretion clearance: encourage the patient to cough, administer chest physical therapy if cough is impaired and a trial appears effective.
   c. Treat the underlying disease process (e.g., antibiotics, diuretics).
5. Prevent complications of the disease process and minimize iatrogenic complications.
   a. Pulmonary thromboembolism prophylaxis: use subcutaneous heparin if no contraindications exist.
   b. Gastrointestinal complications: administer prophylaxis for gastrointestinal bleeding.
   c. Hemodynamics: if the patient is ventilated, monitor and minimize auto-PEEP.
      (1) Treat the underlying obstruction.
      (2) Minimize minute ventilation; use controlled hypoventilation.
      (3) Use small tidal volumes; increase the inspiratory flow rate to decrease the inspiratory time and lengthen the expiratory time.
   d. Cardiac arrhythmias: maintain oxygenation and normalize electrolytes.

ARF = acute respiratory failure; F_{IO_2} = fraction of inspired oxygen; Pa_{O_2} = partial pressure of oxygen in arterial blood; PEEP = positive end-expiratory pressure; Sa_{O_2} = oxygen saturation.

Site of Care

Many patients with COPD and acute respiratory failure can be managed on a general medical hospital floor rather than in an intensive care unit if the precipitating cause of acute respiratory failure has been diagnosed and is potentially responsive to appropriate therapy, if any blood gas abnormalities respond to O_2 therapy and are not life-threatening, if the patient can cooperate with the treatment, and if appropriate nursing and respiratory care can be provided (Chapter 88). An unstable patient who requires closer observation and monitoring should be admitted to an intensive care unit.

Mechanical Therapy

The decision to use mechanical ventilation in patients with COPD and acute respiratory failure must be made on clinical grounds and is not dictated by any particular arterial blood gas values. In general, if the patient is alert and is able to cooperate with treatment, mechanical ventilation is unlikely to be necessary. If ventilatory support is required (Chapter 105), the decision is whether to use noninvasive positive-pressure ventilation therapy (without endotracheal intubation) or endotracheal intubation with positive-pressure ventilation. Many studies have demonstrated that noninvasive positive-pressure ventilation is preferred for patients with COPD and can decrease mortality if applied in appropriate patients with no factors that are likely to lead to complications.■

TABLE 104-5 DISORDERS ASSOCIATED WITH ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

COMMON
Sepsis (gram-positive or gram-negative bacterial, viral, fungal, or parasitic infection)
Diffuse pneumonia (bacterial, viral, or fungal)
Aspiration of gastric contents
Trauma (usually severe)
LESS COMMON
Near-drowning (fresh or salt water)
Drug overdose
Acetylsalicylic acid
Heroin and other narcotic drugs
Massive blood transfusion (likely a marker of severe trauma, but also seen with severe gastrointestinal bleeding, especially in patients with severe liver disease)
Leukoagglutination reactions
Inhalation of smoke or corrosive gases (usually requires high concentrations)
Pancreatitis
Fat embolism
UNCOMMON
Miliary tuberculosis
Paraquat poisoning
Central nervous system injury or anoxia (neurogenic pulmonary edema)
Cardiopulmonary bypass

PROGNOSIS

Acute respiratory failure in patients with severe COPD is associated with an in-hospital mortality of 6 to 20%. The severity of the underlying disease and the severity of the acute precipitating illness are important determinants of hospital survival. Hospital mortality is higher if the respiratory failure is associated with a pH less than 7.25. The pH, the $Paco_2$, and other clinical characteristics are not very reliable in predicting a particular patient's chances of survival.

Acute Lung Injury/Acute Respiratory Distress Syndrome

DEFINITION

ARDS was first described in 1967 as the abrupt onset of diffuse lung injury characterized by severe hypoxemia (shunting) and generalized pulmonary infiltrates on the chest radiograph in the absence of overt cardiac failure. In the early 1990s the term *acute lung injury* was officially introduced to include traditional ARDS and less severe forms of lung injury. Both acute lung injury and ARDS, by definition, require bilateral pulmonary infiltrates compatible with pulmonary edema in the absence of clinical heart failure (usually determined by the lack of elevated left atrial pressures). The two are differentiated by the degree of abnormal oxygenation: Patients are defined as having acute lung injury if the Pa_{O_2} divided by the F_{IO_2} (Pa_{O_2}/F_{IO_2}, also called the P/F ratio) is less than or equal to 300. When the Pa_{O_2}/F_{IO_2} is less than or equal to 200, the patient meets the criteria for ARDS.

EPIDEMIOLOGY

Acute lung injury and ARDS are major public health problems and major causes of death. The annual incidence of acute lung injury is about 80 cases per 100,000 adult population. Case-fatality rates are 30 to 50% and are highly dependent on disease severity and the underlying predisposing condition.

ETIOLOGY

Acute lung injury is a clinical syndrome triggered by some other cause (Table 104-5). This underlying precipitating factor may affect and injure the lungs directly, such as in diffuse pneumonia or aspiration of gastric contents, or it may affect the lungs indirectly, such as in severe sepsis (Chapter 108) or severe nonthoracic trauma (Chapter 112). Severe sepsis is the most common precipitating cause of acute lung injury worldwide. The organisms vary widely, ranging from gram-negative and gram-positive bacteria and viruses (e.g., H1N1 influenza in 2009) to leptospiral infections or malaria. It may be difficult to determine whether pneumonia is diffuse, with endobronchial spread involving most of the lungs, or whether localized pneumonia has precipitated a sepsis syndrome, with secondary injury to other parts of the lung.

PATHOBIOLOGY

Pathology

Despite the variety of underlying disease processes leading to acute lung injury, the response to these insults in the lung is monotonously characteristic, with similar clinical findings, physiologic changes, and morphologic abnormalities. The pathologic abnormalities in acute lung injury and ARDS are nonspecific and are described as *diffuse alveolar damage* by pathologists. The initial process is inflammatory, with neutrophils usually predominating in the alveolar fluid. Hyaline membranes develop, similar to those seen in premature infants with infant respiratory distress syndrome, presumably related to the presence of large-molecular-weight proteins that have leaked into the alveolar space. Alveolar flooding leads to impairment of surfactant, which is abnormal in quantity and quality. The result is microatelectasis, which may be associated with impaired immune function. Cytokines and other inflammatory mediators are usually markedly elevated, although with different patterns over time in the bronchoalveolar lavage fluid and the systemic blood. Lung repair is also disturbed; early evidence of pro-fibrotic processes includes the appearance of breakdown products of pro-collagen in the bronchoalveolar lavage fluid, followed by scarring. The pulmonary fibrosis observed on lung biopsy or at autopsy is identical to that seen in patients with idiopathic pulmonary fibrosis (Chapter 92). Because lung function improves over time in survivors of ARDS, however, it has been assumed that this scarring is often reversible.

Pathophysiology

The physiologic abnormalities are dominated by severe hypoxemia with shunting, decreased lung compliance, decreased functional residual capacity, and increased work of breathing. Initially, the $Paco_2$ is low or normal, usually associated with increased alveolar ventilation. The initial abnormalities in oxygenation are thought to be related to alveolar flooding and collapse. As the disease progresses, especially in patients who require ventilatory support, fibroproliferation develops; the lungs (including alveoli, blood vessels, and small airways) remodel and scar, with a loss of microvasculature. These changes may lead to pulmonary hypertension and increased dead space; marked elevations in minute ventilation are required to achieve a normal $Paco_2$, even as oxygenation abnormalities are improving.

CLINICAL MANIFESTATIONS

In most cases of acute lung injury, the onset either coincides with or occurs within 72 hours of the onset of the underlying disease process; the mean time from onset of the underlying cause to onset of acute lung injury is 12 to 24 hours. The presenting picture is dominated by respiratory distress and the accompanying laboratory findings of severe hypoxemia and generalized infiltrates or opacities on the chest radiograph. Alternatively, it may be dominated by manifestations of the underlying disease process, such as severe sepsis with hypotension and other manifestations of systemic infection.

DIAGNOSIS

The key to diagnosis is to distinguish ARDS from cardiogenic pulmonary edema (Table 104-6). No specific biochemical test exists to define ARDS. Certain blood or bronchoalveolar lavage (Chapter 85) abnormalities are frequent but are not sufficiently specific to be useful clinically.

TABLE 104-6 FEATURES ASSOCIATED WITH NONCARDIOGENIC AND CARDIOGENIC PULMONARY EDEMA*

NONCARDIOGENIC EDEMA (ARDS)	CARDIOGENIC EDEMA/VOLUME OVERLOAD
PRIOR HISTORY	
Younger	Older
No history of heart disease	Prior history of heart disease
Appropriate fluid balance (difficult to assess after resuscitation from shock or trauma)	Hypertension, chest pain, new-onset palpitations; positive fluid balance
PHYSICAL EXAMINATION	
Flat neck veins	Elevated neck veins
Hyperdynamic pulses	Left ventricular enlargement, lift, heave, dyskinesis
Physiologic gallop	S_3 and S_4; murmurs
Absence of edema	Edema: flank, presacral, legs
ELECTROCARDIOGRAM	
Sinus tachycardia, nonspecific ST-T wave changes	Evidence of prior or ongoing ischemia, supraventricular tachycardia, left ventricular hypertrophy
CHEST RADIOGRAPH	
Normal heart size	Cardiomegaly
Peripheral distribution of infiltrates	Central or basilar infiltrates; peribronchial and vascular congestion
Air bronchograms common (80%)	Septal lines (Kerley's lines), air bronchograms (25%), pleural effusion
HEMODYNAMIC MEASUREMENTS	
Pulmonary artery wedge pressure <15 mm Hg, cardiac index >3.5 L/min/m^2	Pulmonary capillary wedge pressure >18 mm Hg, cardiac index <3.5 L/min/m^2 with ischemia, may be >3.5 L/min/m^2 with volume overload

*These features are neither highly sensitive nor specific. Although the findings are more commonly associated with the type of pulmonary edema as listed, they do not have high positive or negative predictive value.
ARDS = acute respiratory distress syndrome.

TREATMENT

Rx

Treatment for acute lung injury and ARDS consists predominantly of respiratory support and treatment of the underlying disease (Fig. 104-4). Although sepsis is a common predisposing condition for the development of acute lung injury, a small study examining the usefulness of activated protein C in patients with acute lung injury did not demonstrate any beneficial effects in terms of ventilator-free days or mortality.

Mechanical Therapy

Current recommendations for mechanical ventilation via endotracheal intubation (Table 104-7) emphasize lower tidal volumes based on the patient's predicted body weight (Chapter 105).[A] PEEP is a mainstay in the ventilatory strategy for acute lung injury; although the method for determining the optimal level of PEEP has not been established, higher PEEP levels appear to benefit patients with ARDS.[A,B] PEEP may allow a lower Fio_2 to provide adequate oxygenation, thus avoiding O_2 toxicity. It also may prevent the cyclic collapse and reopening of lung units, a process that is thought to be a major cause of ventilator-induced lung injury, even when adequate oxygenation can be obtained at relatively low levels of Fio_2. The early use of cisatracurium besylate (15 mg rapid infusion followed by 37.5 mg/hr for 48 hours), a neuromuscular blocker, can reduce ARDS mortality rates by about 25%.[B] In patients with severe ARDS who do not respond to standard therapy but otherwise have a reasonable life expectancy, extracorporeal membrane oxygenation can improve the 6-month survival from 47 to 63% at an acceptable cost of about $35,000 per quality-adjusted year of life saved.[B]

Acute Respiratory Failure without Lung Disease

Acute respiratory failure without pulmonary abnormalities (see Table 104-2) is seen in patients with depressed ventilatory drive secondary to central nervous system dysfunction and in patients with severe neuromuscular disease. The prototypical patient with suppressed ventilatory drive has taken an overdose of a sedative or tranquilizing medication (Chapter 110). The prototypical patient with neuromuscular disease has Guillain-Barré syndrome (Chapter 428). The treatment for both types of patients is supportive. In the case of a patient with a sedative overdose, the threshold for intubation with mechanical ventilatory support should be low because this temporary condition is quickly reversible when the responsible drug is eliminated. Such a patient may require intubation for airway protection against aspiration of gastric contents.

Patients with Guillain-Barré syndrome or other forms of progressive neuromuscular disease should be monitored with serial measurements of vital capacity. In general, when the vital capacity decreases to less than 10 to 15 mL/kg body weight, intubation and mechanical ventilatory support should be considered without regard to the patient's $Paco_2$.

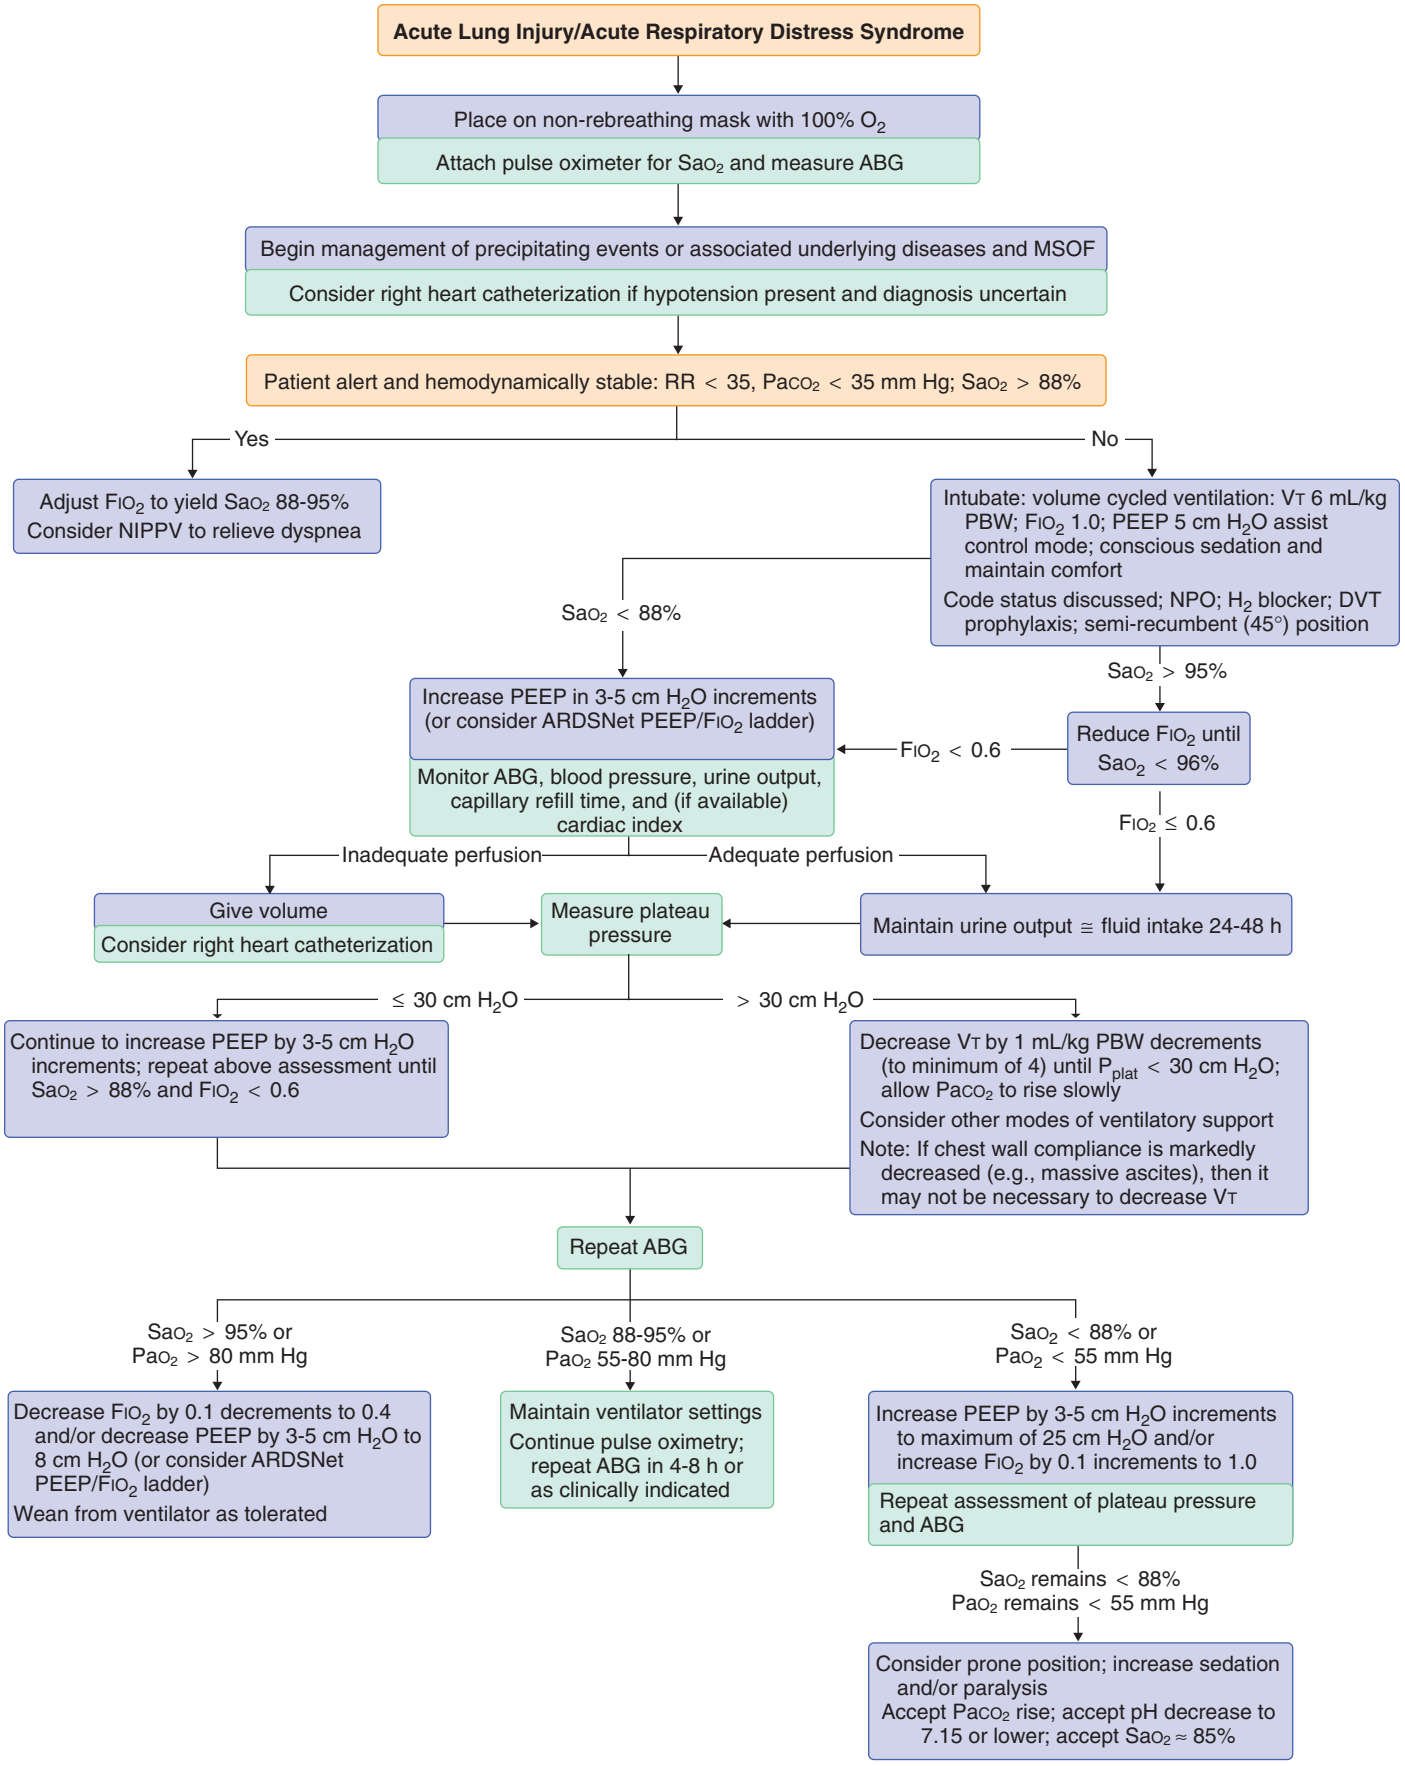

FIGURE 104-4. Algorithm for the initial management of acute respiratory distress syndrome. ABG = arterial blood gas analysis; CO_2 = carbon dioxide; DVT = deep vein thrombosis; FIO_2 = inspired oxygen concentration; MSOF = multisystem organ failure; NIPPV = noninvasive intermittent positive-pressure ventilation; O_2 = oxygen; $PaCO_2$ = arterial partial pressure of carbon dioxide; PaO_2 = arterial partial pressure of oxygen; PBW = predicted body weight; PEEP = positive end-expiratory pressure; P_{plat} = plateau pressure; RR = respiratory rate; SaO_2 = arterial oxygen saturation; VT = tidal volume.

TABLE 104-7 ARDSNet VENTILATORY MANAGEMENT PROTOCOL FOR TIDAL VOLUME AND PLATEAU PRESSURE

Calculate PBW:
- Male PBW: 50 + 2.3 (height in inches − 60) or 50 + 0.91 (height in centimeters − 152.4)
- Female PBW: 45.5 + 2.3 (height in inches − 60) or 45.5 + 0.91 (height in centimeters − 152.4)

Select assist control mode
Set initial V_T at 8 mL/kg PBW
Reduce V_T by 1 mL/kg at intervals < 2 hr until V_T = 6 mL/kg PBW
Set initial RR to approximate baseline minute ventilation (maximum RR = 35/min)
Set inspiratory flow rate higher than patient's demand (usually > 80 L/min)
Adjust V_T and RR further to achieve P_{plat} and pH goals
- If P_{plat} > 30 cm H_2O: decrease V_T by 1 mL/kg PBW (minimum = 4 mL/kg PBW)
- If pH ≤ 7.30, increase RR (maximum = 35)
- If pH < 7.15, increase RR to 35; consider sodium bicarbonate administration or increase V_T

PBW = predicted body weight; P_{plat} = plateau pressure (airway pressure at the end of delivery of a tidal volume breath during a condition of no airflow); RR = respiratory rate; V_T = tidal volume. See the ARDSNet website (*http://www.ardsnet.org*) for further details about the protocol, including the approach for setting positive end-expiratory pressure and fraction of inspired oxygen.

MECHANICAL VENTILATION

ARTHUR S. SLUTSKY AND LEONARD D. HUDSON

DEFINITION

Mechanical ventilation, a life-sustaining therapy for patients with respiratory failure (Chapter 104), is provided partially or fully by external sources through a variety of mechanical strategies termed *modes of ventilation.* In addition to providing ventilation, the treating physician can also alter the inspired oxygen tension, the pressure at the airway opening at the end of a breath, and other facets of the volume or pressure time pattern imposed on the patient. Current approaches focus on ventilatory strategies that minimize iatrogenic injury through the use of tidal volumes on the order of 6 mL/kg of predicted body weight or end-inspiratory airway pressures of 25-30 cm H_2O or less, even if the arterial blood gases achieved are not in the "normal range."

TYPES OF MECHANICAL VENTILATORS

Negative-Pressure Ventilators

Delivery of gas to the lungs requires a hydrostatic pressure gradient between the airway opening and the airways and alveoli. During spontaneous breathing, this pressure gradient is generated by development of a negative pleural pressure as a result of contraction of the respiratory muscles. Some ventilators operate by generating negative pressure around the chest wall (e.g., cuirass) or the entire body below the neck (e.g., iron lung). Such ventilators have two major advantages: there is no need to intubate the patient to apply mechanical ventilation, and the detrimental hemodynamic consequences are minimized if the ventilators generate negative pressure solely around the chest wall. However, these ventilators have several difficulties. First, the device around the chest wall or the patient's body used to apply the negative pressure must have an adequate seal so that the negative pressure is not dissipated to the room—a task that is not always easy to accomplish in a manner that is comfortable for the patient. Second, the nursing care of patients in such ventilators can be difficult, especially with iron lungs, which enclose the entire patient from the neck down. Although this type of ventilator was widely used during the polio epidemic of the mid-1950s, its only current use is for patients who have relatively normal lungs but who require long-term ventilation for neuromuscular problems.

Positive-Pressure Ventilators

The most widely used mechanical ventilation approach is to deliver gas to the lung using positive-pressure ventilation (PPV) applied through an endotracheal tube, a tracheostomy, or a tight-fitting mask. The approach using a mask is considered noninvasive ventilation (NIV) and is considered separately.

The most basic mode of PPV is *controlled ventilation,* in which a preset tidal volume at a predetermined rate is delivered to the patient regardless of the patient's requirements or efforts. This form of ventilation is usually used in patients who cannot initiate spontaneous breaths (e.g., heavily sedated or paralyzed patients) or in those who need full ventilatory support because of extremely severe pulmonary or cardiovascular disease (e.g., severe shock). This mode is not routinely used in patients who are able to make spontaneous ventilatory efforts because it can lead to asynchrony between the patient's efforts and the breaths generated by the ventilator. *Assisted ventilation* is the term used when spontaneous ventilatory efforts are present; the onset of a breath is triggered by the patient's respiratory efforts, rather than being based strictly on the time between breaths.

Mechanical ventilation can be applied using either volume-controlled or pressure-controlled modes. In volume-controlled ventilation, the desired tidal volume and respiratory rate are set by the user, and the airway pressure is the dependent variable that changes with the mechanical properties of the patient's respiratory system and with the flow settings on the ventilator. In pressure-controlled ventilation, the pressure imposed at the airway opening and the respiratory rate are set by the user, and the tidal volume becomes the dependent variable.

Positive End-Expiratory Pressure

A key characteristic that can be used with any of the modes of ventilation is the level of the end-expiratory pressure. Positive end-expiratory pressure (PEEP) is used in patients with diffuse pulmonary diseases (e.g., pulmonary edema, acute respiratory distress syndrome [ARDS]) to recruit collapsed alveolar regions and to maintain them in a recruited state, to reopen collapsed airways, to redistribute fluid in the lung, to increase functional residual capacity, and to redistribute ventilation to dependent regions. All these changes can improve the ratio of ventilation to perfusion as well as oxygenation, thereby allowing the fractional inspiratory concentration of oxygen (F_{IO_2}) to be reduced. PEEP does not usually improve alveolar ventilation and, in fact, may increase dead space by overdistending alveoli, with a concomitant decrease in alveolar capillary blood flow in certain regions of the lung. PEEP can also be administered to spontaneously breathing subjects by using a technique termed *continuous positive airway pressure.* Continuous positive airway pressure and PEEP can be used in patients with exacerbations of chronic obstructive pulmonary disease (COPD) to overcome auto-PEEP (see later) and to minimize the work of breathing, provided the magnitude of the PEEP is low enough that it does not cause additional hyperinflation.

Volume-Controlled Ventilation

The term *volume-controlled ventilation* (or *volume-limited ventilation*) refers to mechanical ventilation in which the tidal volume is preset. The major advantage is that the delivered tidal volume is maintained even if lung mechanics change, thereby ensuring a more constant partial pressure of arterial carbon dioxide ($Paco_2$). The potential disadvantage is that if lung mechanics deteriorate, higher pressures may be required to achieve the tidal volume goal, and regions of overinflation with lung injury may result. Although controlled ventilation as described earlier can be either volume limited (preset tidal volume) or pressure limited (preset peak airway pressure), clinicians usually use the term *controlled mechanical ventilation* to refer to volume-limited ventilation with a set rate. In volume-controlled ventilation, an upper limit to applied airway pressure is commonly included for safety reasons.

The most common form of volume-controlled ventilation is one in which the patient assists the ventilator, thus triggering at least some of the breaths. The term *assisted mechanical ventilation* can refer either to volume-limited ventilation or to pressure-limited ventilation when the patient triggers some or all of the breaths, but the ventilator will always deliver a minimum number of breaths if apnea occurs. This mode is also referred to as *assist/control* (A/C).

Intermittent Mandatory Ventilation

The term *intermittent mandatory ventilation* (IMV) refers to a mode in which the patient is allowed to breathe spontaneously through an endotracheal tube or tracheostomy but also receives some preset (and thus mandatory) volume-limited breaths from the ventilator. In current ventilators, the mandatory breaths are triggered by the patient and thus are synchronized (synchronized IMV); however, if the patient ceases spontaneous ventilatory efforts, breaths at the rate set on the ventilator will still be delivered. Synchronized IMV is a form of partial ventilatory support because some breaths are spontaneous, rather than full ventilatory support, in which all breaths are delivered by the ventilator. This mode allows the patient to do a variable amount of the respiratory work but with the security of a set minimal backup rate should spontaneous ventilatory efforts stop.

Pressure-Control Ventilation

Pressure-control ventilation is a type of ventilation in which the ventilator delivers pressure-limited breaths to the patient; delivered volume becomes a dependent variable. The initiation of each breath may be triggered by the patient (assisted breaths) or may be initiated by the ventilator (controlled breaths). The delivered tidal volume depends on the preset pressure, the ventilatory rate, the inspiratory-to-expiratory ratio, and the patient's respiratory mechanics (resistance, compliance, and auto-PEEP). At a fixed preset pressure and inspiratory-to-expiratory ratio, tidal volume decreases as respiratory frequency increases. In patients with COPD, the tidal volume at low frequencies is relatively high but decreases substantially as the respiratory rate is increased, whereas in patients with stiff respiratory systems (e.g., ARDS), the tidal volume does not change much with respiratory frequency because the lung fills with gas quickly.

Pressure-Support Ventilation

Pressure-support ventilation is a pressure-limited, patient-triggered ventilatory mode. Once the patient triggers the ventilator, by creating either a small negative pressure or a low inspiratory flow at the airway, the ventilator switches to inspiratory mode and provides the airflow needed to maintain a preset level of pressure. In contrast to pressure-control ventilation, inspiration terminates when the inspiratory airflow decreases to a threshold level (the specific algorithm varies from ventilator to ventilator). This mode provides flexibility for the patient with respect to tidal volume, inspiratory flow, and ratio of time allowed for inspiration as compared with expiration. Tidal volume depends on patient-related factors (effort), respiratory system mechanics, and the level of pressure set for support. Pressure-support ventilation is a form of partial ventilatory support in which the size of each breath is determined partially by the patient's muscular effort and partially by the ventilator. This mode can compensate for the added work of breathing imposed by the resistance of the endotracheal tube compared with the natural airway. Pressure-support ventilation has largely been used to wean patients from ventilatory support because it provides a simple way to reduce the magnitude of mechanical support while the patient assumes a larger fraction of the ventilatory work than with most other modes of assisted ventilation.

High-Frequency Ventilation

The term *high-frequency ventilation* refers to certain ventilatory modes that have the common feature of providing ventilation using frequencies that are substantially greater than those used during normal breathing. Several different approaches are used for the delivery of high-frequency ventilation: high-frequency PPV, high-frequency jet ventilation, and high-frequency oscillatory ventilation. During high-frequency ventilation, tidal volumes may be less than the dead space, so adequate gas transport takes place by various convective and diffusive mechanisms. Interest in using these modes of ventilation has waxed and waned over the past 2 decades. In recent years, interest in high-frequency ventilation has had a resurgence, based on the concept that it may be the ideal way to minimize ventilator-induced lung injury because the small tidal volumes make it easier to avoid both overdistention of lung units and injury that occurs during ventilation at low lung volumes. Animal data in support of this approach are very strong in models of acute lung injury. Recent data in infants with respiratory distress syndrome and in adults with ARDS suggest that high-frequency ventilation may be as effective as conventional mechanical ventilatory assistance.

Proportional Assist Ventilation and Neurally Adjusted Ventilatory Assist

One of the difficulties when providing assisted ventilation to patients is ensuring that there is adequate synchrony between the patient's respiratory drive and the delivery of each breath from the ventilator. This issue is particularly problematic for patients with severe obstructive airways disease, especially if they have significant auto-PEEP. Two newer modes of ventilation, proportional assist ventilation (PAV) and neurally adjusted ventilatory assist (NAVA), have been developed and implemented on some ventilators in part to address this concern. Both these modes deliver ventilation in proportion to the instantaneous effort of the patient, but the underlying principles are different. Although both of these modes improve patient-ventilator synchrony, data are insufficient to know whether either will improve clinically important outcomes.

PAV is based on the mathematical relationships between airway pressure and airflow; these state that the pressure applied by the respiratory muscles is used to overcome the elastic forces (i.e., compliance) and the resistive forces of the respiratory system. With PAV, the pressure that is applied during inspiration varies based on the patient's inspiratory effort and respiratory system mechanics. This form of ventilation is not in widespread use currently, in part because of its complexity and the need to estimate the patient's compliance and resistance on a regular basis. This latter issue has been addressed in new versions of the technique in which intermittent measurements of compliance and resistance are automatically measured repeatedly.

By contrast, NAVA makes use of the electrical activity of the diaphragm (Edi) as measured by an array of electrodes attached to a nasogastric tube inserted into the esophagus. Pressure is then delivered by the ventilator in direct proportion to the (virtually) instantaneous Edi. Because the initiation and delivery of the breath by the ventilator is not dependent on measurement of pressures in the lung, patient-ventilator synchrony is improved in patients with auto-PEEP. The mode is relatively easy to use; the only parameter to set is the proportionality factor linking the Edi and the pressure delivered by the ventilator.

Noninvasive Positive-Pressure Ventilation

Since the mid-1990s, interest in providing PPV through a mask rather than through an endotracheal tube has increased. This method has been termed *noninvasive* because the patient is not intubated. This approach, although conceptually simple, requires appropriate implementation and monitoring for its successful application. Of particular importance are the selection of patients and the appropriate training of hospital personnel. Patients must be alert, cooperative, and hemodynamically stable. Patients must also have intact upper airway reflexes, so they do not aspirate upper airway materials into the lung, and they must not have any facial trauma that would preclude the use of a mask. Once patients are started on NIV, they should be carefully monitored, and NIV should be discontinued if the patient does not tolerate the mask, if it becomes clear from clinical examination that the patient may aspirate, if cardiovascular instability exists, or if the patient's mental status is deteriorating. NIV can also be delivered through a "helmet" that avoids some of the problems associated with the use of face masks.

NIV has certain potential advantages compared with invasive ventilation. It is relatively easy to apply and can be used for short intervals because it can

be started and stopped very easily. The major advantages are that it avoids the complications associated with intubation, it is usually more comfortable for the patient, and it reduces the need for sedation. Patients receiving NIV are able to communicate verbally with medical staff and family members, are likely able to sleep better, and are able to eat if they are sufficiently stable to remove the mask for short periods of time.

However, NIV has several disadvantages. Implementation of NIV takes more time from caregivers at the bedside initially, and the time course of correction of blood gases is slower than usually occurs in patients who are intubated and ventilated. Gastric distention is an unusual occurrence; medical staff should be aware of this complication and should watch for signs of abdominal distention. Data strongly support the use of NIV for patients with COPD (see later), and it is preferred in cardiogenic pulmonary edema, but whether it provides better outcomes in other forms of respiratory failure is uncertain.

COMPLICATIONS

Intubation

Endotracheal intubation can be used to secure a patient's airway, to act as a conduit to deliver gas from the ventilator to the patient, to prevent aspiration, and to help with pulmonary toilet when secretions are increased. However, intubation can be associated with certain complications, including upper airway trauma, disruption of normal host defense mechanisms, and the risk of aspiration during insertion of the endotracheal tube. Pressure from the cuff of the tube that provides a pneumatic seal between the tube and trachea can lead to regions of tracheal ischemia and may eventually cause tracheal stenosis as a result of injury repair processes. The endotracheal tube causes an increase in airway resistance because its diameter is smaller than the airway into which it is inserted. The magnitude of the increase depends on the length, diameter, and shape of the tube as well as the buildup of secretions and mucus that narrow the tube's diameter. Furthermore, the upper airway is normally a very effective means of heating and humidifying inspiratory gases. This natural system is bypassed by an endotracheal tube; inadequately humidified inspiratory gases can reduce mucociliary clearance and can lead to inspissation of tracheal secretions.

Cough is impaired in patients in whom an endotracheal tube has been placed. Normally, cough involves an increase in airway pressure as respiratory muscles are contracted against a closed glottis. When the glottis opens, expiratory flow sharply increases, resulting in dynamic compression of major airways. The presence of an endotracheal tube limits the buildup of airway pressure and alters the dynamics of expiratory flow, thereby greatly impairing the efficacy of the patient's cough.

A cuffed endotracheal tube helps to prevent gross aspiration, but pharyngeal secretions that pool at the top of the cuff often seep into the lungs and increase the probability of developing nosocomial pneumonia (Chapter 97). Endotracheal tubes also make swallowing and communication difficult. Silver-coated tubes reduce the risk of ventilator-associated pneumonia but are considerably more expensive than conventional endotracheal tubes and are unlikely to be used routinely for initial intubation. Endotracheal tubes with a port that allows suctioning of secretions above the cuff may also reduce the incidence of ventilator-associated pneumonia, although results of studies have been mixed.

Hemodynamic Compromise

The major mechanical determinants of cardiovascular hemodynamics during mechanical ventilation are intrathoracic pressure, changes in lung volume, and the patient's circulatory volume status. An increase in lung volume can cause a beneficial decrease in pulmonary vascular resistance, if lung units that had been closed are opened as a result of mechanical ventilation, or it can lead to a detrimental increase in pulmonary vascular resistance related to overdistention of the lung with concomitant compression and lengthening of alveolar vessels.

PPV can have a major impact on cardiovascular hemodynamics through its effect on pleural pressure, an effect that is directly related to changes in lung volume and not necessarily directly reflected in measurements of airway pressure; the relation between alveolar pressure and lung volume depends on respiratory system mechanics. For example, in a patient with stiff lungs (e.g., ARDS), a given increase in plateau pressure (Pplat) will lead to much less of an increase in lung volume than in a patient with COPD, so the increase in pleural pressure will be much less in the patient with ARDS. As a result, patients with ARDS tolerate relatively high PEEP levels, whereas similarly high levels in patients with normal lungs (e.g., in a drug overdose) or in patients with COPD would markedly reduce cardiac output. At very high lung volumes, a direct effect of the pressure of the lung on the heart can increase pericardial pressure and can thereby decrease cardiac filling.

Auto-PEEP and Dynamic Hyperinflation

A key factor that affects cardiovascular hemodynamics and other physiologic variables during mechanical ventilation is the development of *auto-PEEP,* defined as the difference between alveolar pressure and airway pressure at the end of expiration. Auto-PEEP leads to dynamic hyperinflation, which is an increase in the end-expiratory lung volume higher than the value that would be obtained if there were complete exhalation to the static functional residual capacity. This phenomenon occurs whenever time is insufficient for a complete exhalation to occur; the respiratory system is thus prevented from reaching its static end-expiratory volume. The major determinants of auto-PEEP and hence dynamic hyperinflation are increased expiratory airway resistance, high minute ventilation, increased respiratory system compliance, and decreased expiratory time.

Auto-PEEP is more likely to occur in patients with airway obstruction. Avoidance of high levels of auto-PEEP using approaches such as controlled hypoventilation is a fundamental principle when ventilating patients with airways obstruction.

Auto-PEEP may not be detected by routine measurements of pressure at the airway opening because the major pressure drop occurs across the airways. Moreover, measurements of auto-PEEP are difficult to make in spontaneously breathing patients. When patients are not making spontaneous breathing efforts, auto-PEEP can be assessed as the difference in pressure between the set PEEP and the pressure obtained when the airway opening is occluded at the end of expiration (Fig. 105-1). It can also be assessed using the change in Pplat after a prolonged pause during volume cycle ventilation. If it is considered safe for the patient, a rapid estimate of the effect of auto-PEEP on cardiovascular hemodynamics can be obtained by transiently disconnecting the ventilator and allowing the auto-PEEP to approach zero during a long expiration. If the auto-PEEP is less than 5 cm H_2O, it is unlikely to cause clinically important changes in the measured intravascular pressures.

If auto-PEEP is not considered in the interpretation of respiratory mechanics, measurements of respiratory system compliance will be falsely low.

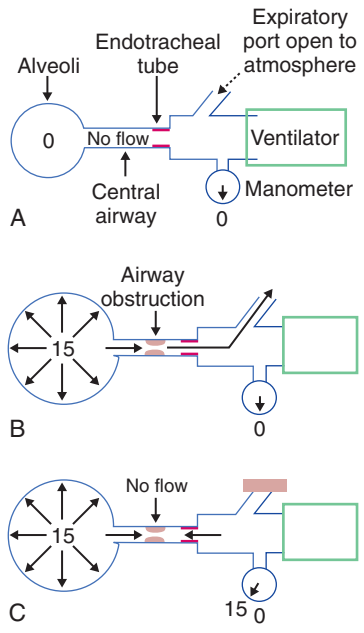

FIGURE 105-1. The relationships among alveolar, central airway, and ventilator circuit pressure at the end of exhalation under the following conditions: A, Normal conditions (no auto–positive end-expiratory pressure [auto-PEEP]). **B,** Severe dynamic airway obstruction with the expiratory port open. **C,** Severe dynamic airway obstruction with the expiratory port occluded at the end of exhalation. The auto-PEEP level is identified by creating an end-expiratory hold, thereby allowing the alveolar, central airway, and ventilator circuit pressures to equilibrate because there is no flow in the circuit. During equilibration, the level of auto-PEEP can be read on the manometer in the ventilator circuit (Adapted from Pepe PE, Marini JJ. Occult positive end-expiratory pressure in mechanically ventilated patients with airflow obstruction: the auto-PEEP effect. *Am Rev Respir Dis.* 1982;126: 166-170.)

Dynamic hyperinflation can be measured as the volume of gas that is released when the expiratory time of a given breath is lengthened by 20 to 30 seconds. These techniques are based on the assumptions that no respiratory efforts are made and that the alveoli communicate with the airway opening, thereby allowing equilibration of pressures or exhalation of trapped gas. However, this assumption is not necessarily correct in patients with very severe airways obstruction (e.g., status asthmaticus).

Auto-PEEP should be suspected whenever flow at the end of expiration is detectable or when a patient fails to trigger the ventilator consistently with inspiratory efforts. This failure to trigger the ventilator occurs because the patient must generate sufficient pressure to overcome the level of auto-PEEP before a negative deflection of pressure or generation of inspiratory flow (either of which may be used by the ventilator to detect the onset of inspiration) is sensed at the airway opening.

Auto-PEEP and dynamic hyperinflation have numerous detrimental consequences. In a patient who is not breathing spontaneously, the dynamic hyperinflation increases pleural pressure and right atrial pressure, thereby leading to a decrease in the driving pressure for venous return, with a concomitant decrease in cardiac output. This effect can be magnified in the patient with airway obstruction immediately after intubation and initiation of mechanical ventilation because compensatory mechanisms to enhance venous return are impaired by pharmacologic agents that are often used to prepare the patient for endotracheal tube insertion and that also reduce venous and arterial tone. In such patients, auto-PEEP can also lead to gross misinterpretation of vascular pressures. For example, the absolute value of capillary wedge pressure will be directly affected by the increase in intrathoracic pressure during auto-PEEP. The clinician may interpret this high (absolute) capillary wedge pressure as indicating adequate ventricular filling, when, in fact, transmural capillary wedge pressure is low because intrathoracic pressure is also high. This misinterpretation, coupled with the decreased cardiac output related to the high intrathoracic pressure, may suggest the diagnosis of cardiogenic shock, rather than the correct diagnosis of auto-PEEP.

Treatment of the detrimental hemodynamic consequences of auto-PEEP include decreasing the level of auto-PEEP by increasing the expiratory time, decreasing airway resistance (e.g., bronchodilators, when appropriate), or decreasing minute ventilation. The last approach is usually the most effective ventilatory maneuver but results in an increase in the $Paco_2$. Cardiovascular hemodynamics can also usually be restored by infusion of fluids.

In a spontaneously breathing patient, dynamic hyperinflation can markedly increase the oxygen cost of breathing for two reasons. First, because the respiratory system is stiffer at higher lung volumes, more energy is required to complete each ventilatory cycle. Second, to initiate flow into the lung, the patient must generate a pressure in the alveolar zone that is lower than atmospheric pressure. However, if dynamic hyperinflation is present, the patient first has to generate an inspiratory effort sufficient to overcome the (positive) end-expiratory alveolar pressure before he or she begins to lower alveolar pressure to less than atmospheric pressure to initiate airflow. The increase in lung volume associated with dynamic hyperinflation also has an impact on the effectiveness of the ventilatory muscles: at high lung volumes, the diaphragm is relatively flat, so it is at a mechanical disadvantage in producing changes in pleural pressure. Mechanical ventilation for just 18 to 69 hours causes extensive atrophy of diaphragmatic muscle fibers.

Ventilator-Induced Lung Injury

Mechanical ventilation itself can lead to numerous types of lung injuries (Fig. 105-2). The term *barotrauma* refers to large pulmonary air leaks, such as pneumothorax and pneumomediastinum. However, a much more subtle injury, *diffuse alveolar damage* presenting as pulmonary edema, also occurs. For both types of injuries, the critical factor is the degree of overdistention of the lung, best assessed by the transpulmonary pressure (Ptp, the airway opening minus pleural pressure). The esophageal pressure, measured using an esophageal balloon, estimates pleural pressure (Ppl), although this measurement has not been routinely performed in clinical practice.

The usual pressures measured during mechanical ventilation are airway pressures referenced to atmospheric pressure. The peak inspiratory pressure (PIP) is easy to measure, but its interpretation is not always simple. PIP represents the sum of the pressure required to inflate the lungs plus the pressure needed to overcome the resistance to flow. Thus, a high PIP does not necessarily indicate an increased propensity to the development of ventilator-induced lung injury. For example, if inspiratory flow is constant and a smaller endotracheal tube is used, PIP will increase even though the danger of pulmonary overdistention is no greater than would be present with ventilation using a larger-bore tube. The Pplat, which is the airway pressure at the end of an end-inspiratory pause (>0.5 second), is the pressure that can be most easily measured at the bedside and that bears some relationship, depending on Ppl, to the development of overdistention; however, there is no single value of Pplat that is "dangerous" from a lung injury perspective because Ppl can vary so much. However, based on the ARDS Clinical Network (ARDSNet) study, a reasonable maximal value of Pplat in patients with acute lung injury is 30 cm H_2O. Certain caveats should be noted in interpreting Pplat and PIP, related to associated changes in Ppl. If the patient is breathing spontaneously, Ppl will be negative, and overdistention may occur even with a Pplat lower than 30 cm H_2O. Conversely, in a patient who is either paralyzed or not making ventilatory efforts and who has a very stiff chest wall (e.g., due to ascites, obesity, pregnancy), as airway pressure increases, most of the pressure drop will be dissipated across the chest wall, thus leading to values of Ppl that are positive. In this setting, a high Pplat may not be indicative of a high Ptp and hence may not indicate increased lung distention. Thus, the physician caring for a patient receiving mechanical ventilatory support must analyze the measured airway pressures within their clinical context. Measurement of Ppl, as noted earlier, may help resolve these difficulties.

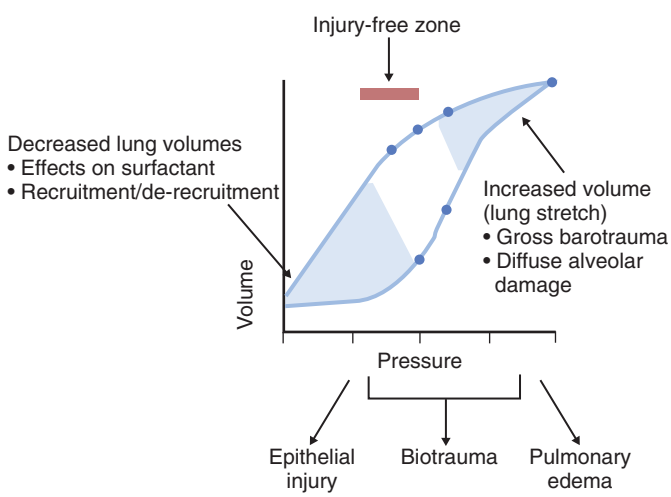

FIGURE 105-2. Schematic representation of the pressure-volume curve of a lung with diffuse alveolar edema. Mechanical ventilation can induce or worsen lung injury by numerous mechanisms when ventilation occurs at high lung volumes or when ventilation occurs at low lung volumes. Lung-protective strategies during ventilation of patients with acute respiratory distress syndrome should try to keep the ventilatory pattern in the *injury-free zone.* Data in patients confirm the benefit of ensuring that overdistention does not occur.

During mechanical ventilation, some areas of the lung may undergo cyclic recruitment and derecruitment. This process, which is of particular importance in patients who have acute lung injury or ARDS, has been termed *atelectrauma* and can cause significant lung injury. The precise mechanisms of injury are not entirely clear but are thought to result from shear stress owing to opening and closing of lung units, regional hypoxia in atelectatic lung units, and effects on surfactant. Prevention of this type of injury provides part of the rationale for the use of PEEP to maintain recruitment of lung units during tidal ventilation.

Finally, evidence suggests that mechanical ventilation strategies that promote overdistention and atelectrauma can lead to an inflammatory response in the lung, a mechanism of injury termed *biotrauma,* through the release of certain pro-inflammatory cytokines and chemokines. To the extent that these mediators can translocate from the lung into the systemic circulation, they could potentially lead to dysfunction of other organs (Fig. 105-3). This concept suggests that optimal ventilatory strategies are important not only for maintenance of lung function but also for preventing the development of multiple-organ dysfunction (Chapter 104) that commonly occurs in this setting. This hypothesis may explain the decreased mortality recently observed with a strategy designed to avoid overdistention in a large randomized trial of mechanical ventilation in patients with ARDS.

SPECIFIC COMMON TREATMENT SCENARIOS

Initiation of Mechanical Ventilation

The initiation of mechanical ventilation involves several steps in clinical decision making (Table 105-1). Despite the utility of such guidelines, each

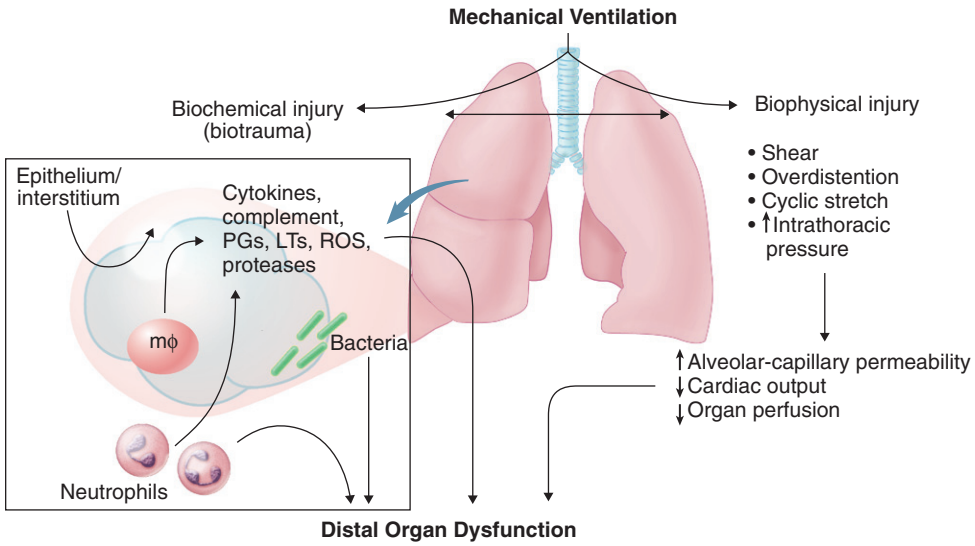

FIGURE 105-3. Mechanisms by which mechanical ventilation may lead to distal organ dysfunction. LTs = leukotrienes; mø = macrophages; PGs = prostaglandins; ROS = reactive oxygen species. (Adapted from Slutsky AS, Tremblay LN. Multiple system organ failure: is mechanical ventilation a contributing factor? *Am J Respir Crit Care Med*. 1998;157:1721-1725.)

TABLE 105-1 STEPS AND GUIDELINES FOR INITIATING MECHANICAL VENTILATION*

1. Ventilatory mode
   Unintubated patients:
   - NIV for patients with COPD and acute hypercapnic respiratory failure if alert, cooperative, and hemodynamically stable
   - NIV not routinely recommended for acute hypoxemic respiratory failure

   Intubated patients:
   - Assist/control with volume-limited ventilation as initial mode
   - Consider specific indications for PCV or HFOV (see text) in acute lung injury
   - SIMV: consider if some respiratory effort, dyssynchrony
   - PSV: consider if patient's effort good, ventilatory needs moderate to low, and patient more comfortable during PSV trial
2. Oxygenation
   - If infiltrates on chest radiograph, then
     F_{IO_2}: begin with 0.8-1.0, reduce according to S_{PO_2}
     PEEP: begin with 5 cm H_2O, increase according to P_{AO_2} or S_{PO_2}, F_{IO_2} requirements, and hemodynamic effects; consider PEEP/F_{IO_2} "ladder" (see Fig. 105-4); goal of S_{PO_2} >90%, $F_{IO_2} \leq 0.6$
   - No infiltrates on chest radiograph (COPD, asthma, PTE),
     F_{IO_2}: start at 0.4 and adjust according to S_{PO_2} (consider starting higher if pulmonary embolism is strongly suspected)
3. Ventilation
   - Tidal volume: begin with 8 mL/kg PBW (see Fig. 105-4 for formulas); decrease to 6 mL/kg PBW over a few hours if acute lung injury present (see Fig. 105-4)
   - Rate: begin with 10-20 breaths/min (10-15 if not acidotic; 15-20 if acidotic); adjust for pH; goal pH > 7.3 with maximal rate of 35; may accept lower goal if minute ventilation high
4. Secondary modifications
   - Triggering: in spontaneous modes, adjustment of sensitivity levels to minimize effort
   - Inspiratory flow rate of 40-80 L/min; higher if tachypneic with respiratory distress or if auto-PEEP present, lower if high pressure in ventilator circuit leads to a high-pressure alarm
   - Assessment of auto-PEEP, especially in patients with increased airways obstruction (e.g., asthma, COPD)
   - I/E ratio: 1:2, either set or as function of flow rate; higher (1:3 or more) if auto-PEEP present
   - Flow pattern: decelerating ramp reduces peak pressure
5. Monitoring
   - Clinical: blood pressure, ECG, observation of ventilatory pattern including assessment of dyssynchrony, effort or work by the patient; assessment of airflow throughout expiratory cycle
   - Ventilator: tidal volume, minute ventilation, airway pressures (including auto-PEEP), total compliance
   - Arterial blood gases, pulse oximetry

*Decisions within this algorithm will be influenced by the specific conditions of the individual patient.
COPD = chronic obstructive pulmonary disease; ECG = electrocardiogram; F_{IO_2} = fraction of inspired oxygen; HFOV = high-frequency oscillatory ventilation; I/E ratio = inspiratory-to-expiratory ratio; NIV = noninvasive ventilation; P_{AO_2} = partial pressure of oxygen in arterial blood; PBW = predicted body weight; PCV = pressure control ventilation; PEEP = positive end-expiratory pressure; PSV = pressure support ventilation; PTE = pulmonary thromboembolism; SIMV = synchronized intermittent mandatory ventilation; S_{PO_2} = arterial oxygen saturation by pulse oximetry.

patient must be evaluated for specific factors that could modify the recommendation or mandate an alternative.

Acute Respiratory Distress Syndrome

Patients with ARDS (Chapter 104) have noncardiogenic pulmonary edema, with a reduced functional residual capacity and a mortality rate of 30 to 60%. Although therapy may be available for the underlying disease process that led to the development of ARDS (e.g., antibiotics for a predisposing pneumonia), no effective therapy is directly aimed at the diffuse alveolar damage. These patients require mechanical ventilation as supportive therapy to improve oxygenation and to decrease the oxygen cost of breathing until their lungs recover from the primary insult that led to the alveolar damage.

The lungs in a patient with ARDS are stiff and are characterized on computed tomographic scans by patchy, heterogeneous infiltrates that consist of airless atelectatic or consolidated regions. Many patients have a dependent region that is consolidated, atelectatic, or fluid filled; a nondependent region that looks relatively normal; and a middle region that has some areas that look like the dependent regions but can be recruited to resemble the nondependent regions if high enough tidal volumes or increased levels of airway pressure are used transiently; these latter approaches are called *recruitment maneuvers*.

The challenge in ventilating patients with ARDS is to provide adequate gas exchange while at the same time not causing further lung injury (see earlier), an approach termed *lung protective ventilation strategy*. Arterial oxygen saturation can often be increased by high tidal volumes but at the expense of regional overdistention of those lung units that were not affected by the disease process itself, thereby improving oxygen saturation initially but, over time, worsening lung injury and clinical outcome.

The injury caused by mechanical ventilation can be reduced by using ventilatory strategies that avoid or minimize regional lung overdistention: limiting inspiratory pressure to some "safe" level or using smaller tidal volumes to limit end-inspiratory stretch, or both. However, in some patients, this lower "dose" of ventilation results in higher levels of P_{ACO_2} (so-called permissive hypercapnia) and a lower pH. Higher tidal volumes (12 mL/kg predicted body weight) yielded more normal blood gases, but lower tidal volumes (6 mL/kg predicted body weight) decreased mortality by 22% (from an absolute value of 40 to 31%) in a large clinical trial (Fig. 105-4).

Data also suggest that limiting tidal volume in ventilated patients who are intubated for reasons other than acute lung injury prevents injury later in the course of their intensive care unit stay. A lung protective strategy with limitation of tidal volume should be considered in ventilated patients who are at high risk of developing acute lung injury or ARDS.

Positive End-Expiratory Pressure

PEEP has been used traditionally to improve oxygenation while at the same time allowing reduction in F_{IO_2} to relatively nontoxic levels. Within the context of the current paradigm of trying to minimize iatrogenic complications of mechanical ventilation, PEEP is viewed as a therapy that potentially can abrogate or minimize the injury caused by ventilation at low lung volumes, by recruiting lung units and keeping them open. No definitive answer exists regarding how PEEP levels should be set in patients with ARDS; outcomes

Ventilatory Strategy for Patients with ARDS*

Goal 1: Low Vt/Pplat

Initiation:

Calculate PBW
—Male:
50 + 2. 3 (height [inches] − 60)
—Female:
45.5 + 2.3 (height [inches] − 60)

Initiate volume assist control
—start with 8 mL/kg, and ↓ to 6 mL/kg over a few hours

↓

Keep Pplat (based on 0.5-sec pause) <35 cm H_2O

If Pplat > 30 cm H_2O, ↓ Vt by 1 mL/kg to 5 or 4 mL/kg

If Pplat < 25 AND Vt < 6 mL/kg, ↑Vt by 1 mL/kg until Pplat > 25 cm H_2O OR Vt = 6 mL/kg

If patient severely distressed and/or breath stacking, consider ↑Vt to 7 or 8 mL/kg, as long as Pplat ≤ 30 cm H_2O†

Goal 2: Adequate Oxygenation

Specific goal:

PaO_2 55-80 mm Hg
or
SpO_2 88-95%

Use only FIO_2 /PEEP combinations shown below to achieve this target

- if oxygenation is low, choose FIO_2 /PEEP combination (from FIO_2 /PEEP table) to the right
- if oxygenation is high, choose FIO_2 /PEEP combination to the left

Goal 3: Arterial pH

Goal:

pH: 7.30–7.45

Acidosis algorithm
If pH 7.15–7.30
- ↑ set rate until pH > 7.30 or $PaCO_2$ < 25 mm Hg (max RR = 35)
- if RR = 35 & pH < 7.30 $NaHCO_3$ may be given

If pH < 7.15
- ↑ set RR to 35
- if set RR = 35 & pH < 7.15, Vt may be ↑ in 1 mL/kg steps until pH > 7.15

(Pplat target may be exceeded)

Alkalosis algorithm
If pH > 7.45
- ↓ set RR until patient RR > set RR

(minimum set RR = 6/min)

FIO_2/PEEP Table

FIO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7	0.7	0.8	0.9	0.9	0.9	1.0
PEEP	5	5	8	8	10	10	10	12	14	14	14	16	18	20–24

*Based on ARDS Network Algorithm
† If compliance of the chest wall is markedly decreased (e.g., massive ascites), it may not be reasonable or necessary (if the patient is very hypoxemic) to allow a Pplat >30 cm H_2O.

FIGURE 105-4. Ventilatory strategy for patients with the acute respiratory distress syndrome (ARDS). Several caveats should be considered when using the low tidal volume strategy: (1) tidal volume (Vt) is based on predicted body weight (PBW), not actual body weight; PBW tends to be about 20% lower than actual body weight; (2) the protocol mandates decreases in the Vt lower than 6 mL/kg of PBW if the plateau pressure (Pplat) is greater than 30 cm H_2O and allows for small increases in Vt if the patient is severely distressed and/or if there is breath stacking, as long as Pplat remains at 30 cm H_2O or lower; (3) because arterial carbon dioxide (CO_2) levels will rise, pH will fall; acidosis is treated with increasingly aggressive strategies dependent on the arterial pH; (4) the protocol has no specific provisions for the patient with a stiff chest wall, which in this context refers to the rib cage and abdomen; in such patients, it seems reasonable to allow Pplat to increase to more than 30 cm H_2O, even though it is not mandated by the protocol; in such cases, the limit on Pplat may be modified based on analysis of abdominal pressure, which can be estimated by measuring bladder pressure. RR = respiratory rate; SpO_2 = oxygen saturation based on pulse oximeter.

appear to be similar with the routine use of higher (≈13 cm H_2O) and lower (≈8 cm H_2O) levels of PEEP. The critical issues are how to assess the level of PEEP in an individual patient and how to determine whether the procedures to recruit the lung units and keep them open are less harmful than allowing the lung units to remain de-recruited. One experimental option is chest computed tomography to assess whether areas of the lung are recruited, but this technique is not practical for routine assessment. A second approach is to measure the mechanical properties of the respiratory system by generating a pressure-volume curve (see Fig. 105-2). Investigators have suggested that the optimal strategy is to set PEEP just higher than the lower inflection point, which is thought to represent the opening pressure of the lung, and to adjust tidal volume so that Pplat is just lower than the upper inflection point, at which compliance decreases. Although lung continues to be recruited well above the lower inflection point, and the upper inflection point may not indicate overdistention, two clinical studies that based their lung protection strategies on the pressure-volume curve demonstrated reductions in mortality; however, both studies also included other features to reduce lung injury, so use of the pressure-volume curve to set PEEP levels and tidal volume (or pressure limits) cannot be recommended at this time. In the trial that demonstrated the benefit of lower tidal volumes, PEEP levels were individualized based on a PEEP/FIO_2 table (see Fig. 105-4); a subsequent trial using PEEP about 5 cm H_2O higher found no additional benefit. Higher PEEP (to achieve a plateau pressure of 28 to 30 cm of H_2O) can reduce the duration of ventilation and organ failure but not mortality compared with moderate PEEP (5 to 9 cm H_2O). Multifaceted ventilation therapy protocols using low tidal volumes, recruitment maneuvers, and high PEEP can improve oxygenation but not reduce barotrauma or mortality compared with conventional therapy. PEEP guided by esophageal pressure measured by an intraesophageal balloon may result in significantly higher PO_2 levels and better respiratory compliance than treatment guided by a standard protocol. Pooled results of all trials suggest higher PEEP improves survival only in patients with ARDS.

Obstructive Airways Diseases

The major pathophysiologic abnormality in patients with obstructive airways diseases is an increase in airway resistance leading to expiratory airflow limitation; patients may also have a concomitant increase in minute ventilation. These factors may lead to dynamic hyperinflation, which is associated with numerous complications, including respiratory muscle compromise, an increased oxygen cost of breathing, and hemodynamic compromise. Thus, the main goals in the ventilatory support of patients with obstructive airway diseases (COPD, asthma) are to minimize auto-PEEP, to rest the respiratory muscles, to maintain adequate gas exchange, and to decrease the oxygen cost of breathing while simultaneously minimizing the iatrogenic complications of mechanical ventilation and allowing time for the successful diagnosis and treatment of the primary cause of the exacerbation and the resulting increase in airway obstruction (Chapters 87 and 88).

Noninvasive Ventilation

For patients with acute respiratory failure resulting from an exacerbation of COPD, the preferred approach is NIV if the patient is hemodynamically stable, alert, and cooperative and does not need to be intubated to protect the airway. It is important to choose a comfortable mask and to reassure the patient because some patients find the mask difficult to tolerate. This strategy may be applied using several ventilation modes, including pressure support or bilevel positive airway pressure. The ventilation settings are adjusted to improve gas exchange and to ensure the patient's comfort. Despite this approach, some patients with COPD require intubation and ventilation because of cardiac or respiratory arrest, agitation, increased sputum, or other concomitant severe disorders.

Intubation and Ventilation

The key goal after intubation is to minimize the detrimental effects of dynamic hyperinflation. The most effective way to minimize dynamic hyperinflation is to decrease the minute ventilation, even if this means an increase in $PaCO_2$, a strategy known as *permissive hypercapnia* or *controlled hypoventilation*. Judicious use of sedation may decrease carbon dioxide production and improve patient-ventilator synchrony, although the avoidance of sedation can reduce the duration of ventilation and hospitalization. In a randomized study, no difference was found between dexmedetomidine and midazolam in time at targeted sedation level, but dexmedetomidine resulted in less time on

mechanical ventilation, less delirium, and less hypertension and with less tachycardia but more bradycardia.■ Care must be taken in the use of paralytic agents, especially when patients with asthma are also receiving corticosteroids. However, early neuromuscular blockade using cisatracurium besylate (15 mg rapid infusion followed by 37.5 mg/hr for 48 hours) can reduce mortality by 25% in patients with ARDS.■

Increasing expiratory time by using a higher peak inspiratory flow may be somewhat helpful, but it is not nearly as effective as decreasing minute ventilation. What level of $Paco_2$ (and pH) should be tolerated is not known with certainty, but maintaining pH higher than approximately 7.15 is a reasonable target, although much lower values have been reported in clinical studies.

In patients with COPD who are spontaneously breathing, the addition of external (set) PEEP at a level that is just less than what is necessary to overcome the auto-PEEP fully may not increase Pplat and may decrease the inspiratory effort that the patient needs to generate to initiate inspiratory airflow. This strategy does not appear to be as effective in patients with status asthmaticus, in whom it may cause an increase in Pplat. Measurements of auto-PEEP by airway occlusion may be inaccurate in some patients with status asthmaticus, likely because of gas trapping at the end of expiration with closed-off lung regions that do not communicate with the central airways.

ADJUNCTS

Tracheal gas insufflation involves washing out the carbon dioxide–rich gas in the anatomic dead space with fresh gas through a special catheter or endotracheal tube, thereby allowing a reduction in tidal volume while maintaining the same $Paco_2$. A clinically significant outcome benefit has not yet been demonstrated with tracheal gas insufflation.

The prone position compared with the supine position in patients with acute lung injury results in improved oxygenation in approximately 70% of patients and has a rationale (through more even distribution of pleural pressure) for preventing ventilator-induced lung injury and decreasing FIO_2. Trials in adults, however, have not demonstrated an outcome benefit, including a trial of prone positioning for 16 hours per day with all patients ventilated with the so-called lung-protective ventilation strategy used in the ARDSNet trial. Based on current studies, the prone position cannot be recommended for routine use but should be considered in patients with severe gas exchange abnormalities (e.g., $P/F \leq 100$) who require high PEEP and high FIO_2.

Inhaled nitric oxide is a potent vasodilator and bronchodilator that can enhance arterial oxygenation. It has not been shown to improve outcome in clinical trials, however, so its routine use cannot be recommended.

DISCONTINUATION OF MECHANICAL VENTILATION

To minimize the iatrogenic consequences of intubation and mechanical ventilation, discontinuation of ventilatory support and extubation should occur as expeditiously as possible. However, if discontinuation is attempted too early, patients may deteriorate and require urgent reintubation.

From the moment that mechanical ventilation is instituted, it is important for the clinician to start planning for eventual discontinuation of ventilatory support. A key aspect of this approach is serial evaluation, with aggressive treatment of the factors contributing to the patient's ventilatory dependence, including respiratory systems factors (e.g., respiratory muscles), cardiovascular factors (e.g., myocardial ischemia), neurologic factors (e.g., respiratory muscle weakness), and metabolic factors (e.g., increased oxygen consumption).

Two major types of weaning strategies have been used historically: (1) a ventilatory mode thought to hasten the weaning process and (2) daily monitoring of the patient for criteria to suggest the likelihood of successful weaning and a trial of spontaneous breathing for those deemed likely to succeed. Studies of ventilatory modes of weaning have included trials in which patients are allowed to breathe spontaneously from a fresh gas supply delivered to the endotracheal tube (a so-called T-tube), trials of IMV, and studies of pressure-support ventilation. With all approaches, the level of support is gradually decreased until extubation is tolerated by the patient. These methods have been compared in randomized controlled trials, with mixed results, although weaning with IMV appeared less favorable in most trials. Likewise, using ventilatory criteria to predict weaning success has been disappointing, mainly because some patients who fail to meet the criteria will be successfully weaned if they are given the opportunity to breathe spontaneously. The

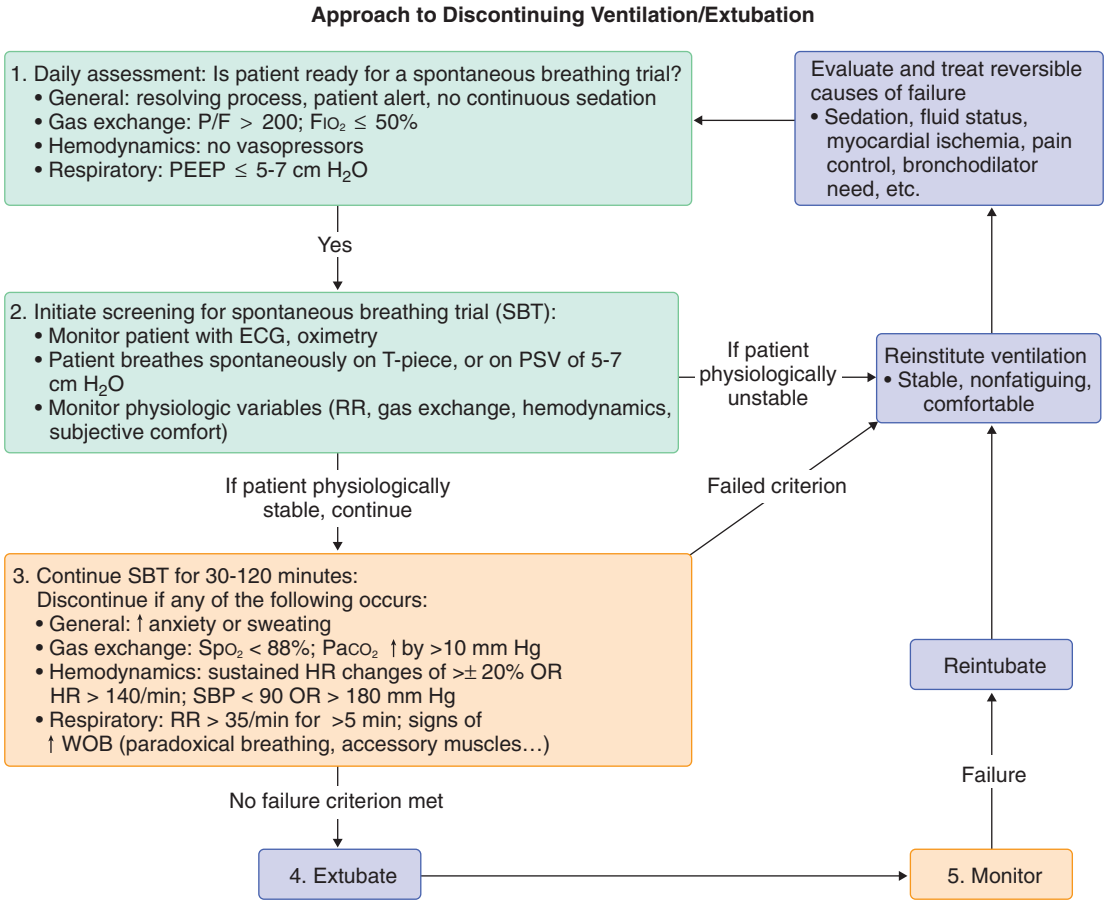

FIGURE 105-5. Algorithm for assessing whether a patient is ready to be liberated from mechanical ventilation and extubated. ECG = electrocardiogram; HR = heart rate; $P/F = PaO_2/FIO_2$ ratio; PSV = pressure support ventilation; RR = respiratory rate; SBP = systolic blood pressure; SpO_2 = oxygen saturation based on pulse oximeter; WOB = work of breathing.

criterion with the greatest predictive accuracy is the so-called rapid shallow breathing index, in which the respiratory rate is divided by tidal volume (in liters), with a value less than 105 suggesting the ability to wean; however false-negative and false-positive test results occur.

More recently, the approach to weaning has been based on the concept that a patient is ready to be removed from ventilatory support when the underlying disease process that led to the intubation has resolved or improved substantially. Rather than applying rigorous ventilatory criteria, the only requirements are that the patient be clinically stable (i.e., has shown improvement in the underlying process), be hemodynamically stable, and have oxygen requirements that can be met by face mask once the patient is extubated. If the patient meets these general criteria, a spontaneous breathing trial is recommended (Fig. 105-5); if the patient passes the trial, the patient can be extubated. A corollary is that a gradual weaning is not necessary; instead, patients should be assessed on a daily basis regarding their suitability to be removed from ventilatory support, and, if they are not ready, a comfortable, nonfatiguing form of mechanical ventilation should be used between the assessments. Assisted modes of ventilation are preferred between the spontaneous breathing trials.

An important recommendation in relation to weaning or discontinuing mechanical ventilation relates to evidence that intensive care units should develop weaning or discontinuation protocols that are designed to be implemented by health care professionals other than physicians. Three large randomized trials demonstrated that protocols implemented by health care professionals other than physicians improved care and were associated with substantial savings in costs compared with standard management approaches, even though the specifics of the protocols were different. More recently, a strategy that paired spontaneous awakening, based on the interruption of sedatives, with spontaneous breathing trials improved extubation rates, reduced intensive care length of stay, and decreased mortality by 32%.[6]

A major issue to assess before extubation is the patency of the patient's airway and whether the patient will be able to clear secretions after extubation. Assessment of the likely patency of the upper airway can be achieved using the *cuff-leak volume,* which is the difference between the inspiratory and expiratory tidal volume when the cuff of the endotracheal tube is deflated. If this volume is greater than 110 mL, it is usually an indication that major upper airway obstruction will not occur after extubation. Although this test is not required before extubation, a low *cuff-leak volume* warrants added precautions, such as the availability of equipment and personnel for managing a difficult intubation, when extubating the patient. In patients who have been ventilated for more than 36 hours, methylprednisolone (20 mg intravenously) started 12 hours before a planned extubation and repeated every 4 hours until tube removal substantially reduces postextubation laryngeal edema and reduces the need for reintubation by 50%.[10]

Despite the use of all these techniques, approximately 5 to 25% of patients will have to be reintubated and have mechanical ventilation reinstituted. Once a patient is reintubated, it is again necessary to reevaluate the respiratory and nonrespiratory reasons for the failure.

The choice of the specific weaning protocol should be left to the individual institution and should be individualized to the specific group of patients considered. In instituting such protocols, several key issues should be recognized. First, protocols are guides that should not replace clinical judgment. If a clinician does not follow some aspect of the protocol, there should be a mechanism in place for keeping track of what recommendations were not accepted, with an explanation of the rationale; these data should be collated and used to reassess the protocol. Second, protocols should be viewed as dynamic structures that are open to change and should be reevaluated on a regular basis. Third, implementation of a protocol requires adequate resources, and an institution must make a commitment not only to develop protocols but also to implement and assess them.

106 APPROACH TO THE PATIENT WITH SHOCK

EMANUEL P. RIVERS

DEFINITION

The key feature of shock is tissue hypoperfusion, not a specific level of systemic arterial blood pressure. The clinical picture may be cryptic or obvious.

EPIDEMIOLOGY

More than 1 million patients present in shock or develop shock in U.S. hospitals each year, at an annual cost of more than $100 billion. Shock can be categorized as hypovolemic, cardiogenic (Chapter 107), extracardiac/obstructive, distributive, or dissociative.

PATHOBIOLOGY

The delivery and utilization of oxygen are essential for cellular viability, and the failure to deliver or utilize oxygen is central to the concept of shock and its pathogenesis (Fig. 106-1). Systemic oxygen delivery—that is, the amount of oxygen delivered to tissues by the arterial blood—depends on the concentration of hemoglobin in the blood, the fractional saturation of the hemoglobin with oxygen (Sao_2), the amount of oxygen dissolved in the blood (Pao_2), and cardiac output. Cardiac output is a product of stroke volume and heart rate. Stroke volume is determined by ventricular preload and afterload, as well as contractility of the right or left heart. Systemic vascular resistance (SVR), the force resisting cardiac contraction, can be calculated using equation 1:

$$SVR = (MAP - CVP) * 80 / CO \quad (1)$$

$$MAP = \text{Diastolic blood pressure} + (\text{Systolic} - \text{Diastolic blood pressure})/3 \quad (2)$$

MAP denotes the mean systemic arterial blood pressure, CVP denotes central venous pressure, and CO denotes cardiac output. SVR is determined primarily by the degree of vasomotor tone in the precapillary smooth muscle sphincters.

The systemic circulation is normally autoregulated, so that when systemic arterial pressure increases, vessel diameter decreases to maintain flow at a steady level. The clinical significance of these relationships is apparent when

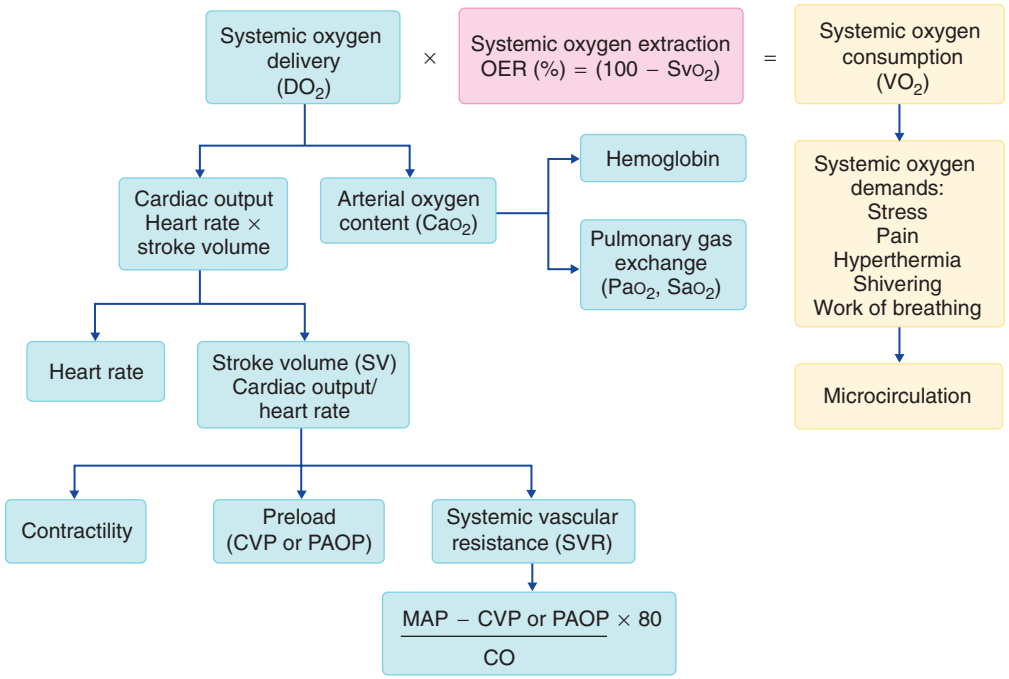

FIGURE 106-1. The hemodynamic, oxygen transport, and oxygen utilization components of shock management. Systemic oxygen delivery is impacted by cardiac output (CO) and arterial oxygen content. The cardiac, pulmonary, and blood determinants of systemic oxygen delivery are shown. CVP = central venous pressure; MAP = mean arterial pressure; PAOP = pulmonary artery occlusion pressure.

a patient presents with a decrease in cardiac output, but a compensatory increase in systemic vascular resistance maintains a near-normal mean arterial blood pressure. Despite the near-normal blood pressure, however, the patient is in "cryptic shock" because of tissue hypoperfusion. Compensatory mechanisms are organ specific. Blood flow to organs such as the heart and brain is carefully regulated and maintained over a wide range of blood pressures. In other organs, however, such as the intestine or liver, autoregulation is not as tightly maintained.

Systemic oxygen consumption, which is the amount of oxygen consumed by the body per minute, is calculated as the systemic oxygen delivery multiplied by the systemic oxygen extraction ratio. Oxygen demand is the amount of oxygen required by the tissues to avoid anaerobic metabolism. Normally, systemic oxygen delivery is sufficient so that systemic oxygen consumption is not altered by or dependent on changes in delivery. However, if systemic oxygen delivery drops below a critical value, a compensatory increase in the oxygen extraction ratio maintains systemic oxygen consumption at adequate levels to meet systemic oxygen demands. When this compensatory response in the oxygen extraction ratio is inadequate to meet systemic oxygen demands, a switch occurs from aerobic metabolism to the less efficient anaerobic metabolism. The result is depletion of adenosine triphosphate (ATP) and intracellular energy reserves. Intracellular acidosis occurs, and anaerobic glycolysis leads to the production of lactate. Below this critical value of systemic oxygen delivery, systemic oxygen consumption is dependent on systemic oxygen delivery, a relationship termed *physiologic oxygen supply dependency.*

A pathologic oxygen delivery dependency exists in patients with sepsis, trauma, and acute respiratory distress syndrome (ARDS) and after resuscitation from prolonged cardiac arrest. These patients have systemic oxygen delivery in the normal or elevated range but an impairment of oxygen utilization. This condition of cytopathic tissue hypoxia is a result of maldistribution of blood flow or a defect in the utilization of substrate at the microcirculatory or subcellular level. This pathologic supply dependency is accompanied by very high mixed venous oxygen saturation levels or venous hyperoxia, as well as by elevated lactate levels. This process is believed to be an important mechanism of cellular damage in various forms of shock.

Compensatory Responses

Minor decreases in arterial blood pressure and systemic oxygen delivery activate the baroreceptor reflex via stretch receptors or sensing mechanisms located in the carotid sinus, splanchnic vasculature, aortic arch, right atrium, and juxtaglomerular apparatus of the kidney, as well as chemoreceptors sensitive to concentrations of carbon dioxide or oxygen located in the central nervous system, mostly in the medulla. These compensatory responses mediated by activation of the sympathetic nervous system include (1) release of cortisol, aldosterone, and epinephrine; (2) activation of the renin-angiotensin system; (3) release of arginine vasopressin (AVP) from the posterior pituitary; (4) augmentation of myocardial contractility and heart rate; (5) constriction of arterial and venous capacitance vessels, particularly in the splanchnic bed, thereby augmenting venous return; (6) redistribution of blood flow away from skeletal muscle beds and the splanchnic viscera; and (7) creation of a local tissue environment to enhance the unloading of oxygen to tissues and improve its extraction because of acidosis, pyrexia, and increased red blood cell 2,3-diphosphoglycerate.

Noncompensatory Responses

Noncompensatory responses develop when physiologic adjustments are exaggerated or lead to pathologic results. Vasodilatory shock results from many sources, including unregulated nitric oxide synthesis, inadequate ATP synthesis in vascular smooth muscle cells, activation of the enzyme poly (ADP ribosyl) polymerase (PARP)-1, lipid mediators, and opening of ATP-sensitive potassium channels in vascular smooth muscle cells. This multifaceted insult leads to interstitial fluid and cellular edema, which impairs oxygen diffusion from capillary to cell, causing a failure of energy-dependent ion transport, the production of lactate, and the inability to maintain normal transmembrane gradients of potassium, chloride, and calcium. Cells lose their ability to utilize available oxygen as a result of mitochondrial dysfunction, abnormal carbohydrate metabolism, and failure of many energy-dependent enzyme reactions.

Acidosis commonly accompanies shock. When a molecule of ATP is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate, the reaction also generates a proton. The net yield of protons is positive when ATP is hydrolyzed in the cell and then regenerated only by the anaerobic breakdown of glucose. Thus, during anaerobic glycolysis, the use of ATP to power cellular processes, coupled with the anaerobic production of ATP by substrate-level phosphorylation reactions, results in the development of acidosis.

Cells in organs such as the kidneys, liver, and brain can convert lactate into glucose via gluconeogenesis or oxidize lactate to pyruvate and then, ultimately, to carbon dioxide and water.

Lactate levels are a reflection of tissue hypoxia, clearance, and alternative sources of production. When the splanchnic circulation is compromised in shock, hepatic lactate clearance is impaired, contributing to the buildup of lactate levels in the circulation. In sepsis, however, the rate of glycolysis increases even in the absence of tissue hypoxia. This phenomenon, which has been termed *accelerated aerobic glycolysis,* may reflect a change in the ratio of the active to the inactive form of pyruvate dehydrogenase, which is the rate-limiting step for the entry of substrate into the mitochondrial tricarboxylic acid cycle.

When systemic oxygen delivery continues to fail to meet systemic oxygen demands, the oxygen debt accumulates. Three stages of shock can ensue. The first stage, which is called early, reversible, or compensated shock, is characterized by compensatory responses to minimize tissue injury. This stage of shock can be self-limited, with full recovery and minimal residual morbidity, if the cause is recognized and treated early. If substantial oxygen debt persists without timely repayment or resolution, inflammation and cellular and microvascular injury define the second stage of shock, which is associated with a prolonged recovery and is typically complicated by organ failure, including acute lung injury and acute tubular necrosis. The third stage is late, irreversible, or decompensated shock. In this situation, the oxygen debt is large, and repayment is slow to nonexistent. When shock reaches this point, cellular and tissue injury is extensive and largely irreversible. Progression to multisystem organ failure and/or death is inevitable, regardless of therapy.

CLINICAL MANIFESTATIONS

The five general types of shock are cardiogenic, distributive, hypovolemic, obstructive, and dissociative. The distinction among these five shock syndromes can be made by combining the history, clinical picture, and hemodynamic measurements. Cardiogenic shock (Chapter 107) and shock syndromes related to sepsis (Chapter 108) are covered in detail elsewhere.

The clinical manifestation of shock is variable and depends on the initiating cause and the response of multiple organs. Shock typically presents as absolute or relative systemic arterial hypotension and evidence of end-organ dysfunction (Table 106-1). The extremities are cool and pale if shock is associated with peripheral vasoconstriction, which is typical of hypovolemic, cardiogenic, and obstructive shock, but they are typically warm and pink with the peripheral vasodilation of distributive shock and dissociative shock (cyanide poisoning).

The most frequent neurologic finding in shock is alteration in the level of consciousness, ranging from confusion to coma. Many of the clinically apparent manifestations of cardiac involvement in shock result from sympathoadrenal stimulation, with tachycardia being the most sensitive indicator that shock is present. Acute lung injury causes impaired gas exchange; the work of breathing is increased, and respiratory muscle fatigue and ventilatory failure require mechanical ventilation. Hypovolemia with or without acute tubular necrosis results in oliguria, although polyuria may be seen in early shock.

Typical clinical manifestations of gut involvement during shock include abdominal pain, ileus, erosive gastritis, pancreatitis, acalculous cholecystitis, and submucosal hemorrhage. If the integrity of the gut barrier is compromised, bacteria and their toxins are translocated into the blood stream. The most common manifestation of liver involvement in shock is a mild increase in serum levels of aminotransferases and lactate dehydrogenase. With severe hypoperfusion, shock liver may manifest with massive aminotransferase elevations and extensive hepatocellular damage.

Thrombocytopenia may result from dilution during volume repletion or from immunologic platelet destruction, which is especially common during septic shock. Activation of the coagulation cascade can lead to disseminated intravascular coagulation (Chapter 178), which results in thrombocytopenia, decreased fibrinogen, elevated fibrin split products, and microangiopathic hemolytic anemia.

Hypovolemic Shock

Hemorrhagic shock, be it from internal or external bleeding, is the most common cause of hypovolemic shock (Table 106-2). Nonhemorrhagic hypovolemic shock can be caused by severe dehydration owing to massive urinary or gastrointestinal fluid losses. Such losses are common in conditions such as diabetic ketoacidosis (Chapters 236) or diarrhea from some infectious diseases, such as cholera (Chapter 310). Massive insensible losses of water or perspiration can precipitate shock in patients with major burn injuries (Chapter 112) or heatstroke (Chapter 109). Sequestration of fluid in the extravascular compartment, commonly referred to as "third spacing," can cause shock in patients as a result of surgery, bowel obstruction, hepatic failure (Chapter 157), systemic inflammation, acute pancreatitis (Chapter 146), or thermal injuries (Chapter 112). Regardless of whether hypovolemic shock is due to hemorrhage or fluid losses, the rate of loss is a critical component of the presentation. If volume is lost at a slow rate, compensatory mechanisms are usually effective, and any given amount of volume depletion is often better tolerated than if the same volume were lost acutely. In addition, underlying diseases, especially those that limit cardiac reserve, can substantially influence the clinical severity of a hypovolemic insult.

TABLE 106-1 PHYSICAL EXAMINATION AND SELECTED LABORATORY SIGNS IN SHOCK

Central nervous system	Acute delirium, restlessness, disorientation, confusion, and coma, which may be secondary to decreased cerebral perfusion pressure (mean arterial pressure minus intracranial pressure). Patients with chronic hypertension or increased intracranial pressure may be symptomatic at normal blood pressures. Cheyne-Stokes respirations may be seen with severe decompensated heart failure. Blindness can be a presenting complaint or complication.
Temperature	Hyperthermia results in excess tissue respiration and greater systemic oxygen delivery requirements. Hypothermia can occur when decreased systemic oxygen delivery or impaired cellular respiration decreases heat generation.
Skin	Cool distal extremities (combined low serum bicarbonate and high arterial lactate levels) aid in identifying patients with hypoperfusion. Pallor, cyanosis, sweating, and decreased capillary refill and pale, dusky, or clammy extremities indicate systemic hypoperfusion. Dry mucous membranes and decreased skin turgor indicate low vascular volume. Low toe temperature correlates with the severity of shock.
General cardiovascular	Neck vein distention (e.g., heart failure, pulmonary embolus, pericardial tamponade) or flattening (e.g., hypovolemia), tachycardia, and arrhythmias. Decreased coronary perfusion pressures can lead to ischemia, decreased ventricular compliance, and increased left ventricular diastolic pressure. A "mill wheel" heart murmur may be heard with an air embolus.
Heart rate	Usually elevated. However, paradoxical bradycardia can be seen in patients with preexisting cardiac disease and severe hemorrhage. Heart rate variability is associated with poor outcomes.
Systolic blood pressure	May actually increase slightly when cardiac contractility increases in early shock and then fall as shock advances. A single episode of undifferentiated hypotension with a systolic blood pressure <80 mm Hg carries an in-hospital mortality of 18%.
Diastolic blood pressure	Correlates with arteriolar vasoconstriction and may rise early in shock and then fall when cardiovascular compensation fails.
Pulse pressure	Defined as systolic minus diastolic pressure and related to stroke volume and the rigidity of the aorta. Increases early in shock and decreases before systolic pressure decreases.
Pulsus paradoxus	An exaggerated change in systolic blood pressure with respiration (systolic blood pressure declines >10 mm Hg with inspiration) seen in asthma, cardiac tamponade, and air embolus.
Mean arterial blood pressure	Diastolic blood pressure + [pulse pressure/3]
Shock index	Heart rate/systolic blood pressure. Normal = 0.5 to 0.7. A persistent elevation of the shock index (>1.0) indicates impaired left ventricular function (as a result of blood loss and/or cardiac depression) and is associated with increased mortality.
Respiratory	Tachypnea, increased minute ventilation, increased dead space, bronchospasm, hypocapnia with progression to respiratory failure, acute lung injury, and adult respiratory distress syndrome.
Abdomen	Low-flow states may result in abdominal pain, ileus, gastrointestinal bleeding, pancreatitis, acalculous cholecystitis, mesenteric ischemia, and shock liver.
Renal	Because the kidney receives 20% of cardiac output, low cardiac output reduces the glomerular filtration rate and redistributes renal blood flow from the renal cortex toward the renal medulla, leading to oliguria. Paradoxical polyuria in sepsis may be confused with adequate hydration.
Metabolic	Respiratory alkalosis is the first acid-base abnormality, but metabolic acidosis occurs as shock progresses. Hyperglycemia, hypoglycemia, and hyperkalemia may develop.

TABLE 106-2 CLASSIFICATION OF HEMORRHAGIC SHOCK*

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (mL)	Up to 750	750-1500	1500-2000	>2000
% Volume	Up to 15	15-30	30-40	>40
Pulse rate (per min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (per min)	14-20	20-30	30-40	>35
Urine output (mL/hr)	>30	20-30	5-15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

*Estimates based on a 70-kg patient.

Distributive Shock

The most important and prevalent cause of distributive shock is septic shock (Chapter 108), but anaphylaxis (Chapter 261), drug overdose (Chapter 33), neurogenic insults, and addisonian crisis (Chapter 234) can also produce vasodilatory shock. Sepsis can be a combination of hypovolemia, vasodilation, myocardial suppression, and impaired tissue oxygen use (dissociative shock). In approximately 10 to 15% of septic shock patients, myocardial dysfunction results in a low-cardiac-output form of shock. Early interventions (Chapter 108) can improve outcomes substantially.

Cardiogenic Shock

Cardiogenic shock (Chapter 107) is defined by a decrease in systemic oxygen delivery caused by an acute or chronic deterioration of cardiac function owing to myocardial, valvular, structural, toxic, or infectious causes. The clinical picture of cardiogenic shock is variable, depending on which structural component of the ventricle is impaired.

Extracardiac Obstructive Shock

This form of shock results from acute obstruction to flow in the circulation. Examples include impaired diastolic filling of the right ventricle (e.g., superior vena cava syndrome; Chapter 187), obstruction of right ventricular output (e.g., massive pulmonary embolism; Chapter 98), or an air embolus from cardiopulmonary bypass or central line placement (Chapter 98). Systemic arterial hypertension (Chapter 67) severe enough to impair left ventricular function or acute pericardial tamponade or constrictive pericarditis (Chapter 77) can also produce an obstructive shock pattern.

Dissociative Shock

Dissociative shock results from microvascular abnormalities, with maldistribution or shunting of blood flow, or cytopathic tissue hypoxia. Dissociative shock includes disorders that inhibit oxygen utilization, such as cyanide poisoning, sodium nitroprusside use, and sepsis.

Mixed Shock States

Shock may arise from multiple causes. For example, a patient with pneumonia and a history of ischemic cardiomyopathy may present in a hypodynamic rather than a hyperdynamic state when combined with sepsis. Thus, a mixture of hypovolemic, distributive, and cardiogenic shock can be seen in the same patient.

DIAGNOSIS

A key element in the approach to shock is a problem-directed history and physical examination. Some patients present with few symptoms other than generalized weakness, lethargy, or altered mental status. A discussion with the patient and family members should specifically address symptoms that suggest volume depletion, including bleeding, vomiting, diarrhea, excessive urination, insensible losses due to fever, or orthostatic lightheadedness. The history should also inquire about prior or current evidence of cardiovascular disease, especially episodes of chest pain (Chapter 50) or symptoms of heart failure (Chapter 58). Prior neurologic diseases can render patients more susceptible to complications from hypovolemia. Medication use, both prescribed and nonprescribed, must be ascertained. Some medications cause volume depletion (e.g., diuretics), whereas others depress myocardial contractility (e.g., β-blockers, calcium-channel blockers). The possibility of an anaphylactic reaction to a new medication or cardiovascular depression owing to drug toxicity should be considered. A recent or remote history of steroid use may suggest adrenal insufficiency (Chapter 34).

Findings on the physical examination can provide critical information to aid in the diagnosis (see Table 106-1). Traditionally, shock is defined by a systolic blood pressure less than 90 mm Hg or 40 mm Hg less than the baseline systolic blood pressure if the patient has a history of hypertension.

Acidosis

A common theme in shock is that tissue hypoxia leads to acidosis (Chapter 120), which develops as a consequence of anaerobic metabolism and generally parallels the severity of shock. Laboratory manifestations may include a base deficit, low arterial and venous pH levels, and an elevated serum lactate level. Base deficit is the absolute decrease in the serum concentration of bicarbonate (normal minus the patient's bicarbonate). A mild base deficit is −2 to −5, moderate is −6 to −14, and severe is −15 mM/L or greater. When patients are resuscitated using large volumes of normal saline, the large fluid load can cause a dilutional acidosis, and the large chloride load can induce metabolic acidosis even in the absence of tissue hypoxia and anaerobic metabolism. Base deficit can also be caused by cocaine, alcohol, and diabetic ketoacidosis. Despite its limitations, base deficit provides the clinician with a quick indicator to assess the severity of tissue hyperfusion and the adequacy of resuscitation in relieving anaerobic metabolism and oxygen debt.

The low pH of metabolic acidosis can result from different acids. Acidosis caused by lactate and unidentified anions produces an ion gap. The blood lactate concentration rises with increased anaerobic metabolism, as is seen in shock but also in diabetic ketoacidosis (Chapter 236) , total parenteral nutrition (Chapter 224), seizures (Chapter 410), thiamine deficiency (Chapter 225), treatment of HIV infection with protease inhibitors (Chapter 396), and administration of metformin, salicylate, isoniazid, propofol, and cyanide (Chapter 110). A lactate concentration greater than 4 mmol/L is unusual in normal and non–critically ill hospitalized patients and warrants concern. A lactate concentration greater than 4 mmol/L is associated with an in-hospital mortality exceeding 25%, regardless of the cause, and failure to decrease lactate levels over the first 6 hours of shock is associated with an increased inflammatory response, the development of organ failure, and mortality.

Urine Output

The kidneys normally receive 20% of the systemic oxygen delivery, and because of this large amount of blood flow per gram of tissue, they are highly sensitive to changes in renal blood flow. Urine output is a valuable indicator of renal perfusion and vital organ blood flow. Although a significant drop in urine output indicates reduced renal blood flow, an adequate urine output does not always indicate successful resuscitation. Other factors that may affect urine output include the use of mannitol or diuretics. Preexisting conditions, such as renal failure, may also limit the ability of this measure to reflect the adequacy of resuscitation.

TREATMENT Rx

The goal of initial management is to restore global and microvascular perfusion to levels that sustain aerobic cellular respiration. Multiple randomized trials have shown significant and consistent reductions in mortality when shock is reversed aggressively before organ failure develops. Once this initial management is accomplished, the definitive diagnosis leads to more specific therapy based on the cause of shock.

Markers of shock serve not only as diagnostic tools for risk stratification but also as targets or end points for the early restoration of adequate tissue perfusion. Clinical monitoring of tissue oxygenation and organ function commonly involves measuring traditional end points of resuscitation, such as heart rate, blood pressure, mentation, urine output, and skin perfusion. Many clinicians continue to use these parameters as indicators that systemic oxygenation imbalances have been corrected. However, there is increasing evidence that clinical parameters may be poor indicators of the ongoing tissue hypoxia that is associated with increased mortality.

Initial Management

The initial management of shock requires immediate diagnostic and therapeutic interventions, including attention to airway, breathing, circulation, and definitive diagnosis and treatment (Chapter 63). The first step to optimize

systemic oxygen delivery is to provide supplemental oxygen to increase arterial oxygen content. If any doubt exists about the patency of the airway or the adequacy of ventilation, endotracheal intubation should be performed and mechanical ventilation initiated (Chapter 105). Mechanical ventilation helps provide adequate oxygenation and carbon dioxide elimination and decreases oxygen utilization by the respiratory muscles, which may be responsible for up to 40% of systemic oxygen consumption and lactate production.

Although endotracheal intubation and mechanical ventilation may be critical for patients in shock, the sudden increase in airway pressure can lead to a series of deleterious hemodynamic complications, especially in patients who are hypovolemic or vasodilated or have compromised cardiac function. In such patients, the resulting decreased venous return, increased pulmonary vascular resistance, and decreased ventricular compliance may lead to hypotension and cardiovascular collapse. Furthermore, when sedatives, anxiolytics, or induction agents are used during and after intubation, the decrease in catecholamine levels, peripheral vascular resistance, and cortisol levels may result in hypotension. If possible, preparations should be made to monitor physiologic variables, ensure adequate fluid administration, and provide rapid access to vasopressors should systemic arterial pressure fall to dangerously low levels.

Upon initial presentation, it is good practice to place one or two large-bore (≥16 gauge) peripheral intravenous catheters and to administer a crystalloid solution (normal saline or Ringer's lactate solution). If MAP is less than 60 to 65 mm Hg, systolic blood pressure is less than 90 mm Hg, or evidence of tissue hypoperfusion is present, an intravenous fluid challenge (20 to 40 mL/kg crystalloid or colloid) should be given rapidly. A bolus of 500 mL every 30 minutes titrated to MAP or measurement of preload is recommended. In an 80-kg person, the average intravascular volume is 5 L. In shock states, such as septic shock, in which intravascular hypovolemia is a predominant feature, 5 to 6 L of fluid over the first 6 hours is considered an average volume resuscitation. If hemorrhage is the likely cause of shock, blood should be used to replace volume. Fluids should not be withheld, even in patients with end-stage renal disease.

Central venous access and arterial blood pressure monitoring should be established to monitor hemodynamics and venous and arterial blood gases, respectively. Electrocardiographic monitoring and continuous measurement of oxygen saturation by pulse oximetry are useful adjuncts. Because the Trendelenburg position may impair gas exchange and promote aspiration, an alternative is to raise the patient's legs above the level of the heart with the patient in the supine position.

If the patient remains hypotensive, vasopressors such as norepinephrine, dopamine, or Neo-Synephrine (Table 106-3) should be administered to restore adequate systemic arterial pressure while the diagnostic evaluation is ongoing. Treatment with vasopressors should not be postponed while trying to achieve euvolemia by using fluid boluses, because patients with cerebrovascular and coronary artery disease may be intolerant of the hypotensive interval. However, vasopressors may also mask hypovolemia when they increase blood pressure. If the volume status remains undefined or the hemodynamic condition requires repeated fluid challenges or vasopressor treatment, a central venous catheter should be placed to determine central venous oxygen saturation, ventricular filling pressures, and intravascular volume status while echocardiography is performed. Based on these data, patients can usually be classified and managed according to their hemodynamic and oxygen transport patterns (Figs. 106-2 and 106-3).

Fluid Replacement

Rapid and appropriate restoration of vascular volume decreases the need for vasopressor therapy, adrenal replacement therapy, and invasive monitoring; in addition, it modulates the inflammation that arises when a patient progresses to severe shock. The goal of fluid resuscitation is not merely to achieve a predetermined volume but rather to titrate fluid to optimize systemic oxygen delivery and meet tissue oxygen demands.

To assess the adequacy of cardiac preload during the resuscitation of a patient with shock, a central venous catheter is as good as a pulmonary artery catheter.■ However, the CVP does not correlate well with left ventricular end-diastolic volume: although a low CVP indicates hypovolemia, a "normal" CVP does not exclude inadequate preload as a cause of shock. A fluid challenge in a volume-responsive patient increases cardiac output by about 20% for each 2 cm H_2O change in CVP; by comparison, cardiac output does not change if the CVP is raised in a patient with adequate left ventricular volume.

When intrathoracic pressure increases during the application of positive airway pressure in a mechanically ventilated patient, venous return decreases and, as a consequence, left ventricular stroke volume also decreases. The variation in pulse pressure or stroke volume during a positive-pressure breath can also predict the responsiveness of cardiac output to changes in preload. Pulse pressure variation is defined by equation 3:

$$100 \times (\text{PPmax} - \text{PPmin}) / [(\text{PPmax} + \text{PPmin}) / 2] \quad (3)$$

PPmax and PPmin are the maximal and minimal pulse pressures, respectively, in a respiratory cycle. Pulse pressure variation values of 13 to 15% suggest that hypovolemia is present and that the cardiac index will increase by at least 15% after the rapid infusion of 500 mL of crystalloid. Pulse pressure variation is generally the best predictor of volume status and response to fluids, although atrial arrhythmias can interfere with the usefulness of this technique.

Types of Fluids

The two most commonly used crystalloid solutions are 0.9% sodium chloride solution (normal saline) and Ringer's lactate solution. Although these two solutions have been regarded as essentially interchangeable, accumulating data suggest that large volumes of normal saline, but not Ringer's lactate solution, promote the development of hyperchloremic metabolic acidosis and coagulopathy (Table 106-4).

Colloids are higher-molecular-weight solutions that increase plasma oncotic pressure; they are classified as natural (albumin) or artificial (starches, hetastarch, pentastarch, dextrans, and gelatins). Colloids are dissolved in either normal saline or a balanced salt solution. There are no clinically significant differences among the various colloid solutions when they are used for shock resuscitation. When compared with saline-based solutions, hetastarch dissolved in a calcium-containing, low-chloride, balanced salt solution may be

TABLE 106-3 VASOPRESSOR AGENTS

		Peripheral Vasculature		*Cardiac Effects*			
AGENT	**DOSE RANGE**	**VASOCONSTRICTION**	**VASODILATION**	**HEART RATE**	**CONTRACTILITY**	**DYSRHYTHMIAS**	**TYPICAL USE**
Dopamine	1-4 μg/kg/min	0	1+	1+	1+	1+	"Renal dose" does not improve renal function; may be used with bradycardia and hypotension
	5-10 μg/kg/min	1-2+	1+	2+	2+	2+	
	11-20 μg/kg/min	2-3+	1+	2+	2+	3+	Vasopressor range
Vasopressin	0.04-0.1 units/min	3-4+	0	0	0	1+	Septic shock, post–cardiopulmonary bypass shock state, no outcome benefit in sepsis
Phenylephrine	20-200 μg/min	4+	0	0	0	1+	Vasodilatory shock, best for supraventricular tachycardia
Norepinephrine	1-20 μg/min	4+	0	2+	2+	2+	First-line vasopressor for septic shock, vasodilatory shock
Epinephrine	1-20 μg/min	4+	0	4+	4+	4+	Refractory shock, shock with bradycardia, anaphylactic shock
Dobutamine	1-20 μg/kg/min	1+	2+	1-2+	3+	3+	Cardiogenic shock, septic shock
Milrinone	37.5-75 μg/kg bolus followed by 0.375-0.75 μg/min	0	2+	1+	3+	2+	Cardiogenic shock, right heart failure, dilates pulmonary artery; caution in renal failure

associated with less acidosis and less use of blood products, but its use in severe sepsis and septic shock has been associated with increased renal failure and mortality.[2]

Colloids stay in the intravascular space significantly longer than crystalloids do, with an intravascular half-life of 16 hours for albumin versus 30 to 60 minutes for normal saline and lactated Ringer's. When titrated to the same volume status, colloids and crystalloids restore tissue perfusion to the same magnitude, but a two to four times greater volume of crystalloids is required to achieve the same end point. Various types of fluids have potential advantages and disadvantages, but the outcomes of patients with hypovolemic shock are equivalent for crystalloids and albumin (see Table 106-4).[3]

Fluid Management Strategies

Initial aggressive fluid resuscitation usually occurs within 6 hours of presentation, but different strategies are needed for the longer-term management of fluid status, especially in patients with acute lung injury. For example, conservative volume therapy (euvolemia) beginning an average of 47 hours after admission to the intensive care unit (ICU) and 24 hours after the establishment of acute lung injury results in significantly better lung and central nervous system function and a decreased need for sedation, mechanical ventilation, and ICU care.[4] However, patients who receive conservative volume replacement transiently may need more vasopressor support.

Optimal Hemoglobin

In hemorrhagic shock, the rapid administration of packed red blood cells and, if indicated, platelets and thawed fresh-frozen plasma can be life-saving. Whenever possible, fully cross-matched packed red blood cells are preferable, but type-specific blood can often be given safely when immediate therapy is warranted (Chapter 180). In dire emergencies, type O Rh-negative blood can be administered to women of childbearing potential, and type O

Comments: Preexisting heart disease may alter the filling pressures	Comments: If there is a VSD, there may be $ScvO_2/SvO_2$ or a step up from the right atrium to right ventricle to the pulmonary artery. Large V wave is seen on PA catheter with mitral regurgitation.	Comments: Equalization of intracardiac diastolic pressure is consistent with pericardial tamponade. A rapid x and blunted y descent on CVP wave form indicates the inability of the heart to fill.	Comments: In the early stage, filling pressures are low, leading to low to normal cardiac output and variable $ScvO_2/SvO_2$. If myocardial depression accompanies, then a similar profile of cardiogenic shock is seen. After resuscitation a hyperdynamic circulation is seen.	Comments: Filling pressures can be variable, depending on stage of the disease. Cardiac output is generally increased. SVR is decreased and $ScvO_2/SvO_2$ and lactate are increased.
Therapy				
Rapid replacement of blood, colloid or crystalloid Identify source of blood/fluid loss Replace deficient coagulation factors Consider factor VIIa Endoscopy/colonoscopy Angiography CT/MRI/US or other	LV infarction: intra-aortic balloon pump (IABP) coronary angiography Recanalization: thrombolytic therapy, angioplasty, coronary bypass surgery RV infarction: fluids and inotropes with PA catheter Mechanical abnormality: echocardiography, cardiac catheterization Corrective surgery: mechanical assist devices, transplantation	Pericardial tamponade: pericardiocentesis, surgical drainage (if needed) Pneumothorax: chest tube Pulmonary embolism: heparin ventilation-perfusion lung scan pulmonary angiography consider thrombolytic therapy, embolectomy Severe hypertension: afterload reduction	Identify site of infection Antimicrobial agents Early goal-directed therapy fluids vasopressors inotropic agents Goals: $ScO_2 > 70\%$ CVP > 8 mm Hg MAP > 65 mm Hg Improving organ function Decreasing lactate levels Consider activated protein C Requiring vasopressors, consider corticosteroids	Toxin antidote or remove agent, hyperbaric oxygen therapy Recombinant activated protein C Nitroglycerin (speculative) Prostacyclin (speculative)

FIGURE 106-3, cont'd.

TABLE 106-4 FLUID THERAPY

Normal saline	Normal saline is a slightly hyperosmolar solution containing 154 mEq/L of both sodium and chloride. Owing to the relatively high chloride concentration and low pH, normal saline carries a risk of inducing hyperchloremic metabolic acidosis when given in large amounts.
Lactated Ringer's solution (LR)	Lactate is metabolized to carbon dioxide (CO_2) and water by the liver, leading to the release of CO_2 in the lungs and excretion of water by the kidneys. LR is preferred over normal saline and buffers acidemia. Because LR contains a very small amount of potassium, there is a small risk of inducing hyperkalemia in patients with renal insufficiency or renal failure. LR may be incompletely metabolized in severe hepatic failure.
Albumin	Albumin is a protein derived from human plasma and is available in varying concentrations from 4 to 25%. A study comparing fluid resuscitation with albumin versus saline found similar 28-day mortalities and secondary outcomes in each arm. However, a post-hoc subset analysis of patients with sepsis and acute lung injury resuscitated with albumin showed a trend toward a decrease in mortality. There was a significant increase in mortality in trauma patients, particularly those with head injury.
Hydroxyethyl starch (HES)	HES, which is a synthetic colloid derived from hydrolyzed amylopectin, causes renal impairment at recommended doses and impaired long-term survival at high doses. HES can also cause coagulopathy and bleeding complications from reduced factor VIII and von Willebrand factor levels, as well as impaired platelet function. HES increases the risk of acute renal failure and reduces the probability of survival in patients with sepsis.
Dextrans	Dextrans are artificial colloids synthesized by *Leuconostoc mesenteroides* bacteria grown in sucrose media. Dextrans are used more frequently to lower blood viscosity than for rapid plasma expansion. They can cause renal dysfunction as well as anaphylactoid reactions.
Gelatins	Gelatins are produced from bovine collagen. Because they have a small molecular weight, they are not very effective at expanding plasma volume, but they cost less than other options. They have been reported to cause renal impairment as well as allergic reactions ranging from pruritus to anaphylaxis. Gelatins are not currently available in North America.

Rh-negative or Rh-positive blood can be given to men or postmenopausal women.

The appropriate hemoglobin level in shock remains controversial, but a value of 10 mg/dL is often recommended as long as the patient has increased lactate levels, decreased venous oxygen saturation, or evidence of systemic hypoperfusion. A more conservative transfusion strategy (hemoglobin value of 7 to 10 mg/dL) is appropriate when the patient is in the more convalescent phase of critical illness.

Vasopressor Therapy

To optimize end-organ perfusion, the second phase of intervention after adequate fluid therapy is to maintain perfusion pressure. A specific MAP goal has not been established for all shock states, but a MAP of at least 60 to 65 mm Hg is a reasonable target.

The most common vasopressors are agonists at various adrenergic receptors. Receptors include peripheral α-adrenergic receptors that lead to vasoconstriction, cardiac β_1 receptors with both chronotropic and inotropic effects, β_2 receptors located in the circulation and airways that mediate vasodilation and bronchodilation, and dopaminergic receptors located throughout the cardiovascular, mesenteric, and renal circulations. Based on these mechanisms, therapy can be tailored to a specific circumstance. For example, a patient with severe tachycardia would be best served by an agent with more α-selective activity and less β activity to avoid tachycardia and increased myocardial oxygen consumption (see Table 106-3).

Norepinephrine, which is a vasoconstrictor and an inotrope, provides better splanchnic oxygen utilization compared with dopamine. It is generally considered the first-line vasopressor for treating persistent hypotension in septic patients despite adequate resuscitation, and it may be superior to dopamine in treating cardiogenic shock. For example, a randomized trial comparing dopamine with norepinephrine in patients with shock showed no significant difference in mortality for hypovolemic and septic shock but a significant benefit of norepinephrine in cardiogenic shock. In addition, there was a significant two-fold increase in arrhythmic events with dopamine compared with norepinephrine (24.1 vs. 12.4%).

Dopamine's effects result from transduction at dopaminergic receptors in the renal, mesenteric, coronary, and systemic circulations. The positive chronotropic and inotropic effects of dopamine can lead to tachycardia and tachyarrhythmias; this effect frequently limits its dosing because the increased myocardial oxygen requirements promote the development of myocardial ischemia, especially in the presence of coronary artery disease.

Phenylephrine is a synthetic catecholamine that is a selective α-adrenergic agonist and is ideal in patients with tachycardia. However, the resulting increase in myocardial oxygen consumption, decrease in splanchnic blood flow, and decrease in cardiac output can be detrimental for patients with septic shock.

Epinephrine, which is a potent α-, β_1-, and β_2-adrenergic agonist, increases peripheral arteriolar tone as well as cardiac contractility. It is the first-line agent for the treatment of anaphylactic shock and is used to support myocardial contractility following cardiac surgery. Epinephrine increases the white blood cell count and the blood lactate concentration because of accelerated aerobic glycogenolysis and/or maldistribution of blood flow.

Vasopressin deficiency accompanies vasodilatory shock. Vasopressin is not a potent vasopressor in normal subjects, but very low doses (0.04 unit/minute) markedly increase arterial blood pressure in septic patients with intractable hypotension. In addition, vasopressin enhances the pressor response to catecholamines.

Adrenal Dysfunction

Beyond their metabolic functions, glucocorticoids are required to maintain responsiveness to vasopressors, intravascular volume, vascular permeability, and myocardial contractility. If the hypothalamic-pituitary-adrenocortical axis is depressed in shock, clinical findings can include unexplained fever, hypoglycemia, metabolic acidosis, hypotension refractory to fluid resuscitation, and eosinophilia. Cortisol levels and the results of cosyntropin stimulation testing may not be clinically helpful. If adrenal insufficiency is strongly suspected, or if patients have refractory hypotension despite vasopressors and hemodynamic optimization, stress doses of intravenous hydrocortisone (e.g., 50 mg every 6 hours) are recommended.

PROGNOSIS

Clinical characteristics associated with a poor outcome include the severity of shock; its temporal duration, underlying cause, and reversibility; and preexisting vital organ dysfunction. Direct noninvasive measurement of maximal oxygen uptake predicts outcome in patients who have cardiogenic shock. Persistently elevated lactate levels are prognostic in trauma, septic shock, and after cardiac arrest, and an anion gap acidosis is associated with significantly higher hospital mortality than is hyperchloremic acidosis. Regional measurements of pH are highly predictive of outcome; for example, if the gastric mucosal pH remains below 7.3 for 24 hours, the hospital mortality rate is about 50%. The severity of the base deficit correlates with the development of multisystem organ failure in trauma. The mortality for an undiagnosed patient who is sent to a general medical floor and develops shock is three times higher than for a patient who is admitted directly to the ICU.

107 CARDIOGENIC SHOCK

STEVEN HOLLENBERG

DEFINITION

Cardiogenic shock is the syndrome that ensues when the heart is unable to deliver enough blood to maintain adequate tissue perfusion. The hemodynamic picture includes sustained systemic hypotension, pulmonary capillary wedge pressure (PCWP) greater than 18 mm Hg, and cardiac index less than 2.2 L/minute/m^2 (Table 107-1). Although systolic blood pressure less than 90 mm Hg is a commonly accepted threshold for shock, a decrease of 30 mm Hg from baseline can also be used. The diagnosis of cardiogenic shock is often made on clinical grounds—hypotension combined with signs of poor tissue perfusion, including oliguria, clouded sensorium, and cool extremities, all in the setting of myocardial dysfunction. To make the diagnosis, it is important to document myocardial dysfunction and to exclude or correct factors such as hypovolemia, hypoxemia, and acidosis.

EPIDEMIOLOGY

The predominant cause of cardiogenic shock (Fig. 107-1) is left ventricular failure secondary to acute myocardial infarction (MI)—an extensive first acute MI, cumulative loss of myocardial function in a patient with previous MI or cardiomyopathy, or a mechanical complication of MI (Chapter 73). However, any cause of severe left ventricular (LV) or right ventricular (RV) dysfunction can lead to cardiogenic shock, including end-stage cardiomyopathy (Chapter 60), prolonged cardiopulmonary bypass, valvular disease (Chapter 75), myocardial contusion (Chapter 112), sepsis with unusually profound myocardial depression (Chapter 108), and fulminant myocarditis (Chapter 60) (Table 107-2). Stress-induced (takotsubo) cardiomyopathy (Chapter 60), a syndrome of acute apical LV dysfunction that occurs after emotional distress, may also present with cardiogenic shock. Acute valvular regurgitation, most often caused by endocarditis (Chapter 76) or chordal rupture (Chapter 75), can lead to shock, as can physiologic stress in the setting of severe valvular stenosis. Cardiac tamponade (Chapter 77) and massive pulmonary embolism (Chapter 98) with acute RV failure can cause shock without pulmonary edema.

The incidence and mortality associated with cardiogenic shock appear to be declining. In the past 30 years the incidence has fallen from about 8% to 6% of MIs, largely because of the benefit of early perfusion strategies (Chapter 73). In parallel, mortality from cardiogenic shock has decreased from 70 to 80% to 50% or less, suggesting that increasingly effective early treatment and more widespread adoption of early revascularization have improved the outcomes of patients in whom shock has already developed.

TABLE 107-1 DIAGNOSIS OF CARDIOGENIC SHOCK

CLINICAL SIGNS
Hypotension
Oliguria
Clouded sensorium
Cool and mottled extremities
HEMODYNAMIC CRITERIA
Systolic blood pressure < 90 mm Hg or > 30 mm Hg decrease from baseline for > 30 min
Cardiac index < 2.2 L/min/m^2
Pulmonary capillary wedge pressure > 18 mm Hg
OTHER
Documented myocardial dysfunction
Exclusion of hypovolemia, hypoxia, and acidosis

Risk factors for the development of cardiogenic shock in MI parallel those for LV dysfunction and the severity of coronary artery disease. Patient characteristics include older age, anterior MI, diabetes, hypertension, multivessel coronary artery disease (CAD), previous MI, and peripheral vascular and cerebrovascular disease. Clinical risk factors include decreased ejection fractions, larger infarctions, and lack of compensatory hyperkinesis in myocardial territories remote from the infarction. Clinical harbingers of impending shock include the degree of hypotension and tachycardia at hospital presentation. The factors that predict mortality reflect the severity of the acute insult as well as comorbid conditions.

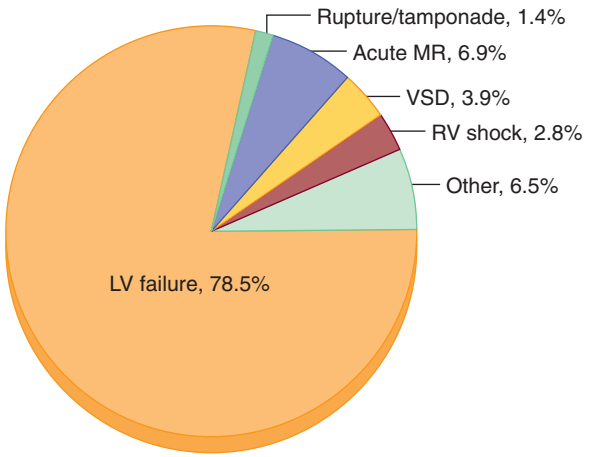

FIGURE 107-1. Causes of cardiogenic shock in patients with myocardial infarction in the SHOCK trial registry. LV = left ventricular; MR = mitral regurgitation; RV = right ventricular; VSD = ventricular septal defect. (Adapted from Hochman JS, Boland J, Sleeper LA, et al. Current spectrum of cardiogenic shock and effect of early revascularization on mortality. Report of an international registry. SHOCK registry investigators. *Circulation.* 1995;91:873-881).

TABLE 107-2 CAUSES OF CARDIOGENIC SHOCK

ACUTE MYOCARDIAL INFARCTION
Pump failure
Large infarction
Smaller infarction with preexisting left ventricular dysfunction
Infarct extension
Reinfarction
Infarct expansion
Mechanical complications
Acute mitral regurgitation due to papillary muscle rupture
Ventricular septal defect
Free wall rupture
Pericardial tamponade
Right ventricular infarction
CARDIOMYOPATHY
Myocarditis
Peripartum cardiomyopathy
End-stage low-output heart failure
Hypertrophic cardiomyopathy with outflow tract obstruction
Stress cardiomyopathy
VALVULAR HEART DISEASE
Acute mitral regurgitation (chordal rupture)
Acute aortic regurgitation
Aortic or mitral stenosis with tachyarrhythmia or other comorbid condition causing decompensation
Prosthetic valve dysfunction
TACHYARRHYTHMIA
OTHER CONDITIONS
Prolonged cardiopulmonary bypass
Septic shock with severe myocardial depression
Penetrating or blunt cardiac trauma
Orthotopic transplant rejection
Massive pulmonary embolism
Pericardial tamponade

Coronary angiography most often demonstrates multivessel CAD. About 30% of patients have a left main coronary artery occlusion, about 60% have three-vessel coronary disease, and only about 20% have single-vessel disease. Multivessel CAD helps explain the failure to develop compensatory hyperkinesis in remote myocardial segments, because of either previous infarction or high-grade coronary stenoses.

Only one fourth of patients who develop cardiogenic shock are in shock when they initially present to the hospital; in the others, shock usually evolves over several hours, suggesting that early treatment may prevent shock. Comparison of the clinical characteristics of patients with early and late shock shows similar demographic, historical, clinical, and hemodynamic characteristics, but shock tends to develop earlier in patients with single-vessel CAD than in those with triple-vessel disease. This finding suggests that early shock in the setting of acute MI may be more amenable to revascularization of the culprit vessel via thrombolysis or angioplasty (Chapter 73), whereas shock developing later may require more complete revascularization with multivessel percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) surgery (Chapter 74).

PATHOBIOLOGY

Cardiogenic shock is characterized by a downward cascade in which myocardial dysfunction reduces stroke volume, cardiac output, and blood pressure; these changes compromise myocardial perfusion, exacerbate ischemia, and further depress myocardial function, cardiac output, and systemic perfusion. Concomitant diastolic dysfunction increases left atrial pressure, which leads to pulmonary congestion and hypoxemia and exacerbates myocardial ischemia and impairs ventricular performance.

Compensatory mechanisms include sympathetic stimulation, which increases heart rate and contractility, and renal fluid retention, which increases preload. Increases in heart rate and contractility increase myocardial oxygen demand and exacerbate ischemia. Another compensatory mechanism, vasoconstriction to maintain blood pressure, increases myocardial afterload, further impairing cardiac performance and increasing myocardial oxygen demand. In the face of inadequate perfusion, this increased demand can worsen ischemia and perpetuate a vicious circle that, if unbroken, may culminate in death. Interrupting this circle of myocardial dysfunction and ischemia is the basis for therapeutic regimens for cardiogenic shock.

In cardiogenic shock, LV dysfunction is not always severe. In one large study, the mean LV ejection fraction was 30%, indicating that mechanisms other than primary pump failure were operative. Furthermore, systemic vascular resistance is not always elevated, suggesting that compensatory vasoconstriction is not universal. Inflammatory responses may contribute to the vasodilation and myocardial dysfunction in cardiogenic shock.

Patients in cardiogenic shock may have areas of nonfunctional but viable myocardium owing to stunning or hibernation. Myocardial stunning represents postischemic dysfunction that persists despite restoration of normal blood flow. Hibernating myocardial segments have persistently impaired function at rest owing to severely reduced coronary blood flow; function in these segments might be normalized by improving blood flow. Although hibernation is conceptually different from stunning, the two conditions may not differ much clinically. Repetitive episodes of myocardial stunning can occur in areas of viable myocardium subtended by a critical coronary stenosis. Such episodes can recapitulate the hibernation phenotype, blurring the distinction between myocardial stunning and hibernation. Regardless of the degree of overlap, the therapeutic implications make distinguishing the two conditions vital in patients with cardiogenic shock. The contractile function of hibernating myocardium improves with revascularization, whereas stunned myocardium retains inotropic reserve and can respond to inotropic stimulation. In addition, the severity of the antecedent ischemic insult determines the intensity of stunning, providing a rationale for reestablishing the patency of occluded coronary arteries in patients with cardiogenic shock. Finally, the notion that some myocardial tissue may recover function emphasizes the importance of measures to support the patient hemodynamically and minimize myocardial necrosis in patients with shock.

CLINICAL MANIFESTATIONS

The physical examination should be geared toward evaluating congestion and systemic perfusion to characterize the patient's hemodynamic profile (Table 107-3). An assessment of whether the patient is "wet" or "dry" and "cold" or "warm" is integral to management. Signs of congestion (Chapter 58) include jugular venous distention (see Fig. 50-3 in Chapter 50) and pulmonary rales and may include peripheral edema and ascites. Whether the patient is "cold" or "warm" is an indication of systemic perfusion.

TABLE 107-3 CLINICAL SIGNS OF VOLUME STATUS AND PERFUSION

SIGNS AND SYMPTOMS OF CONGESTION
Orthopnea, paroxysmal nocturnal dyspnea
Jugular venous distention
Abdominojugular reflux
Rales
Hepatomegaly
Edema
Right upper quadrant tenderness
POSSIBLE EVIDENCE OF LOW PERFUSION
Narrow pulse pressure
Obtundation
Cool extremities
Cachexia, muscle loss
Decreased exercise tolerance
Renal/hepatic dysfunction
Hypotension with angiotensin-converting enzyme inhibition

The majority of the cardiogenic shock patients present "wet" and "cold." Patients with shock are usually ashen or cyanotic, and they have cool skin and mottled extremities. Cerebral hypoperfusion may cloud the sensorium. Pulses, which are rapid and faint, may be irregular in the presence of arrhythmias. Jugular venous distention and pulmonary rales are usually present, although their absence does not exclude the diagnosis. A precordial heave resulting from LV dyskinesis may be palpable. The heart sounds may be distant, and third and/or fourth heart sounds are usually present. A systolic murmur of mitral regurgitation or a ventricular septal defect may be heard, but either complication can occur without an audible murmur (Chapter 73).

DIAGNOSIS

After recognizing the clinical manifestations of apparent cardiogenic shock, the clinician must confirm its presence and assess its cause while simultaneously initiating supportive therapy before there is irreversible damage to vital organs. The clinician must balance overzealous pursuit of an etiologic diagnosis before achieving stabilization with overzealous empirical treatment without establishing the underlying pathophysiology.

An electrocardiogram (ECG) should be performed immediately. In cardiogenic shock caused by acute MI, the ECG most commonly shows ST elevation, but ST depression or nonspecific changes are found in 25% of cases. If RV infarction is suspected, ST elevation in modified right-sided leads may be diagnostic (Chapter 73). The ECG may also provide information on previous MIs and rhythm abnormalities. A relatively normal ECG or one showing only diffuse, nonspecific changes in a patient with clinical cardiogenic shock should suggest myocarditis (Chapter 60), especially if the patient has arrhythmias. In end-stage heart failure, the ECG may show Q waves and/or bundle branch block, indicative of extensive disease.

Other initial diagnostic tests include a chest radiograph, complete blood count, and measurement of arterial blood gases, electrolytes, and cardiac biomarkers. A high-quality chest film can assess signs of pulmonary edema and is helpful when signs suggest an alternative diagnosis, such as a widened mediastinum indicative of aortic dissection (Chapter 78).

Echocardiography

Echocardiography should be performed as early as possible, preferably with color flow Doppler, to provide an expeditious assessment of cardiac chamber size, LV and RV function, valvular structure and motion, atrial size, and the pericardium (Chapter 55). Echocardiography can also assess or diagnose overall and regional systolic function, diastolic function, papillary muscle rupture, acute ventricular septal defect, free wall rupture, degree of mitral regurgitation, presence of RV infarction, cardiac tamponade, and valvular stenosis.

Right Heart Catheterization

If the history, physical examination, chest radiograph, and echocardiogram demonstrate systemic hypoperfusion, low cardiac output, and elevation of venous pressures, right heart catheterization may not be necessary for

diagnosis. However, therapy with vasopressors and inotropic agents is best optimized using hemodynamic measurements. Right heart catheterization can exclude other causes of shock such as volume depletion and sepsis, and it helps diagnose mechanical complications. A step-up in oxygen saturation between the right atrium and pulmonary artery can indicate a ventricular septal defect (Chapter 69), and large "V" waves in the PCWP waveform can reflect acute severe mitral regurgitation. RV infarction should be suspected when the PCWP is normal but right-sided filling pressures are notably elevated.

Right heart catheterization is most useful, however, to optimize therapy in unstable patients. In such patients, clinical estimates of filling pressures can be unreliable, and changes in myocardial performance or therapeutic interventions can change cardiac output and filling pressures precipitously. Although patients with a low cardiac index (<2.2 L/minute/m^2) and a PCWP greater than 18 mm Hg meet the definition of cardiogenic shock, optimal filling pressures may be even higher in individual patients with LV diastolic dysfunction.

TREATMENT

Initial Management

Initial stabilization of the patient with suspected cardiogenic shock consists of venous access, supplemental oxygen, and continuous ECG monitoring (Fig. 107-2). Many patients require endotracheal intubation and mechanical ventilation (Chapter 105), if only to reduce the work of breathing and facilitate sedation and stabilization before cardiac catheterization. Electrolyte abnormalities should be corrected. Morphine (1 to 2 mg every 5 minutes) relieves pain and anxiety, reduces excessive sympathetic activity, and decreases oxygen demand, preload, and afterload. Atrial bradyarrhythmias or tachyarrhythmias (Chapter 64) or ventricular tachyarrhythmias can reduce cardiac output and should be corrected promptly with antiarrhythmic drugs (see Table 64-7 in Chapter 64), cardioversion, or pacing (Chapter 66).

If the cause is likely an acute MI, aspirin and heparin should be given immediately (Chapter 73). Some therapies routinely used in acute MI (e.g., nitrates, β-blockers, angiotensin-converting enzyme inhibitors) have the potential to exacerbate hypotension in cardiogenic shock and should be avoided in patients with a tenuous hemodynamic status until they stabilize.

An initial assessment of fluid status and systemic perfusion should be performed. Patients are commonly diaphoretic, and relative hypovolemia may be present. Ischemia produces diastolic dysfunction, so high filling pressures may be necessary to maintain stroke volume in some patients. Some patients may benefit from judicious fluid replacement with predetermined rapid infusions of 100 to 200 mL of normal saline titrated to clinical end points. Patients who do not respond rapidly to initial treatment should be considered for invasive hemodynamic monitoring to identify the filling pressure at which cardiac output is maximized. Maintenance of adequate preload is particularly important in patients with RV infarction.

Following initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed. If tissue perfusion is adequate but significant pulmonary congestion remains, low-dose diuretics may be used, taking care not to remove too much fluid. If tissue perfusion remains inadequate, inotropic support or an intra-aortic balloon pump (IABP) should be initiated.

Vasopressors and Inotropes

Maintenance of adequate blood pressure is essential to break the vicious circle of progressive hypotension and further myocardial ischemia. When arterial pressure remains inadequate, therapy with vasopressor agents, titrated not only to blood pressure but also to clinical indices of perfusion and mixed venous oxygen saturation, may be required. Norepinephrine and dopamine are considered first-line drugs for hypotension in this situation. Dopamine acts as both an inotrope (particularly at 3 to 10 μg/kg/minute) and a vasopressor (10 to 20 μg/kg/minute). Norepinephrine (0.02 to 1.0 μg/kg/minute) acts primarily as a vasoconstrictor, has a mild inotropic effect, and increases

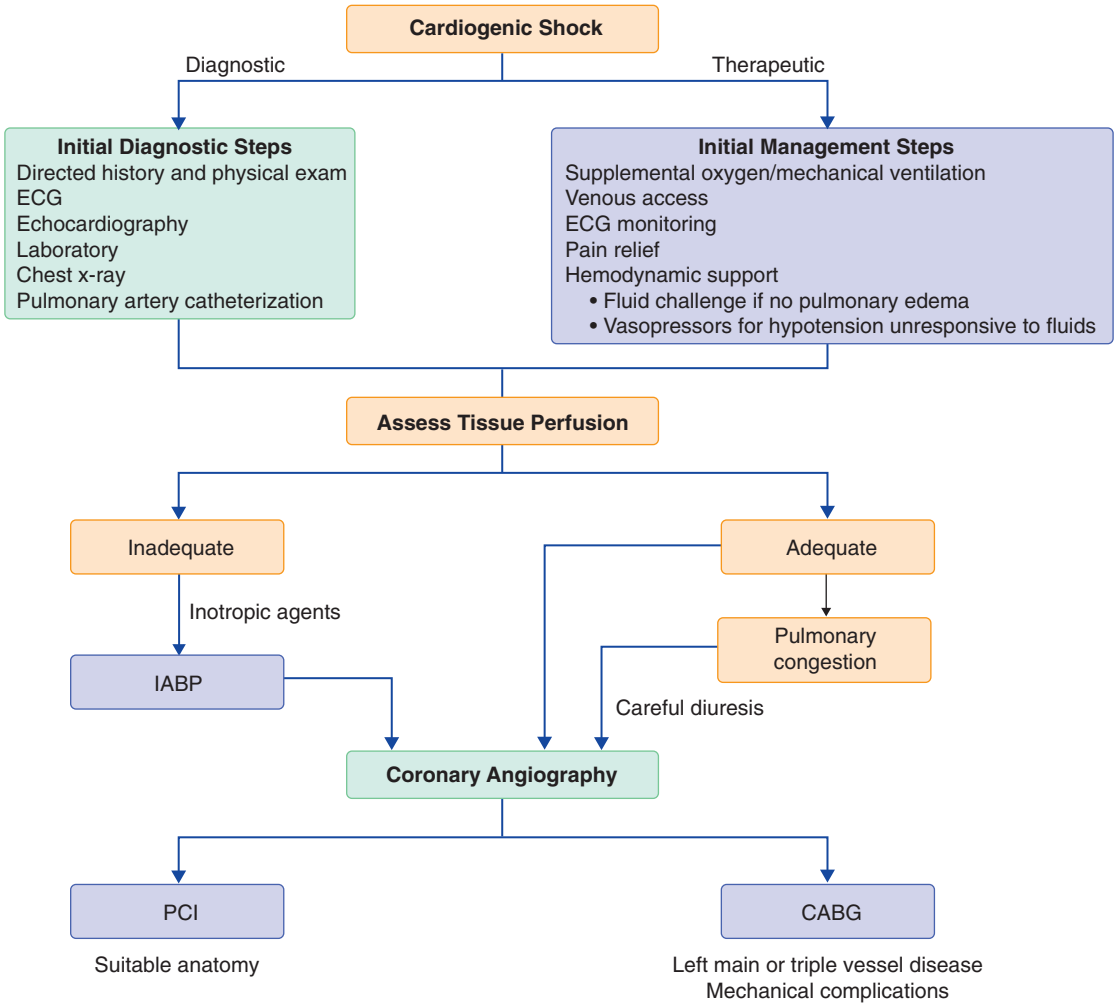

FIGURE 107-2. Approach to the diagnosis and treatment of cardiogenic shock caused by myocardial infarction. Right ventricular infarction and mechanical complications are discussed in the text. CABG = coronary artery bypass graft; ECG = electrocardiogram; IABP = intra-aortic balloon pump; PCI = percutaneous coronary intervention. Adapted from Hochman JS, Boland J, Sleeper LA, et al. Current spectrum of cardiogenic shock and effect of early revascularization on mortality: results of an International Registry. SHOCK Registry Investigators. *Circulation.* 1995;91:873-881.

coronary flow. In a randomized trial of patients with shock, there was no significant difference overall in 28-day mortality between those receiving dopamine and those receiving norepinephrine, but norepinephrine reduced mortality in a prespecified subgroup of patients with cardiogenic shock.[] Vasopressor infusions need to be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Invasive hemodynamic monitoring with an arterial line and right heart catheterization are advisable during the initial titration of vasoactive agents.

If tissue perfusion remains inadequate despite norepinephrine, inotropic therapy should be initiated. Dobutamine (2.5 to 20 μg/kg/minute), a selective β_1-adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output, and it is the initial agent of choice in patients with a low-output syndrome and systolic blood pressures greater than 90 mm Hg. Dobutamine may exacerbate hypotension in some patients owing to its vasodilatory effects, and it can precipitate tachyarrhythmias. Milrinone (0.125 to 0.75 μg/kg/minute), a phosphodiesterase inhibitor, has fewer chronotropic and arrhythmogenic effects than catecholamines, but it has a long half-life and can cause hypotension; in patients whose clinical status is tenuous, it is usually reserved for situations in which other agents have proved ineffective. Levosimendan (0.05 to 0.2 μg/kg/minute) is a calcium sensitizer that has both inotropic and vasodilatory properties and does not increase myocardial oxygen consumption. Levosimendan is more effective than dobutamine in treating low-output heart failure,[] but it may cause hypotension, and it must be used with caution in patients with cardiogenic shock. Attempts to inhibit nitric oxide synthase have not been beneficial.

Intra-aortic Balloon Counterpulsation

An IABP reduces systolic afterload and augments diastolic perfusion pressure. In contrast to the effects of inotropic or vasopressor agents, these benefits occur without an increase in oxygen demand. IABPs do not, however, produce a significant improvement in blood flow distal to a critical coronary stenosis; thus, they act as a bridge, helping patients through a critical period of shock, but they are not definitive therapy.

An IABP should be used for MI patients when cardiogenic shock is not quickly reversed with pharmacologic therapy. Although it has not been shown to improve mortality when used alone, use of an IABP in cardiogenic shock complicating acute MI improves survival at 30 days and 1 year,[] suggesting its efficacy as a stabilizing measure before angiography and prompt revascularization in appropriately selected patients.

Reperfusion

Supportive therapy may improve blood pressure and cardiac output in cardiogenic shock, but it does not interrupt the vicious circle of myocardial dysfunction and ischemia. Rapid restoration of myocardial blood flow is the cornerstone of therapy for patients with cardiogenic shock due to MI (Chapter 73). Fibrinolytic therapy (see Table 73-5 in Chapter 73) restores patency of the infarcted artery and decreases the likelihood of progression to cardiogenic shock. After cardiogenic shock has already developed, however, fibrinolytic therapy is less effective at achieving and maintaining reperfusion, likely due to a combination of hemodynamic, mechanical, and metabolic factors that prevent the achievement and maintenance of patency in the infarct-related artery.

Prompt revascularization is the only intervention that consistently reduces mortality rates in patients with cardiogenic shock. In a randomized trial of patients with LV failure complicating ST elevation MI, cardiac catheterization with PCI or CABG within 48 hours of presentation reduced all-cause mortality marginally at 30 days (47% in the revascularization group vs. 56% in the medical therapy group; $P = 11$) and significantly at 6 months, 1 year,[] and 6 years[] compared with optimal medical management, including IABP, in 86% of patients. Subgroup analyses also revealed benefits in patients younger than 75 years, those with prior MI, and those randomized less than 6 hours from the onset of infarction. Another trial with a similar design was terminated early owing to difficulties in patient recruitment, but it also showed a trend toward reduced 30-day and 1-year mortality. Together, these trials suggest that for each 100 patients treated, 9 lives will be saved at 30 days and 13.2 lives will be saved at 1 year.

On the basis of these results, emergent coronary revascularization, most often with PCI and stents, is the standard of care for cardiogenic shock due to pump failure in acute MI. Outcomes are best when PCI is performed within 6 hours after the onset of symptoms, but survival benefits are still demonstrable up to 48 hours after the onset of MI and 18 hours after the onset of shock. Elderly patients who are suitable for aggressive therapy also appear to benefit.

CABG surgery is more likely to provide complete revascularization and achieves long-term survival rates comparable to PCI, often despite worse coronary anatomy and a higher prevalence of diabetes. In practice, however, emergency CABG is performed less than 10% of the time.

When cardiogenic shock results from mechanical complications of MI (Chapter 73), surgery is recommended when feasible. For acute mitral regurgitation owing to papillary muscle rupture, supportive therapy with an IABP and vasoactive agents is a temporizing measure; definitive therapy requires expeditious surgical valve repair or replacement (Chapter 75). Although mortality is 20 to 40%, survival and ventricular function are improved compared with medical therapy.

Timely surgery is also critical in patients whose cardiogenic shock is caused by ventricular septal or free wall rupture. Because perforations are exposed to shear forces, the rupture site can expand abruptly. Repair can be technically difficult owing to the need to suture in areas of necrosis. Surgical mortality is 20 to 50% and is especially high for serpiginous inferoposterior ruptures, which are typically less well circumscribed than anteroapical ruptures. RV function is an important determinant of outcome in this setting. Timing of surgery has been controversial, but guidelines now recommend that operative repair be undertaken early, within 48 hours of the rupture. Placement of a septal occluding device may be helpful in selected patients.

Circulatory Support

Mechanical support with a left ventricular assist device (LVAD; Chapter 73) can interrupt the downward spiral of myocardial dysfunction, hypoperfusion, and ischemia in cardiogenic shock, allowing time for stunned or hibernating myocardium to recover. In cardiogenic shock after acute MI, percutaneous LVADs can be placed in the catheterization laboratory. These devices provide short-term support and are usually intended as a bridge to recovery or, occasionally, as a bridge to transplantation. Extracorporeal support has been used in selected patients.

Management of Special Conditions

At the end stage of a dilated or restrictive cardiomyopathy (Chapter 60), low cardiac output can result in cardiogenic shock. A search for reversible precipitating causes should be undertaken. Some patients will respond to inotropic therapy and will have a brief period of relative improvement. Appropriate candidates should be referred for evaluation for possible cardiac transplantation (Chapter 82). In selected patients, a surgically placed LVAD, such as a continuous-flow device, can provide 45% two-year survival free of device surgery or disabling stroke.[] LVADs can be used either as a bridge to transplantation or as destination therapy. A discussion about end-of-life care is also warranted.

Acute myocarditis (Chapter 60) can have a fulminant course leading to shock in 10 to 15% of cases. Patients with acute myocarditis are typically younger than those with cardiogenic shock due to MI, and they present more commonly with dyspnea rather than chest pain. Echocardiography usually shows global LV dysfunction. Supportive therapy is indicated; some patients may require circulatory support and even consideration of cardiac transplantation. Immunosuppressive therapy does not improve outcome in this setting.

Patients with hypertrophic cardiomyopathy (Chapter 60) may present with severe outflow tract obstruction and shock. Recognition of this condition is important, because diuretic and inotropic therapy may worsen the obstruction. Careful volume resuscitation and use of a pure α-agonist, such as phenylephrine (0.1 to 0.3 mg/kg/minute), can increase afterload and cavity size. β-Blockers (esmolol 0.05 to 0.2 mg/kg/minute; metoprolol 2.5 to 5 mg IV every 2 to 5 minutes, up to 15 mg) and/or calcium blockers with negative inotropic properties (e.g., diltiazem 5 mg IV every 2 minutes, up to 20 mg) can also be helpful.

Some patients with stress (takotsubo) cardiomyopathy (Chapter 60) may have LV dysfunction severe enough to produce shock. Because the presentation is similar to that of acute MI, with chest pain and ECG changes, the diagnosis is usually made in the catheterization laboratory, when significant coronary obstruction is excluded and the characteristic apical hypokinesis or dyskinesis is documented. Treatment is supportive and may include an IABP. Most patients have recovery of LV function within days to weeks, and the long-term prognosis is excellent.

Acute valvular regurgitation (Chapter 75) presents with pulmonary edema and decreased forward cardiac output. The regurgitant murmur may be soft or inaudible, and the diagnosis is best made by echocardiography. Acute ischemic mitral regurgitation is usually associated with rupture of the posterior papillary muscle, which has a single blood supply. Other causes include spontaneous chordal rupture, infective endocarditis (Chapter 76), rheumatic fever (Chapter 298), and trauma (Chapter 112). Immediate management includes afterload reduction (Chapter 59) and an IABP as temporizing measures. Inotropic or vasopressor therapy may also be needed to support cardiac output and blood pressure. Definitive therapy, however, consists of surgical valve repair or replacement (Chapter 75).

Acute aortic regurgitation most commonly results from infective endocarditis (Chapter 76) with leaflet destruction, but it may also be due to traumatic injury (Chapter 112) or acute aortic dissection (Chapter 78). The pulse pressure is usually narrow, indicating decreased forward stroke volume, and the bounding pulsations seen with chronic aortic regurgitation are usually absent. Temporizing measures include afterload reduction, with vasopressor and inotropic support as needed. IABP is contraindicated, and excessive slowing of the heart rate may worsen hemodynamics by prolonging diastole. Definitive therapy is surgical.

PROGNOSIS

Cardiogenic shock is still the most common cause of death in acute MI. Survival rates are improving, however, coincident with the increasing use of reperfusion therapy in appropriately selected patients. Hemodynamics predict short-term but not long-term mortality. Among patients undergoing revascularization, age, time to revascularization, and restoration of coronary blood flow independently predict survival, but the benefits of revascularization are seen at every level of risk, with an average 1-year survival of 50 to 55%. Encouragingly, the survival benefit of early revascularization is maintained at 6-year follow-up, with 5-year survival approaching 45%. The quality of life in survivors is usually excellent, with 83% either asymptomatic or having only mildly symptomatic heart failure. For patients with end-stage nonischemic myocardial disease, the prognosis is very poor in the absence of heart transplantation.

SHOCK SYNDROMES RELATED TO SEPSIS

JAMES A. RUSSELL

DEFINITION

Sepsis is defined by presence of at least two of the four signs of the systemic inflammatory response syndrome (SIRS): (1) fever (>38°C) or hypothermia (<36°C); (2) tachycardia (>90 beats/minute); (3) tachypnea (>20 breaths/minute), hypocapnia (partial pressure of carbon dioxide <32 mm Hg), or the need for mechanical ventilatory assistance; and (4) leukocytosis (>12,000 cells/mm^3), leukopenia (<4000 cells/mm^3), or a left shift (>0% immature band cells) in the circulating white cell differential and suspected or proven infection. *Bacteremia* is defined as the growth of bacteria in blood cultures, but infection does not have to be proved to diagnose sepsis at the onset. *Severe sepsis* is sepsis in addition to dysfunction of one or more organ systems (e.g., hypoxemia, oliguria, lactic acidosis, thrombocytopenia, decreased Glasgow Coma Scale score). *Septic shock* is defined as severe sepsis in addition to hypotension (systolic blood pressure <90 mm Hg or a >40 mm Hg decrease from baseline) despite adequate fluid resuscitation.

EPIDEMIOLOGY

Approximately 750,000 cases of severe sepsis or septic shock occur every year in the United States. Sepsis causes as many deaths as acute myocardial infarction, and septic shock and its complications are the most common causes of death in noncoronary intensive care units (ICUs). The medical care costs associated with sepsis are approximately $16.7 billion a year in the United States alone. The frequency of septic shock is increasing as physicians perform more aggressive surgery, as more resistant organisms are present in the environment, and as the prevalence of immune compromise resulting from disease and immunosuppressive drugs increases. Recent studies suggest that African Americans have a higher incidence of severe sepsis than whites (6.0 vs. 3.6 per 1000 population) and a higher mortality in ICUs (32.1 vs. 29.3%; $P < .0001$), even after adjusting for poverty levels. The mechanisms of this apparent difference in risk for and mortality from sepsis are not known.

Gram-positive or gram-negative bacteria, fungi, and, very rarely, protozoa or rickettsiae can cause septic shock. Increasingly common causes of septic shock are gram-positive bacteria, especially methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci, penicillin-resistant *Streptococcus pneumoniae*, and resistant gram-negative bacilli.

The common infections causing septic shock are pneumonia, peritonitis, pyelonephritis, abscess (especially intra-abdominal), primary bacteremia, cholangitis, cellulitis, necrotizing fasciitis, and meningitis. Nosocomial pneumonia is the most common cause of death from nosocomial infection.

PATHOBIOLOGY

At onset, septic shock activates inflammation, leading to enhanced coagulation, activated platelets, increased neutrophils and mononuclear cells, and diminished fibrinolysis (Table 108-1). After several days, a compensatory anti-inflammatory response with immunosuppression may contribute to death. Several pathways amplify one another: inflammation triggers coagulation, and coagulation triggers inflammation, resulting in a positive feedback loop that is pro-inflammatory and pro-coagulant. Tissue hypoxia in septic shock also amplifies inflammation and coagulation. Many mediators that are critical for the homeostatic control of infection may be injurious to the host (e.g., tumor necrosis factor-α [TNF-α]), so therapies that fully neutralize such mediators are largely ineffective.

Widespread endothelial injury is an important feature of septic shock; an injured endothelium is more permeable, so the flux of protein-rich edema fluid into tissues such as the lung increases. Injured endothelial cells release nitric oxide, a potent vasodilator that is a key mediator of septic shock. Septic shock also injures epithelial cells of the lung and intestine. Intestinal epithelial injury increases intestinal permeability; this leads to epithelial translocation of intestinal bacteria and endotoxin, which further augments the inflammatory phenotype of septic shock.

Early Infection, the Innate Immune Response, Inflammation, and the Endothelium

Host defense is organized into innate and adaptive immune responses. The innate immune system responds by using pattern recognition receptors (e.g., Toll-like receptors [TLRs]) to pathogen-associated molecular patterns, which are extremely well-conserved molecules of microorganisms. Surface molecules of gram-positive and gram-negative bacteria (peptidoglycan and lipopolysaccharide, respectively) bind to TLR-2 and TLR-4, respectively (Fig. 108-1). TLR-2 and TLR-4 binding initiates an intracellular signaling cascade that culminates in nuclear transport of the transcription factor nuclear factor kappa B (NFκB), which triggers transcription of cytokines such as TNF-α and interleukin (IL)-6. Cytokines upregulate adhesion molecules of neutrophils and endothelial cells, and neutrophil activation leads to bacterial killing. However, cytokines also directly injure host endothelial cells, as do activated neutrophils, monocytes, and platelets. Inhibition of early cytokine mediators of sepsis, such as TNF-α and IL-1β, has not proved successful, likely because TNF-α and IL-1β peak and then decline quickly, before these antagonist therapies can be applied clinically.

After the early cytokine inflammatory response, immune cells, including macrophages and neutrophils, release later mediators, such as high-mobility group box-1 (HMGB-1). HMGB-1 activates neutrophils, monocytes, and endothelium. Unlike TNF-α antagonists, inhibitors of HMGB-1 decrease mortality even when they are given 24 hours after the induction of experimental peritonitis.

Adaptive Immunity Adds Specificity and Amplifies the Immune Response

Microorganisms stimulate specific humoral and cell-mediated adaptive immune responses that amplify innate immunity. B cells release immunoglobulins that bind to microorganisms and thereby facilitate delivery of microorganisms to natural killer cells and neutrophils. In sepsis, type 1 helper T (T_H1) cells generally secrete pro-inflammatory cytokines (TNF-α, IL-1β),

TABLE 108-1 PATHWAYS; MEDIATORS; AND POSITIVE, NEGATIVE, AND POTENTIALLY ATTRACTIVE TRIALS IN SEPTIC SHOCK

*Positive RCTs are pivotal randomized controlled trials powered for mortality as the primary end point.
[†]In a small RCT, polymyxin B hemoperfusion decreased mortality compared with usual care.
[‡]G-CSF is effective in septic patients with profound neutropenia.
[§]Elastase inhibitor was ineffective in a phase II trial in acute lung injury.
[‖]Unfractionated heparin did not decrease mortality in acute sepsis.
[¶]IL-10 was ineffective in a phase II trial in acute lung injury.
[**]Erythropoietin does not decrease red blood cell transfusions in the critically ill and may increase the risk of thrombotic events.
[††]In an RCT of norepinephrine plus dobutamine versus epinephrine alone, there was no difference in mortality.
[‡‡]In a randomized placebo-controlled trial, corticosteroids did not change mortality in septic shock, regardless of whether there was an abnormal corticotropin stimulation test.
[§§]Corticosteroids, which have no effect on overall 28-day mortality, decreased mortality in a subgroup of nonresponders to corticotropin in one study[1,2] but not another.[2]
[‖‖]In an RCT, vasopressin compared with norepinephrine did not change overall mortality, but it was associated with decreased mortality in patients who had less severe septic shock (norepinephrine infusion 5-15 μg/min).
[¶¶]Intensive insulin (compared with conventional insulin) did not change mortality in one RCT and increased mortality in another.
[***]In an RCT, intensive renal support (six times/wk) compared with conventional renal support (three times/wk) did not change mortality in critically ill patients with acute kidney injury (many of whom had sepsis).
↑ = increased; ↓ = decreased; G-CSF = granulocyte colony-stimulating factor; GM-CSF = granulocyte-macrophage colony-stimulating factor; HIF-1α: hypoxia-inducing factor-1α; IL = interleukin; RCT = randomized controlled trial; T_H1 and T_H2 = type 1 and 2 helper T cell, respectively; TNF-α = tumor necrosis factor-α; TLR = Toll-like receptor; TSST-1 = toxic shock syndrome toxin-1; VEGF = vascular endothelial growth factor.

and type 2 helper T (T_H2) cells secrete anti-inflammatory cytokines (IL-4, IL-10).

Coagulation Response to Infection

Septic shock activates the coagulation system (Fig. 108-2) and ultimately converts fibrinogen to fibrin, which is bound to platelets to form microvascular thrombi. Microvascular thrombi further amplify endothelial injury by the release of mediators and by tissue hypoxia because of obstruction to blood flow.

Normally, natural anticoagulants (protein C, protein S, antithrombin, and tissue factor pathway inhibitor) dampen coagulation, enhance fibrinolysis, and remove microthrombi. Thrombin-α binds to thrombomodulin, which activates protein C when protein C is bound to the endothelial protein C receptor (EPCR). Activated protein C dampens the pro-coagulant phenotype because it inactivates factors Va and VIIIa and inhibits the synthesis of plasminogen activator inhibitor-1 (PAI-1). Activated protein C also decreases apoptosis, leukocyte activation and adhesion, and the production of cytokines.

Septic shock decreases the levels of the natural anticoagulants protein C, protein S, antithrombin, and tissue factor pathway inhibitor. Furthermore, lipopolysaccharide and TNF-α decrease thrombomodulin and EPCR, thereby limiting the activation of protein C. Lipopolysaccharide and TNF-α also increase levels of PAI-1, inhibiting fibrinolysis.

Tissue Hypoxia in Septic Shock

Tissue hypoxia independently activates inflammation (by activation of NFκB and cytokines, synthesis of nitric oxide, and activation of HMGB-1), induces coagulation (through tissue factor and PAI-1), and activates neutrophils,

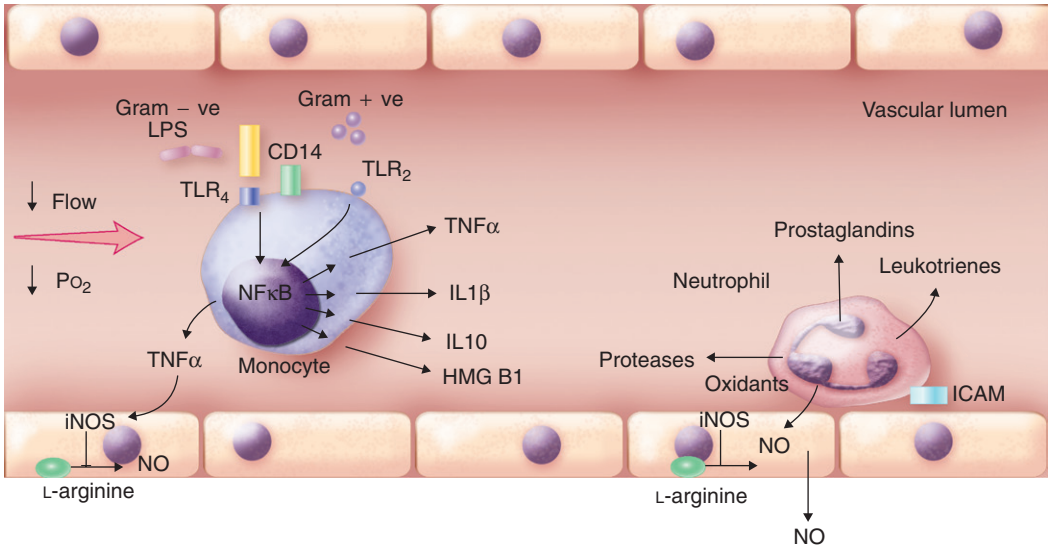

FIGURE 108-1. Inflammatory responses to sepsis. Gram-positive and gram-negative bacteria, viruses, and fungi have unique cell wall molecules called pathogen-associated molecular patterns that bind to pattern recognition receptors (called Toll-like receptors [TLRs]) on the surface of immune cells. The lipopolysaccharide (LPS) of gram-negative bacilli binds to LPS-binding protein–CD14 complex. The peptidoglycan of gram-positive bacteria and the LPS of gram-negative bacteria bind to TLR-2 and TLR-4, respectively. TLR-2 and TLR-4 binding activates intracellular signal transduction pathways that lead to the activation of the cytosolic transcription factor nuclear factor kappa B (NFκB). Activated NFκB moves from the cytoplasm to the nucleus, binds to transcription start sites, and increases the transcription of cytokines such as tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-10 (IL-10). TNF-α and IL-1β are pro-inflammatory cytokines that activate the adaptive immune response but also cause both direct and indirect host injury. IL-10 is an anti-inflammatory cytokine that inactivates macrophages and has other anti-inflammatory effects. Sepsis increases the activity of inducible nitric oxide synthase (iNOS), which increases the synthesis of nitric oxide (NO), a potent vasodilator. Cytokines activate endothelial cells by upregulating adhesion receptors such as intercellular adhesion molecule (ICAM), and they injure endothelial cells by the activation and binding of neutrophils, monocytes, macrophages, and platelets to endothelial cells. These effector cells release mediators such as proteases, oxidants, prostaglandins, and ICAM leukotrienes. Cytokines also activate the coagulation cascade.

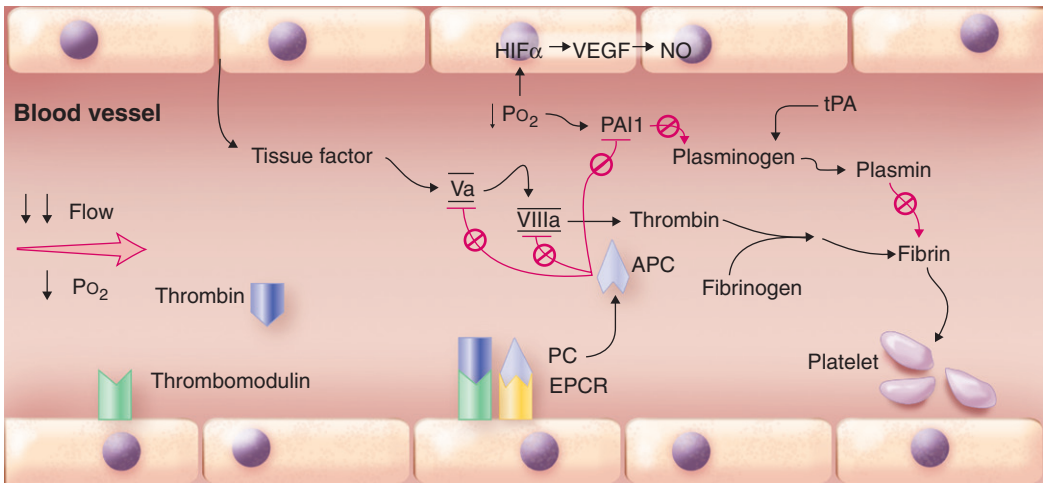

FIGURE 108-2. Pro-coagulant response in sepsis. Sepsis initiates coagulation by activating the endothelium to increase tissue factor. Activation of factors Va and VIIIa leads to the formation of thrombin-α, which converts fibrinogen to fibrin. Fibrin binds to platelets that adhere to endothelial cells, forming microvascular thrombi. Microvascular thrombi amplify injury by the release of mediators and by microvascular obstruction, which causes distal ischemia and tissue hypoxia. Normally, natural anticoagulants—protein C (PC), protein S (PS), antithrombin, and tissue factor pathway inhibitor (TFPI)—dampen coagulation, enhance fibrinolysis, and remove microthrombi. Thrombin-α binds to thrombomodulin on endothelial cells and thus activates the binding of PC to endothelial PC receptor (EPCR). PC forms a complex with its cofactor PS. PC binding to EPCR increases the activation of PC to activated PC (APC). APC proteolytically inactivates factors Va and VIIIa and decreases the synthesis of plasminogen activator inhibitor-1 (PAI-1). Sepsis decreases levels of PC, PS, antithrombin, and TFPI. Lipopolysaccharide and tumor necrosis factor-α (TNF-α) decrease thrombomodulin and EPCR, thus decreasing the activation of PC. Lipopolysaccharide and TNF-α also inhibit PAI-1, so fibrinolysis is inhibited. HIFα = hypoxia-inducing factor-α; NO = nitric oxide; tPA = tissue plasminogen activator; VEGF = vascular endothelial growth factor.

monocytes, and platelets. Hypoxia induces hypoxia-inducing factor-1α (HIF-1α), which upregulates erythropoietin, and vascular endothelial growth factor (VEGF). Erythropoietin is protective to brain and other tissues. VEGF inhibits fibrinolysis and increases inducible nitric oxide synthase, which augments nitric oxide–induced vasodilation. Nitric oxide has a further injurious effect: excessive nitric oxide inhibits the beneficial actions of HIF-1α (e.g., upregulating synthesis of erythropoietin) during hypoxia.

Late Septic Shock, Immunosuppression, and Apoptosis of Immune and Epithelial Cells

After about 1 week of septic shock, death can result from immunosuppression, which is suggested by anergy, lymphopenia, hypothermia, and nosocomial infection. Multiple organ dysfunction may be an anti-inflammatory phenotype because of the apoptosis of immune, epithelial, and endothelial cells. Activated $CD4^+$ T cells evolve into either a T_H1 pro-inflammatory (TNF-α, IL-1β) or a T_H2 anti-inflammatory (IL-4, IL-10) phenotype. Sepsis leads to migration from a T_H1 to a T_H2 phenotype; for example, persistent elevation of IL-10 is associated with an increased risk of death. Immunosuppression also develops because of apoptosis of lymphocytes. Pro-inflammatory cytokines, activated B and T cells, and glucocorticoids induce lymphocyte apoptosis, whereas TNF-α and endotoxin induce apoptosis of lung and intestinal epithelial cells. The fact that glucocorticoids also stimulate apoptosis could be the biologic explanation for the observation that patients with septic shock who are treated with hydrocortisone have more superinfections than do patients treated with placebo.

Death from infectious disease appears to be highly heritable. Sepsis is a prime example of a polygenic disease related to the interaction of multiple

TABLE 108-2 HEMODYNAMIC VARIABLES, ABBREVIATIONS, AND NORMAL VALUES

Arterial pressure: systolic pressure (SAP) (>100 mm Hg), diastolic pressure, pulse pressure, mean arterial pressure (MAP) (>65 mm Hg)
Central venous pressure (CVP): normal 6-12 mm Hg
Pulmonary artery pressure (PAP): normal 25/15 mm Hg
Pulmonary vascular resistance (PVR): normal 150-250 dynes/sec/cm

$$\left(\equiv \frac{PAP - PAOP}{CO} \times 80\right)$$

Pulmonary artery occlusion pressure (PAOP) or pulmonary artery wedge pressure (PAWP): normal 8-15 mm Hg
Systemic vascular resistance (SVR): normal 900-1400 dynes/sec/cm

$$\left(\equiv \frac{MAP - CVP}{CO} \times 80\right)$$

Cardiac output (CO): normal 5 L/min
Left ventricular stroke work index (LVSWI): normal (60-100 grams × meters/beats) = (SV × [MAP − PAWP] × 0.0136)
Oxygen delivery (Do_2): normal 1 L/min (= CO × [Hg × 1.38 × Sao_2] + [0.003 × Po_2])
Oxygen consumption (Vo_2): normal 250 mL/min (= CO × Hg × 1.38 × [Sao_2 − Svo_2] + [0.003 × (Pao_2 − Pvo_2)])
Oxygen extraction ratio: normal 0.23-0.32 (= Vo_2/Do_2)
Hemodynamic variables are often normalized to account for different body mass by dividing by body surface area (BSA):
Pulmonary vascular resistance index (PVRI): normal (= PVR/BSA)
Systemic vascular resistance index (SVRI): normal (= SVR/BSA)
Cardiac index (CI): normal 2.5-4.2 L/min/m^2 (= CO/BSA)
Left ventricular stroke work index (LVSWI): normal (= LVSW/BSA)
Oxygen delivery index (Do_2I): normal 460-650 mL/min/m^2 (= Do_2/BSA)
Oxygen consumption index (Vo_2I): normal 95-170 mL/min/m^2 (= Vo_2/BSA)

genes and an environmental insult (infection). Single nucleotide polymorphisms of cytokines (TNF-α, IL-6, IL-10), coagulation factors (protein C, fibrinogen-β), the catecholamine pathway (β-adrenergic receptor), and innate immunity genes (CD14, TLR-1, TLR-2) have been variably associated with an increased risk of death from sepsis.

Cardiovascular Dysfunction

Inadequate tissue perfusion and tissue hypoxia are the cardinal features of all types of shock. Early in septic shock, most patients have sinus tachycardia and, by definition, decreased blood pressure (<90 mm Hg systolic, a decrease of ≥40 mm Hg from baseline systolic pressure, or mean arterial pressure <65 mm Hg; Table 108-2). Septic shock is the classic form of distributive shock (Chapter 106), characterized by increased pulse pressure (bounding pulses), decreased systemic vascular resistance (warm, flushed skin), and functional hypovolemia (low jugular venous pressure). Distributive shock means that the distribution of systemic blood flow is abnormal, such that areas of both low flow (and low venous oxygen saturation) and high flow (and increased venous oxygen saturation) are present. Nevertheless, about one third of patients with septic shock initially present with findings more typical of hypovolemic shock (low central venous pressure and low central venous oxygen saturation), because the clinical features depend on the stage and severity of septic shock as well as on the degree of fluid resuscitation that has occurred. After fluid resuscitation, patients typically develop the characteristic clinical and hemodynamic features of classic distributive shock.

Ventricular preload is commonly decreased in early septic shock, for several reasons. First, patients may be volume depleted because of decreased fluid intake and because of increased fluid losses as a result of fever, vomiting, and diarrhea if gastrointestinal disease is present. Second, fluid loss from the intravascular to the interstitial space (capillary leak) is caused by mediators that induce widespread endothelial injury, which increases capillary permeability. Increased capillary permeability leads to loss of protein-rich edema fluid into the interstitial space. In the lung, increased permeability is a key component of acute lung injury. A third reason that ventricular preload is decreased in septic shock is venodilation induced by mediators such as nitric oxide. Venodilation increases venous capacitance, leading to relative volume depletion, which compounds the absolute volume depletion. Ventricular afterload is decreased because of excessive release of potent vasodilators such as nitric oxide, prostaglandin I_2, adenosine diphosphate, and other vasodilators.

In addition to abnormal vasodilation, patients have concurrent microvascular vasoconstriction. Microvascular vasoconstriction may not be apparent clinically or hemodynamically, but it can lead to tissue hypoxia, detected by increased arterial lactate concentrations. Microvascular vasoconstriction is caused by increased norepinephrine, thromboxanes, and other local vasoconstrictors. Microvascular vasoconstriction causes focal hypoxia, which is exacerbated by microvascular obstruction by platelets and leukocytes.

The abnormal mismatch of oxygen delivery to oxygen demand can disturb the global relationship of oxygen delivery to oxygen consumption. Normally, oxygen consumption is independent of oxygen delivery over a wide range. When oxygen delivery decreases to less than the critical oxygen delivery level, oxygen consumption decreases and leads to a state in which oxygen consumption depends on oxygen delivery. At levels lower than the critical oxygen delivery level, arterial lactate increases as a result of tissue hypoxia. The clinical implication is that oxygen delivery should be increased (e.g., by increasing cardiac output by volume resuscitation, infusion of dobutamine, or transfusion of erythrocytes) to more than the critical level.

Cardiovascular function is further compromised in septic shock because of decreased ventricular contractility. Decreased ventricular contractility may be difficult to detect clinically and may be diagnosed only by hemodynamic or echocardiographic assessment. Numerous circulating mediators of sepsis, including endotoxin, cytokines (e.g., IL-6, TNF-α), and nitric oxide (locally released into the coronary circulation), decrease contractility. Endotoxin signals via TLRs to upregulate the expression of proteins such as S110A8 and S100A9 to cause a receptor for advanced glycation end products (RAGE)–dependent decrease in calcium flux, which decreases the ejection fraction. Coronary ischemia resulting from microvascular obstruction by leukocytes and oxygen free radicals, which are released by neutrophils adherent to the coronary capillary endothelium, is another mechanism of decreased contractility.

Early in septic shock, patients who survive have increased left ventricular end-diastolic volume, which likely allows them to maintain cardiac output despite decreased contractility. In contrast, nonsurvivors do not have increased left ventricular end-diastolic volume, so their cardiac output is compromised. In some patients with septic shock, concurrent acute lung injury and secondary pulmonary hypertension increase right ventricular afterload, with a secondary shift of the interventricular septum from right to left. This septal shift decreases left ventricular end-diastolic volume and can also limit cardiac output.

CLINICAL MANIFESTATIONS

Cardiovascular dysfunction in septic shock is characterized by decreased preload (because of decreased intake, fluid losses, third spacing resulting from increased permeability, and venodilation), decreased afterload, and often decreased ventricular contractility. Decreased ventricular volume is detected clinically by low jugular venous pressure and hemodynamically by decreased central venous pressure. Left ventricular resistance, or afterload, is also commonly decreased and is detected clinically by warm, flushed skin and hemodynamically by decreased systemic vascular resistance.

DIAGNOSIS

Even as the diagnostic evaluation is beginning, the initial assessment of a critically ill patient must focus immediately on the airway (need for intubation), breathing (respiratory rate, respiratory distress, pulse oximetry), circulation (heart rate, blood pressure, jugular venous pressure, skin perfusion), and rapid initiation of resuscitation (Fig. 108-3). Vital signs and the leukocyte count quickly establish whether the patient has SIRS (two of the four criteria). Arterial blood gases and lactate levels are useful complementary tests. A secondary survey is designed to determine the likely source of infection and the status of organ function. Pneumonia (Chapter 97) is suggested by cough, sputum, and respiratory distress; empyema (Chapter 99) is suggested by pleuritic chest pain. Signs of peritonitis, an abdominal mass, and right upper quadrant tenderness suggest abdominal sepsis. Pyelonephritis (Chapter 292) is likely in patients with dysuria and costovertebral angle tenderness. Integumentary assessment for erythema (cellulitis), line site erythema (line sepsis), tenderness (necrotizing fasciitis), crepitus (anaerobic myonecrosis), and petechiae and purpura (meningococcemia) can be illuminating. Headache, stiff neck, and signs of meningismus raise the suspicion of meningitis (Chapter 420). Focal neurologic signs suggest brain abscess (Chapter 421).

Laboratory investigations that are helpful to identify the source of infection include appropriate cultures and Gram stains (blood, sputum, urine, fluids, and cerebrospinal fluid). Blood cultures are positive in 40 to 60% of patients who have septic shock. The chest radiograph aids in the diagnosis of

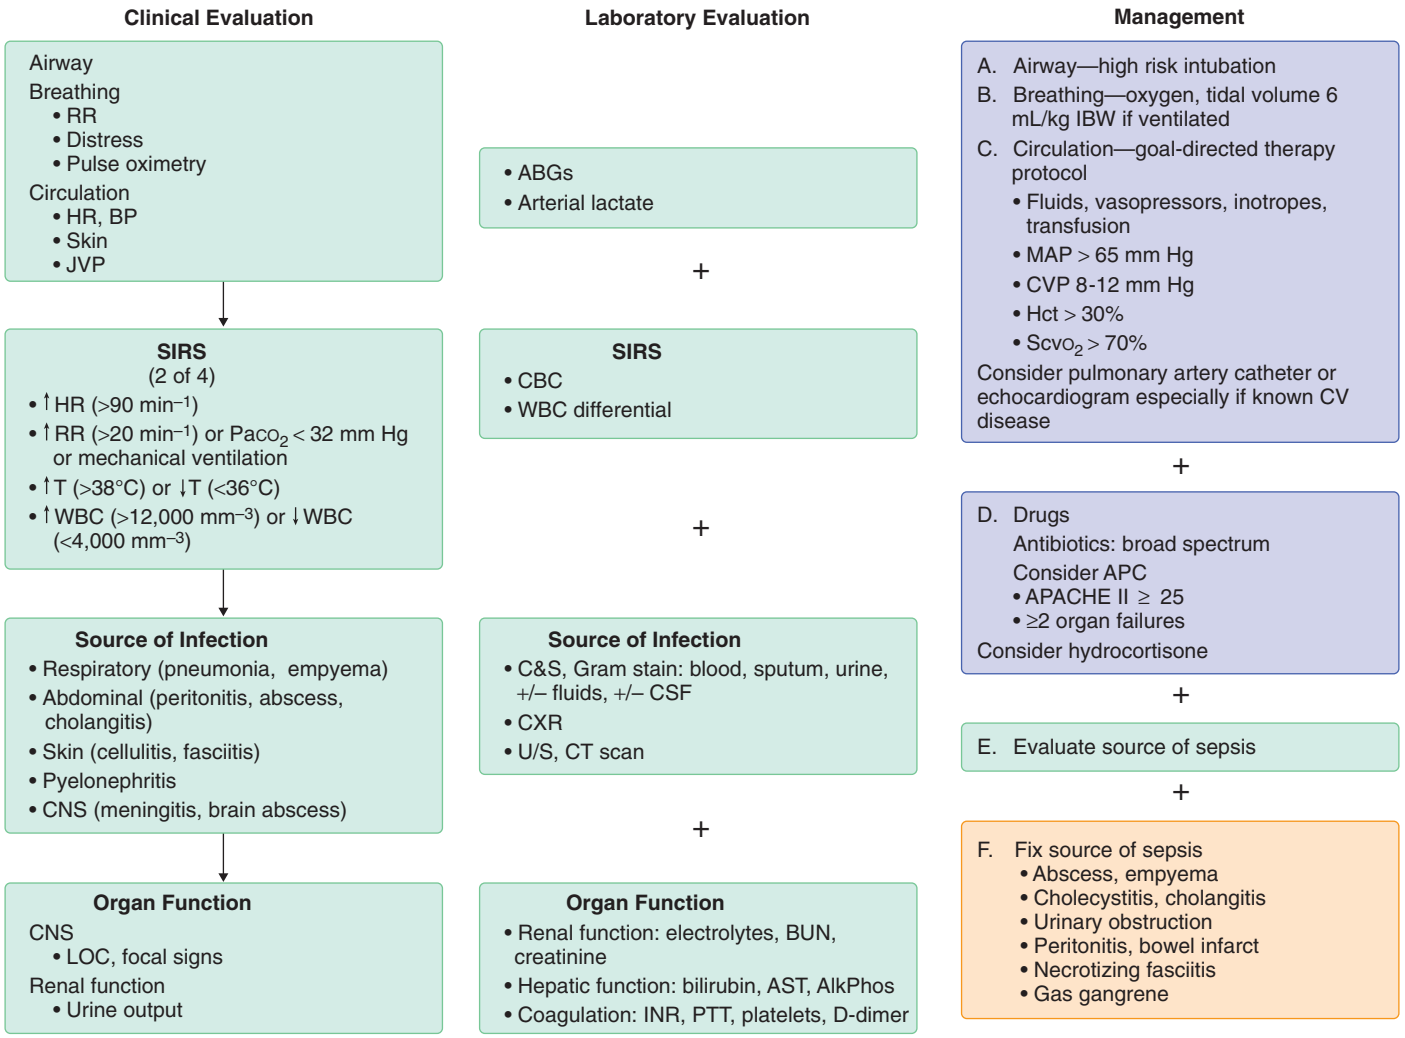

FIGURE 108-3. Algorithm for the clinical and laboratory evaluation and management of septic shock. pneumonia, empyema, and acute lung injury. Abdominal ultrasound and computed tomography are indicated if abdominal sepsis is suspected.

Hemodynamic assessment of the patient includes insertion of a central venous or pulmonary artery catheter. In early septic shock, central venous pressure is usually low and increases in response to volume resuscitation. Central venous oxygen saturation, cardiac output, and ventricular filling pressures may be determined continuously. Pulmonary artery pressure is usually normal but may be increased because septic shock can cause pulmonary hypertension. Pulmonary artery occlusion (or wedge) pressure is usually low before resuscitation, but it may be normal or increased if the patient has underlying preexisting heart disease (e.g., heart failure or coronary artery disease with prior myocardial infarction) or if left ventricular contractility is decreased by sepsis. Cardiac output may be low or normal before fluid resuscitation and typically increases to higher than normal after fluid resuscitation. If fluid resuscitation increases central venous pressure and pulmonary artery occlusion pressure but cardiac output does not increase, left ventricular dysfunction is presumably present.

Echocardiographic features of decreased ventricular contractility include decreased right and left ventricular ejection fractions and increased end-diastolic and end-systolic volumes. Early in septic shock, the left ventricular ejection fraction is decreased, and it remains low in nonsurvivors. In survivors, the left ventricular ejection fraction usually returns to normal over 5 to 10 days.

Renal, hepatic, and coagulation function tests are helpful to evaluate organ function. After determining the source of sepsis, it is crucial to address that source by draining abscesses and empyemas; radiologically or surgically correcting urinary tract obstruction; and surgically managing peritonitis, bowel infarction, cholecystitis, cholangitis, necrotizing fasciitis, and gas gangrene.

Differential Diagnosis

The major differential diagnoses of classic septic shock are other nonseptic causes of SIRS, such as acute pancreatitis (Chapter 146), acute respiratory distress syndrome (Chapter 104), aspiration pneumonitis (Chapter 94), multiple trauma (Chapter 112), and recent major surgery without infection (Chapter 441). Other causes of distributive shock are anaphylactic shock (suggested by angioedema and hives; Chapter 448), spinal shock (recent trauma and paraplegia; Chapter 406), acute adrenal insufficiency ("tanned skin," hyperkalemia, metabolic alkalosis; Chapter 234), and acute or acute-on-chronic hepatic failure (jaundice, ascites, encephalopathy; Chapter 157).

The differential diagnosis of septic shock must include the other causes of shock: hypovolemic, cardiogenic, and obstructive shock (Chapters 106 and 107). Patients with hypovolemic shock (from internal or external fluid losses, hemorrhage) present with a suggestive history and signs of hypovolemia (low jugular venous pressure) and skin hypoperfusion (cool, clammy, cyanotic extremities). Cardiogenic shock (resulting from myocardial infarction or acute-on-chronic congestive heart failure or occurring after cardiovascular surgery) is suggested by the history, signs of increased filling pressure (increased jugular venous pressure, crackles, S_3, pulmonary edema, cardiomegaly), and skin hypoperfusion (Chapter 107). Some patients who have acute myocardial infarction and cardiogenic shock have features of SIRS

TABLE 108-3 RELEVANT RANDOMIZED CONTROLLED TRIALS IN SEVERE SEPSIS, SEPTIC SHOCK, AND ACUTE LUNG INJURY

PATIENT GROUP	INTERVENTION	CONTROL	INTERVENTION MORTALITY (%)*	CONTROL MORTALITY (%)*	NNT

ALI/ARDS = acute lung injury/acute respiratory distress syndrome; NNT = number needed to treat to save one life.

without infection. Obstructive shock (from pulmonary thromboembolism, cardiac tamponade, pneumothorax) manifests similarly to cardiogenic shock.

PREVENTION

Measures to prevent sepsis include handwashing, elevation of the head of the bed, scrupulous sterile techniques for the insertion of catheters, and possibly the use of antibiotic-impregnated catheters. New catheter insertion sites for catheter changes, isolation of patients who have resistant organisms, and isolation of significantly immunocompromised patients may also prevent infection.

Preventing the progression from sepsis to septic shock requires early diagnosis and aggressive resuscitation. Early goal-directed therapy, lung-protective ventilation, antibiotics, and consideration of activated protein C are critical therapies in early septic shock (Table 108-3).

TREATMENT

Respiratory Therapy

All patients in septic shock require oxygen initially, and many require mechanical ventilation. Mechanical ventilation is required in most patients who have septic shock because acute lung injury is the most common complication. Lung-protective ventilation (mechanical ventilation that minimizes lung injury by using a relatively low tidal volume, such as <6 mL/kg of predicted body weight) decreases mortality from acute lung injury and acute respiratory distress syndrome (Chapter 105).[2]

Patients who require ventilation need adequate but not excessive sedation, which can worsen hemodynamic instability, prolong ventilation, and increase the risk of developing nosocomial pneumonia. Sedation should be titrated using objective assessment. Daily interruption of sedation decreases the duration of mechanical ventilation and intensive care. Neuromuscular blocking agents should be avoided because of the risk of prolonged neuromuscular dysfunction.

Circulatory Therapy

Early goal-directed therapy is the cornerstone of emergency management, and this approach decreases hospital, 28-day, and 60-day mortality rates dramatically (see Table 108-3).[3] In general, the goal of resuscitation is to increase tissue oxygen delivery by increasing profoundly low blood pressure, increasing inadequate blood flow, increasing low arterial oxygen saturation, and increasing mixed venous oxygen saturation. Although oxygen delivery is higher in survivors than in nonsurvivors, it is not clear that a specific oxygen delivery target is more beneficial than clinical end points. Several trials have shown that supernormal global oxygen delivery does not decrease mortality rates in sepsis and septic shock. Goal-directed therapy requires continuous monitoring of central venous oxygen saturation, with resuscitation directed to increase and then maintain central venous oxygen saturation greater than 70%.

In patients who have acute lung injury, no difference in outcomes is seen with management using a pulmonary artery catheter versus a central venous catheter; this finding suggests that there is no advantage to using a pulmonary catheter to guide the hemodynamic management of acute lung injury.[4] Patients whose acute lung injury is managed after 24 to 48 hours with a conservative fluid strategy (compared with a liberal fluid strategy) have significantly improved lung function and shorter duration of ventilation and ICU stay.[5]

Fluids should be used to maintain central venous pressure at 8 to 12 mm Hg; at present, no convincing data indicate that albumin is better than normal saline solution.[6] In patients with severe sepsis, modified Ringer's lactate is preferred over 10% hetastarch (a colloid) because of lower rates of both acute kidney injury and the need for renal replacement therapy.[7] If central venous oxygen saturation is less than 70%, packed red cell transfusions should be used to maintain a hematocrit greater than 30%.

Vasopressors (e.g., norepinephrine 1 to 50 µg/minute; epinephrine 1 to 30 µg/minute) should be added if the mean arterial pressure is less than 65 mm Hg. Dobutamine (2.5 to 20 µg/kg/minute) is required if central venous pressure, mean arterial pressure, and hematocrit are optimized but the central venous oxygen saturation remains less than 70%. In a randomized trial of patients with septic shock, the combination of norepinephrine plus dobutamine resulted in a similar mortality as epinephrine alone, with no differences in organ dysfunction, time to resolution of shock, or adverse events.[8] In another randomized trial, norepinephrine was slightly but not significantly better than dopamine for reducing mortality when used as the first-line vasopressor for patients with septic shock[9]; however, norepinephrine was associated with a lower rate of arrhythmias, especially atrial fibrillation. These accumulated data suggest that norepinephrine may be preferable to dopamine as the first vasopressor in septic shock.

Clinicians can use epinephrine alone, norepinephrine alone, or norepinephrine plus dobutamine in patients with low cardiac output.

As a strategic approach to persistent hypotension despite adequate fluid resuscitation, a vasopressor such as norepinephrine (1 to 50 µg/minute) can be added first. If the cardiac index is low or if the mixed venous oxygen saturation is low (<70%) despite an adequate central venous pressure, an inotropic agent such as dobutamine should be added, initially at approximately 2 to 5 µg/kg/minute and increasing until the mixed venous oxygen saturation is adequate. In some patients in septic shock, the cardiac index is inadequate, as reflected by a low mixed venous oxygen saturation despite a high central venous pressure (>12 mm Hg) and/or pulmonary artery wedge pressure (>18 mm Hg), because of underlying cardiovascular dysfunction or because of acute left ventricular dysfunction resulting from sepsis. In such patients, earlier use of an inotropic agent such as dobutamine should be considered to increase left ventricular contractility. The overall goal is to achieve an adequate mean arterial pressure (>65 mm Hg), central venous pressure, and mixed venous oxygen saturation while other indices of adequate perfusion are monitored, such as hourly urine output (>0.5 mL/kg/hour), arterial lactate levels (<2 mmol/L), mental status, and skin perfusion. To assess the adequacy of early resuscitation of severe sepsis and septic shock and to guide ongoing therapy, a central venous oxygen saturation goal greater than 70% or a lactate clearance of at least 10% is an equally good measure.[10]

Transfusion of Erythrocytes and Erythropoietin

Anemia is common in septic shock, but the optimal hemoglobin level for resuscitation is controversial. Goal-directed therapy aims for a hematocrit of 30%, whereas a randomized trial of transfusion in critically ill patients found that a hemoglobin range of 7 to 9 g/dL was equivalent to or better than a higher hemoglobin (10 to 12 g/dL), except possibly in patients with acute myocardial infarction or unstable angina. A reasonable approach is to use a hematocrit level of 30% as the threshold for erythrocyte transfusion for the first 6 hours and then to lower the threshold to a hemoglobin of 7 to 9 g/dL for the rest of the hospital course, except in patients with underlying cardiac disease. Recombinant erythropoietin decreases the need for transfusion in critically ill patients, but it does not decrease mortality.

Drugs

Antibiotics

The infected site and infecting organisms of septic shock are often not known initially. After appropriate cultures are obtained, intravenous broad-spectrum antibiotics should be administered on an emergency basis (within 1 hour) while considering host factors such as immune and allergic status (Chapters 288 and 289; see Fig. 108-3). Outcomes in patients with septic shock

are worse if the organisms causing the sepsis are not sensitive to the initial antibiotic regimen.

Emergency, empirical antibiotic therapy (Table 108-4) should be guided by the greater frequency of gram-positive bacteria, the possibility of resistant organisms, and local bacteriologic features. If a causative organism is identified (<20% of septic patients have negative cultures), the antibiotic regimen should be narrowed to decrease the emergence of resistant organisms. Empirical fluconazole treatment does not result in better outcomes in critically ill, non-neutropenic patients at risk for invasive candidiasis.[11] The duration of antibiotics should be guided by the cause of septic shock, but patients generally require 10 to 14 days of therapy.

Corticosteroids

High-dose corticosteroids do not improve outcomes in the full spectrum of patients with sepsis or acute respiratory distress syndrome, but the evidence supporting the use of low-dose corticosteroids in septic shock is controversial. In one trial, corticosteroids (hydrocortisone 50 mg intravenously every 6 hours, plus fludrocortisone 50-µg tablet/day per nasogastric tube or orally for 7 days) increased survival in septic patients whose serum cortisol response after stimulation with an intravenous infusion of 250 µg corticotropin was 9 µg/dL or less.[12] In a subsequent randomized trial of hydrocortisone (50 mg every 6 hours intravenously for 5 days) versus placebo, however, mortality was not improved, regardless of the patient's response to corticotropin stimulation.[2] Adding fludrocortisone to hydrocortisone does not appear to be better than hydrocortisone alone, and aggressive insulin therapy to address the hyperglycemia that often accompanies corticosteroid treatment is no better than usual glucose control.[13] Hydrocortisone treatment is often associated with a shorter duration of septic shock but can increase the risk of superinfections. Current sepsis guidelines suggest that corticosteroids should be considered only in patients who are poorly responsive to vasopressors.

Corticosteroids administered before antibiotics also decrease the neurologic sequelae of bacterial, especially pneumococcal, meningitis (Chapter 420). Enthusiasm for corticosteroid therapy must be tempered by the risk of complications such as superinfection, neuromyopathy, hyperglycemia, immune suppression, and impaired wound healing.

Recombinant Human Activated Protein C

Activated protein C infusion (24 µg/kg/hour for 96 hours) decreases mortality, improves organ dysfunction, and decreases biomarkers of inflammation and coagulation in severe sepsis and septic shock.[14] Activated protein C is approved for patients who have severe sepsis and a high risk of death, as defined by an Acute Physiology and Chronic Health Evaluation (APACHE) II score of 25 or higher and/or two or more dysfunctional organs (see Fig. 108-3). By comparison, activated protein C is not beneficial in low-risk patients.[15] Activated protein C has not been tested in patients with major trauma, recent surgery (within 12 hours), active hemorrhage, coagulopathy, thrombocytopenia, or recent stroke because of the increased risk of hemorrhage. Even in patients without these risk factors, treatment increases the risk of serious hemorrhage nearly two-fold, and about 0.5% of treated patients develop intracranial hemorrhage. Activated protein C should not be used in surgical patients who have severe sepsis with single-organ dysfunction. If patients are receiving subcutaneous low-dose heparin prophylaxis and activated protein C is to be used, discontinuation of heparin should be weighed carefully: although its discontinuation while using activated protein C reduces bleeding, discontinuation also increases the risk of stroke[16] and may increase the risk of death. The use of activated protein C in septic shock is being reevaluated in

TABLE 108-4 POTENTIAL ANTIBIOTIC REGIMENS FOR PATIENTS WITH SEPTIC SHOCK*

SOURCE OF SEPSIS	INITIAL ANTIBIOTIC REGIMEN	ALTERNATIVE ANTIBIOTIC REGIMEN
Community-acquired pneumonia	Third-generation cephalosporin: cefotaxime 2 g IV q6h; ceftriaxone 2 g IV q12h; ceftizoxime 2 g IV q8h PLUS Fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h, levofloxacin 750 mg IV q24h, moxifloxacin 400 mg IV q24h) OR Macrolide (azithromycin 500 mg IV q24h)	Piperacillin-tazobactam 3.375 g IV q6h PLUS Fluoroquinolone OR Macrolide
Hospital-acquired pneumonia	Imipenem 0.5 g IV q6h OR Meropenem 1 g IV q8h	Fluoroquinolone (ciprofloxacin 400 mg IV q12h) PLUS Vancomycin 1.5 g IV q12h OR Piperacillin-tazobactam 3.375 g IV q6h PLUS Tobramycin 1.5 mg/kg q8h PLUS Vancomycin
Abdominal (mixed aerobic/anaerobic)	Piperacillin-tazobactam 3.375 g IV q6h OR Imipenem 0.5 g IV q6h (or meropenem 1 g IV q8h)	Ampicillin 2 g IV q4h PLUS Metronidazole 500 mg IV q8h PLUS Fluoroquinolone (ciprofloxacin 400 mg IV q12h)
Urinary tract	Fluoroquinolone (ciprofloxacin 400 mg IV q12h)	Ampicillin 2 g IV q4h PLUS Gentamicin 1.5 mg/kg IV q8h OR Third-generation cephalosporin (cefotaxime 2 g IV q6h, ceftriaxone 2 g IV q12h, OR ceftizoxime 2 g IV q8h)
Necrotizing fasciitis	Imipenem 0.5 g IV q6h	Penicillin G (if confirmed group A streptococci)
Primary bacteremia (normal host)	Piperacillin-tazobactam 3.375 g IV q6h PLUS Vancomycin 1.5 g IV q12h	Imipenem 0.5 g IV q6h PLUS Vancomycin 1.5 g IV q12h
Primary bacteremia (intravenous drug user)	Vancomycin 1.5 g IV q12h PLUS Fluoroquinolone (ciprofloxacin 400 mg IV q12h)	Piperacillin-tazobactam 3.375 g IV q6h PLUS Vancomycin 1.5 g IV q12h
Febrile neutropenia	Cefepime 2 g IV q8h PLUS Vancomycin 1.5 g IV q12h	Piperacillin-tazobactam 3.375 g IV q6h PLUS Gentamicin 1.5 mg/kg q8h OR Imipenem 0.5 g IV q6h PLUS Gentamicin 1.5 mg/kg q8h
Bacterial meningitis	Ceftriaxone 2 g IV q12h PLUS Ampicillin 3 g IV q6h PLUS Vancomycin 1.5 g IV q12h PLUS Dexamethasone 0.15 mg/kg IV q6h for 2-4 days	Gram-positive cocci: Vancomycin PLUS Ceftriaxone 2 g IV q12h Gram-negative diplococci: Cefotaxime 2 g IV q4-6h Gram-positive bacilli: Ampicillin 3 g IV q6h PLUS Gentamicin Gram-negative bacilli: Ceftazidime 2 g IV q8h PLUS Gentamicin 1.5 mg/kg IV q8h All above PLUS Dexamethasone
Cellulitis	Ciprofloxacin 400 mg IV q12h PLUS Clindamycin 900 mg IV q8h	Imipenem 0.5 g IV q6h

*Most antibiotic doses must be adjusted if there is hepatic or renal dysfunction. Some antibiotics require adjustment based on levels (e.g., gentamicin). When selecting a drug, carefully consider the patient's history of antibiotic (especially penicillin) allergy.

a large, multicenter, randomized controlled trial; until that study is completed, activated protein C is still recommended for patients who meet the criteria and have no contraindications to its use.

Controversial Therapies in Septic Shock

Vasopressin Deficiency and Use of Vasopressin

Vasopressin deficiency and downregulation of vasopressin receptors are common findings in septic shock. Vasopressin selectively dilates renal afferent but not efferent glomerular arterioles, and it also dilates pulmonary, cerebral, and coronary arterioles. Low-dose vasopressin infusion (0.03 to 0.04 U/minute) increases blood pressure, urine output, and creatinine clearance while dramatically decreasing the dosage of norepinephrine required to maintain blood pressure in patients with septic shock. In a randomized trial, low-dose vasopressin added to norepinephrine was not significantly better than as-needed norepinephrine alone,[17] although added vasopressin may be useful in patients with less severe shock. Complications of vasopressin include gastrointestinal ischemia, decreased cardiac output, skin or digital necrosis, and cardiac arrest (especially at doses >0.04 U/minute).

Hyperglycemia and Intensive Insulin Therapy

Hyperglycemia and insulin resistance are common in septic shock. Hyperglycemia is a pro-coagulant and pro-apoptotic stimulus; it impairs neutrophil function, increases the risk of infection, impairs wound healing, and is associated with increased mortality. However, the risks of unrecognized hypoglycemia and cerebral injury may be increased in septic shock because of unstable endocrine function and the use of sedation. In addition, brain ischemia and hypoxia increase sensitivity to even transient hypoglycemia. At present, the appropriate glucose range and insulin doses are controversial. Intensive insulin therapy to control hyperglycemia is not beneficial in patients in medical ICUs because of significantly higher rates of hypoglycemia[7,18] and perhaps increased mortality.[19] Therefore, intensive insulin therapy cannot be recommended for patients with septic shock.

Renal Dysfunction and Dialysis

Acute renal failure is an important complication of septic shock because of its associated morbidity, mortality, and resource use (Fig. 108-4). Continuous renal replacement therapy induces less hemodynamic instability compared with intermittent hemodialysis, but no conclusive evidence indicates that continuous renal replacement therapy or more intensive dialysis changes the mortality of acute renal failure. In critically ill patients who have acute kidney injury, hemodialysis six times per week is no better than conventional hemodialysis, and intensive renal replacement therapy is no better than standard therapy overall or in patients who have sepsis.[19]

Low-dose dopamine (2 to 4 µg/kg/minute) does not decrease the need for renal support, does not improve outcomes, and is not recommended. Lactic acidosis is a common complication of septic shock, but administration of sodium bicarbonate in the setting of lactic acidosis does not improve hemodynamics or the response to vasopressors.

A small randomized controlled trial evaluated the use of polymyxin B hemoperfusion in patients with abdominal sepsis to reduce blood endotoxin levels. Polymyxin B hemoperfusion increased blood pressure, decreased vasopressor requirements, improved organ dysfunction, and reduced mortality by one third.[20] However, this intervention requires further evaluation before it can be recommended.

Other Therapies

Deep vein thrombosis prophylaxis using low-dose heparin, which can be administered in combination with activated protein C, is recommended for patients who do not have active bleeding, coagulopathy, or a contraindication to heparin (see Fig. 108-4). Stress ulcer prophylaxis using H_2-receptor antagonists decreases the risk of gastrointestinal hemorrhage. Proton pump inhibitors may also be effective, but they have not been fully evaluated in septic shock.

Enteral nutrition is generally safer and more effective than total parenteral nutrition, but total parenteral nutrition is sometimes required in patients with abdominal sepsis, surgery, or trauma. The use of sedation, neuromuscular blocking agents, and corticosteroids should be minimized because they can exacerbate septic encephalopathy and the polyneuropathy or myopathy of sepsis. Neutropenic patients may benefit from granulocyte colony-stimulating factor (Chapter 170). The risk of nosocomial infection is decreased by narrow-spectrum antibiotics, early weaning from ventilation, and periodic removal and replacement of catheters (Chapter 290).

B. Breathing—Oxygen, with a tidal volume 6 mL/kg IBW if ventilated. Wean according to ARDSNet protocol (Chapters 105 and 106)

C. Circulation
- Fluids, vasopressors, inotropes, transfusion; goals include:
  - MAP > 65 mm Hg
  - CVP 8-12 mm Hg
  - Hg 70-90 g/L
  - $Scvo_2$ > 70%

  Consider pulmonary artery catheter or echocardiogram especially if known cardiovascular disease; goals include:
  - Wedge pressure 8-15 mm Hg
  - Cardiac index: normal or increased

D. Drugs:
- Antibiotics: Narrow spectrum to cause of infection
- APC (if indicated): 24 µg/kg/hour infusion for 96 hours
- Hydrocortisone (if evidence of relative adrenal insufficiency [see text]): hydrocortisone 50 mg intravenously every 6 hours and fludrocortisone 50-µg tab orally or per NG tube daily for 7 days

Other Organ Support
- Renal function: Continuous renal replacement
- DVT prophylaxis: Low-dose heparin 5000 IU subcutaneously every 12 hours
- Stress ulcer prophylaxis: H_2-receptor antagonist (e.g., ranitidine 50 mg intravenously every 8 hours)
- Nutrition: Enteral preferred
- Sedation: Intermittent with daily awakening

FIGURE 108-4. Ongoing critical care support and management in septic shock. APC = activated protein C; CVP = central venous pressure; DVT = deep vein thrombosis; Hg = hemoglobin; IBW = ideal body weight; MAP = mean arterial pressure; NG = nasogastric; $Scvo_2$ = central venous oxygen saturation.

PROGNOSIS

The 28-day mortality of septic shock is 40 to 70%. Early deaths (in the first 72 hours) are usually the result of refractory, progressive shock despite escalating life support. Later deaths from septic shock (after day 3) are usually secondary to multiple organ dysfunction. The number of dysfunctional organs and the progression or lack of improvement of organ dysfunction are indicators of increased risk of death. Other factors that portend a poor prognosis are increased age, underlying medical conditions, high APACHE II score, increased arterial lactate concentrations, and lack of response to vasopressors. Furthermore, recent evidence indicates that a delay in achieving the goals of early goal-directed therapy is associated with increased mortality. Survivors of sepsis who also had acute lung injury (Chapter 104) can have weakness, fatigue, and dyspnea on exertion after hospital discharge owing to pulmonary dysfunction, neuromuscular dysfunction, or other persistent organ dysfunction.

109 DISORDERS DUE TO HEAT AND COLD

WILLIAM WINKENWERDER JR. AND MICHAEL N. SAWKA

TEMPERATURE REGULATION

Body temperature is regulated through two parallel processes that modify body heat balance: behavioral (clothing, shelter, physical activity) and physiologic (skin blood flow, sweating, shivering). Both peripheral (skin) and central (core) thermal receptors provide afferent input to a central nervous system integrator (hypothalamic thermoregulatory center), and any deviation between the controlled variable (body temperature) and a reference variable ("set point" temperature) results in a heat loss or conservation response (Fig. 109-1).

Humans normally regulate body (core) temperature at about 37° C (98.6° F), and fluctuations within the narrow range of 35 to 41° C (95 to 105.8° F) can be tolerated by healthy acclimatized persons; core temperatures outside this range can induce morbidity and mortality. There is no single core temperature because it varies at different deep body sites and during rest and physical exercise. Arterial blood temperature provides the best invasive measurement of core temperature. The most accurate noninvasive index of core temperature is esophageal temperature, followed in order of preference by rectal, gastrointestinal tract (telemetry pill), and oral temperature. Ear (tympanic and auditory meatus) or scanned temporal artery temperature should not be relied on for clinical judgment.

HEAT ILLNESS

DEFINITIONS

Minor heat-related illnesses include miliaria rubra, heat syncope, and heat cramps. Serious heat illness represents a continuum from heat exhaustion to heat injury and heatstroke.

EPIDEMIOLOGY

Body temperature can increase from exposure to environmental heat (impeded heat dissipation), physical exercise (increased heat production), and fever (elevated set point). Febrile persons have accentuated elevations in core temperature when exposed to high ambient temperature, physical exercise, or both. Serious heat illness is associated with a variety of individual factors, health conditions, drugs, and environmental factors (Table 109-1). Anticholinergic and sympathomimetic poisoning (Chapter 110) can induce hyperthermia. Malignant hyperthermia (Chapter 440) is caused by rapid and massive skeletal muscle contraction from exposure to anesthesia. Neuroleptic malignant syndrome (Chapter 442) is hyperthermia caused by skeletal muscle rigidity from treatment with neuroleptic medications (e.g., antipsychotics, antidepressants, antiemetics).

Heat illness can also occur in low-risk individuals who have taken appropriate precautions relative to situations they have been exposed to in the past. Historically, such unexpected cases were attributed to dehydration (which impairs thermoregulation and increases hyperthermia and cardiovascular strain), but it is now suspected that a previous heat exposure or event (e.g., sickness or injury) might make these individuals more susceptible to serious heat illness. One theory is that previous heat injury or illness primes the acute phase response and augments the hyperthermia of exercise, inducing unexpected serious heat illness. Another theory is that previous infection produces pro-inflammatory cytokines that deactivate the cells' ability to protect against heat shock.

PATHOBIOLOGY

Environmental and exercise heat stress challenges the cardiovascular system to provide high blood flow to the skin, where blood pools in warm, compliant vessels such as those found in the extremities. When blood flow is diverted to the skin, reduced perfusion of the intestines and other viscera can result in ischemia, endotoxemia, and oxidative stress. In addition, excessively high

Heavy clothing
Air pollution (nitrogen dioxide)

tissue temperatures (heat shock: >41° C [105.8° F]) can produce direct tissue injury; the magnitude and duration of the heat shock influence whether cells respond by adaptation (acquired thermal tolerance), injury, or death (apoptotic or necrotic). Heat shock, ischemia, and systemic inflammatory responses can result in cellular dysfunction, disseminated intravascular coagulation, and multiorgan dysfunction syndrome. In addition, reduced cerebral blood flow, combined with abnormal local metabolism and coagulopathy, can lead to dysfunction of the central nervous system.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mild heat illness is common and can be recognized by its clinical features. Miliaria rubra (heat rash) results from the occlusion of eccrine sweat gland ducts and can be complicated by secondary staphylococcal infection. Heat syncope (fainting) is caused by temporary circulatory insufficiency as a result of blood pooling in the peripheral veins, especially the cutaneous and lower extremity veins. Heat cramps (skeletal muscles cramps) occur during and after intense exercise and are believed to result from excessive loss of sodium in sweat.

Serious heat illness is often not apparent at the initial evaluation. Patients who exhibit symptoms (e.g., dizziness, unsteady gait, ataxia, headache, confusion, weakness, fatigue, nausea, vomiting, diarrhea) should have an immediate assessment of their mental status, core (rectal) temperature, and other vital signs. Heatstroke should be the working diagnosis in anyone who is a heat casualty and has an altered mental status.

TABLE 109-2 COMPARISON OF CLASSIC AND EXERTIONAL HEATSTROKE

PATIENT CHARACTERISTICS	CLASSIC	EXERTIONAL
Age	Young children or elderly	15-55 yr
Health	Chronic illness	Usually healthy
Fever	Unusual	Common
Prevailing weather	Frequent in heat waves	Variable
Activity	Sedentary	Strenuous exercise
Drug use	Diuretics, antidepressants, anticholinergics, phenothiazines	Ergogenic stimulants or cocaine
Sweating	Often absent	Common
Acid-base disturbances	Respiratory alkalosis	Lactic acidosis
Acute renal failure	Uncommon	Common (≈15%)
Rhabdomyolysis	Uncommon	Common (≈25%)
CK	Mildly elevated	Markedly elevated (500-1000 U/L)
ALT, AST	Mildly elevated	Markedly elevated
Hyperkalemia	Uncommon	Common
Hypocalcemia	Uncommon	Common
DIC	Mild	Marked
Hypoglycemia	Uncommon	Common

ALT = alanine aminotransferase; AST = aspartate aminotransferase; CK = creatine kinase; DIC = disseminated intravascular coagulation.

Heat exhaustion is a mild to moderate illness characterized by an inability to sustain cardiac output with moderate (>38.5° C [101° F]) to high (>40° C [104° F]) body temperatures. It is frequently accompanied by sweaty hot skin, dehydration, and collapse. Heat injury is a moderate to severe illness characterized by organ (e.g., liver, renal) and tissue (e.g., gut, muscle) injury with high body temperatures, usually but not always greater than 40° C (104° F).

Heatstroke is a severe illness characterized by mental status changes with high body temperatures, usually but not always greater than 40° C (104° F). However, patients with a core temperature higher than 40° C do not universally have a heat injury or heatstroke, and the entire clinical picture, including mental status and laboratory results, must be considered. Heatstroke is often categorized as classic or exertional, with the former observed primarily in otherwise sick and compromised individuals and the latter observed primarily in apparently healthy and physically fit individuals (Table 109-2). Heatstroke victims have profound neuropsychiatric impairments that develop early and universally. In addition, heatstroke can be complicated by liver damage, rhabdomyolysis, disseminated intravascular coagulation, water and electrolyte imbalance, and renal failure.

PREVENTION, TREATMENT, AND PROGNOSIS Rx

Heat illness can be prevented by heat acclimatization and acquired thermal tolerance, maintenance of adequate hydration, and avoidance of overwhelming heat exposure. Adequate fluid intake is critical, and oral rehydration solutions may be preferable to other forms of hydration.■

Management of serious heat illness includes cooling, rehydration, and monitoring (Table 109-3). Body cooling should be initiated immediately and continued until the core temperature falls below 38.8° C (102° F). Body cooling lowers tissue temperatures and reduces cardiovascular stress by causing vasoconstriction in the skin. Immersion or soaking the skin in cool or iced water with skin massage is the most effective method, but other effective methods include soaking the skin followed by accelerated evaporation with fans or the use of ice sheets or ice packs. Cooling can induce shivering, which is usually not sufficient to increase body temperature, so shivering need not be treated.

Fluid and electrolyte deficits should be corrected; restoration of plasma volume with isotonic fluids sufficient to sustain adequate perfusion, as judged by urine output, is a priority. Rapid overcorrection of serum electrolytes (e.g., sodium) should be avoided. If rhabdomyolysis (Chapter 115) and myoglobinuria are present, maintaining urine flow helps minimize renal injury. Patients should be monitored for cardiac arrhythmia and acute respiratory failure. Medications to be avoided include antipyretics and sedatives with hepatic toxicities. Lorazepam (1 to 2 mg administered intravenously over a

TABLE 109-3 MANAGEMENT OF HEAT ILLNESS

HEAT EXHAUSTION
Rest and shade
Loosen and remove clothing
Supine position and elevate legs
Actively cool skin
Fluids by mouth
Monitor core temperature
Monitor mental status
HYPERTHERMIA
Protect the airway
Insert at least two large-bore intravenous lines
Monitor core temperature; options include pulmonary artery, rectal probe, esophageal probe
Actively cool the skin until core temperature reaches 39° C (102.2° F)
Ice baths or cool water (≈22° C [71.6° F]) immersion
Wetting with water (avoid alcohol rubs)
Continuous fanning
Exposure to cool environment
Axillary or perineal ice packs and ice sheets
Infusion of room-temperature saline
Gastric or colonic iced saline lavage
Peritoneal lavage with cool saline
Monitor electrocardiogram for arrhythmia
Obtain serial diagnostic studies*

*Electrocardiogram, chest radiograph, complete blood count with differential, platelet count, urinalysis, aminotransferases, alkaline phosphatase, bilirubin, creatine kinase, blood urea nitrogen, creatinine, phosphate, calcium, glucose, electrolytes, uric acid, prothrombin time and partial thromboplastin time, fibrin split products, fibrinogen, arterial blood gases, toxicology screen.

2- to 5-minute period, repeated if necessary) is a safe sedative because of its low hepatotoxicity and rapid metabolism.

A single episode of heat exhaustion does not imply a predisposition to heat illness, and most patients recover within several hours after cooling and rehydration. In contrast, heat injury and heatstroke patients should not be re-exposed to heat until recovery is complete, and about 10% of heatstroke patients remain intolerant of heat. The long-term consequences of heatstroke likely include sustained organ damage, which presumably explains why patients have a higher long-term mortality from cardiovascular, liver, and digestive diseases.

COLD INJURY

DEFINITIONS

Cold injuries are classified as hypothermia and peripheral cold injuries. Hypothermia is whole body cooling, whereas peripheral cold injuries are localized to the extremities and exposed skin. Peripheral cold injuries can be divided into nonfreezing (chilblain, trench foot) and freezing (frostbite). Both hypothermia and peripheral cold injuries often occur simultaneously.

EPIDEMIOLOGY

A variety of individual factors, health conditions, medications, and environmental factors are associated with a predisposition to cold injury (Table 109-4). In trauma patients (Chapter 112), hypothermia is associated with increased morbidity and mortality.

PATHOBIOLOGY

Cold exposure elicits peripheral vasoconstriction to reduce heat transfer between the body's core and shell (skin, subcutaneous fat). If sufficiently cold, the underlying tissues (e.g., muscle) constrict to thicken the isolative shell while reducing the body's core area. This vasoconstrictor response defends core temperature, but at the expense of declining peripheral tissue temperatures, which contribute to peripheral cold injuries. Hypothermia depresses enzymatic activity, interferes with physiologic functions (e.g., clotting, respiration, cardiac conduction and rhythm), impairs the expression of cytokines, and can induce cellular injury and death.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hypothermia is a core temperature below 35° C (95° F), and clinical manifestations are related to the core temperature achieved (Table 109-5). The classic J wave on the electrocardiogram (Fig. 109-2) appears at a core temperature below about 33.8° C (93° F).

Chilblain (Chapter 80) appears as localized inflammatory lesions of the skin most often involving the dorsal surface of fingers, but the ears, face, and exposed shins are other common areas. Trench foot is caused by prolonged

TABLE 109-5 HYPOTHERMIA: STAGES AND ASSOCIATED CLINICAL MANIFESTATIONS

	Core Temperature		
STAGE	**° F**	**° C**	**CLINICAL MANIFESTATIONS**
Normothermia	98.6	37.0	
Mild hypothermia	95.0	35.0	Cold diuresis, maximal shivering
	93.0	33.8	Ataxia, poor judgment, J wave
	91.0	32.7	Amnesia, blood pressure difficult to measure
Moderate hypothermia	89.0	31.6	Stupor, pupils dilated
	87.0	30.5	Shivering ceases
	85.0	30.0	Cardiac arrhythmias, insulin inactive
	82.0	27.8	Unconsciousness, ventricular fibrillation likely
	80.0	26.6	No muscle reflexes
Profound hypothermia	78.0	25.5	Acid-base disturbances, no response to pain
	75.0	23.8	Pulmonary edema, hypotension
	73.0	22.7	No corneal reflexes
	66.0	18.8	Heart standstill
	62.0	16.6	Isoelectric electrocardiogram
	57.6	14.2	Lowest infant survival from accidental hypothermia
	48.2	9.0	Lowest adult survival from accidental hypothermia

TABLE 109-6 TREATMENT OF HYPOTHERMIA

STAGE	MANAGEMENT	BODY REWARMING
Mild hypothermia	Monitor vital signs Warm intravenous saline Oxygen Monitor electrocardiogram for arrhythmia	Insulate Shivering Warm bath Active warming blanket
Moderate hypothermia	Diagnostic studies* Intensive care Anticipate infection and multiorgan dysfunction	Prevent extra heat loss by supplementing with airway rewarming Colonic irrigation Peritoneal dialysis
Profound hypothermia	Diagnostic studies*	Central rewarming

*See Table 109-3. Also lactate dehydrogenase, serum lactate, cortisol, thyroid-stimulating hormone, T_3, and T_4.

cold, wet exposure (e.g., wet socks or gloves), which can cause skin breakdown and nerve damage. Trench foot is often accompanied by infection and increased sensitivity to pain. Frostbite is the freezing of tissues and can be categorized as first degree (superficial, "frostnip"), second degree (full skin), third degree (subcutaneous tissue), and fourth degree (extensive tissue and bone). It may take many days to weeks to determine the severity of frostbite. Frostbite requires early surgical consultation once the diagnosis is made.

PREVENTION, TREATMENT, AND PROGNOSIS Rx

Humans demonstrate minimal cold acclimatization, so prevention depends primarily on avoiding cold exposure and having adequate protection and caloric intake to support metabolism. Management of hypothermia depends on the core temperature (Table 109-6). Patients' wet clothing should be removed, and they should be provided with dry insulation. Shivering is an effective physiologic rewarming mechanism and should not be pharmacologically suppressed. Moderately and profoundly hypothermic patients require active rewarming. Rewarming at a rate of 0.5 to 1.0° C (0.9 to 1.8° F) per hour is acceptable in most cases, except that aggressive rewarming is warranted in patients with significant trauma (because coagulation is hindered by hypothermia) or cardiac arrest.

Patients should be warmed gently because ventricular fibrillation is easily precipitated. When ventricular fibrillation is present, repeated electrical shocks should not be attempted until the patient has been rewarmed to a core temperature higher than 30° C (86° F); instead, cardiopulmonary resuscitation should be maintained during this period. Arrhythmias can be treated with lidocaine, propranolol, or bretylium (Chapter 63). Body cooling induces cold diuresis, so plasma volume needs to be reestablished to support adequate perfusion: patients should receive an intravenous infusion of 250 to 1000 mL of heated (40 to 42° C [104 to 108° F]) 5% dextrose in normal saline. Lactated Ringer's solution should be avoided because the liver cannot metabolize lactate efficiently during hypothermia. Patients should be monitored for disturbances in potassium and glucose. If hypoglycemia, alcohol, or opiate intoxication is contributing to hypothermia, intravenous glucose (10 to 25 g), thiamine (100 mg), or naloxone (1 to 2 mg), respectively, may be indicated.

Frostbitten tissues should be protected from friction or trauma and gently rewarmed in a water bath (38 to 43° C [100 to 108° F]). Frostbitten tissues should not be thawed until there is confidence in the ability to maintain warmth, because refreezing causes more injury. Patients should receive ibuprofen, antibiotics if infection is suspected, and possibly an analgesic.

Hypothermic Syndromes

Exercise-induced bronchospasm (Chapter 87) can be triggered by exercise in cold air, particularly in patients with asthma. Livedo reticularis (Fig. 80-2 in Chapter 80) is patchy mottling of the limbs with cold exposure. Cryoglobulinemia (Chapter 193) occurs when immunoglobulins (IgM, IgG) reversibly precipitate after being cooled and contribute to impaired capillary blood flow in hypothermic tissues. Cold urticaria (Chapters 260 and 448) is the development of localized and general erythema and wheals in skin exposed to cold. Paroxysmal hypothermia is periodic lowering of the thermoregulatory set point and is often associated with hypothalamic abnormalities. Raynaud's phenomenon (Fig. 80-5 in Chapter 80) is intense vasoconstriction with sensitivity to pain in limbs exposed to cold.

Trauma Hypothermia

In trauma patients (Chapter 112), unintended hypothermia (<34° C [93° F]) is associated with increased morbidity and mortality due to impaired coagulation, peripheral vasoconstriction, respiratory depression, and increased risk for cardiac arrhythmias. Shivering aggravates perfusion problems by requiring blood flow to support increased metabolism in contracting muscles. Trauma patients become hypothermic because of heat loss from exposed cavities, environmental exposure, infusion of cool fluids, and ischemia, which depletes cell energy stores. Body temperature should be measured, and appropriate actions should be taken to restore normothermia during the early treatment of trauma patients.

THERAPEUTIC HYPOTHERMIA AND HYPERTHERMIA

Therapeutic Hypothermia

Therapeutic hypothermia provides benefits by suppressing metabolism, free radical production, lipid peroxidation, inflammatory products, excitatory amino acid release, and calcium release. Induction of mild hypothermia (32 to 34° C [89 to 93° F]) for 12 to 24 hours provides long-term benefits to patients after a cardiac arrest (Chapter 63). It is being tested for spinal cord injury but has not consistently shown a benefit in neonates with traumatic brain injury or hypoxic-ischemic encephalopathy. Mild hypothermia may be beneficial for patients suffering from hemorrhagic shock, brain injury, or stroke.

Therapeutic hypothermia should be initiated as soon as possible by either skin cooling (e.g., cooling packs to the axilla, groin, head, and neck while simultaneously treating the patient with a cooling blanket, water mattress, or fan), endovascular cooling, or both. Endovascular cooling can be achieved either by the infusion of cool fluids (e.g., 30 mL/kg crystalloids at 4° C [40° F]) or by indwelling heat transfer devices. Cooling by peritoneal and pleural lavage is not generally used. Endovascular cooling provides a more rapid and better-controlled cooling than skin cooling. Thermoregulatory responses (shivering and peripheral vasoconstriction) will resist induced hypothermia and elevate blood pressure and should therefore be pharmacologically blunted. Low-dose meperidine (e.g., 12.5 mg intravenously) can blunt shivering without excessive toxicity.

Hyperthermia Treatment

Hyperthermia treatment (whole body or regional) is an experimental technique used as an adjunct to chemotherapy or radiation therapy in advanced cancer patients. Hyperthermia (40 to 43° C [104 to 109° F]) alone can damage or kill cancer cells, but more importantly, hyperthermia might potentiate the effectiveness of chemotherapy and radiation by softening the tumor tissue, thus reducing its interstitial pressure.

Whole body hyperthermia is usually induced by externally applied radiant heat, microwaves, or extracorporeal circulation. Target temperatures are usually achieved over 1 to 2 hours and then maintained for approximately 1 hour, followed by a 1-hour cooling phase. Patients are usually sedated while core and skin temperatures are monitored. In regional hyperthermia, the part

of the body where the tumor is located is heated while being perfused or bathed by a warmed solution containing anticancer drugs.

110

ACUTE POISONING

MARSHA D. FORD

EPIDEMIOLOGY

Each year, more than 4 million poisoning cases, suspected or verified, and 300,000 related hospital admissions occur in the United States. Poisoning-related deaths total more than 30,000 per year and are increasing. Unintentional poisonings are now the second leading cause of injury-related death in the United States, and they exceed motor vehicle accidents as the leading cause of injury-related death in adults 34 to 56 years of age. Ninety-two percent of these deaths involve drugs, predominantly prescription opioid analgesics. The incidence of recurrent, purposeful self-poisoning is 12 to 18%, with most events occurring within 3 months of the original attempt. These facts emphasize the need for regulatory measures to improve the safety of opioid analgesic drugs, including appropriate prescribing, and aggressive treatment of poisoned patients, including early psychiatric intervention for suicidal behavior, to reduce fatalities and repeat attempts (Chapter 404).

DIAGNOSIS

Diagnosis and management of poisoned patients require knowledge and skill in five areas to identify and treat the factors that contribute to the risk for death or long-term disability: (1) history taking; (2) physical examination, with recognition of specific toxic syndromes, or *toxidromes;* (3) appropriate use of diagnostic tests; (4) treatment, including initial stabilization and critical care, decontamination, and administration of antidotes for specific poisonings; and (5) use of methods to enhance the elimination of specific toxicants.

History

Details elicited about toxic exposures should include the involved drugs and other toxicants, their estimated or known amounts, the time and routes of exposure, the patient's symptoms and signs, and any treatment already administered. Intoxication may result from acute, chronic, or acute-on-chronic exposure. A *toxicant* is defined as a chemical capable of harming a biologic organism; this definition encompasses toxins, which are derived from living organisms, as well as drugs and industrial and other chemicals. Determination of chronicity is important because signs and symptoms of chronic intoxication (Chapter 21) can differ from those of acute and acute-on-chronic intoxication. For example, a history of acute collapse narrows the toxicant possibilities to a few gases, chemicals, and drugs. A listing of available medications (e.g., medications of the patient, spouse, relatives, or friends); use of nonprescription medications, herbal or dietary supplements, or ethnic remedies; and occupational and avocational activities should be obtained. Occupational and avocational histories should include present and all past jobs and hobbies, with a focus on chemicals, metals, and gases. Known medical conditions may suggest classes of medications available to the patient. The patient's history, which may be incomplete if the patient is confused or suicidal, should be correlated with the clinical manifestations and course. Further history from relatives and friends and findings from the scene as reported by the transporting emergency medical services personnel may be relevant.

Physical Examination

The physical examination should focus on vital signs; the eye, ear, nose, and throat examination; and the neurologic, cardiopulmonary, gastrointestinal, and dermatologic systems. Findings can suggest certain toxidromes, which are clusters of signs and symptoms typical of poisoning with adrenergic, anticholinergic, cholinomimetic, opioid, and sedative-hypnotic agents (Table 110-1). Patients may have some or all of these signs and symptoms; an incomplete clinical picture does not exclude a particular toxidrome, but it can still assist the clinician in identifying the correct category of toxicant involved.

TABLE 110-1 TOXIDROMES AND ASSOCIATED DRUGS AND TOXICANTS

	Syndrome Features		
TOXIDROME	**VITAL SIGNS**	**END ORGAN**	**COMMON DRUGS/TOXICANTS**
Adrenergic	Hypertension, hyperthermia, tachycardia, tachypnea	Agitation, arrhythmias, diaphoresis, mydriasis, seizures	Amphetamines, caffeine, cathinone derivatives, cocaine, ephedrine, pseudoephedrine, *Ephedra* sp, phenylpropanolamine,* theophylline
Anticholinergic	Hyperthermia, tachycardia	Agitation, delirium, decreased or absent bowel sounds, dry flushed skin and mucous membranes, mydriasis or blurred vision, seizures, urinary retention	First-generation H_1-receptor antagonists (e.g., classic antihistamines), belladonna alkaloids (e.g., scopolamine, hyoscyamine) from plants (e.g., *Datura* sp—deadly nightshade, henbane), benztropine, cyclic antidepressants, dicyclomine, muscle relaxants (e.g., orphenadrine, cyclobenzaprine), trihexyphenidyl
Cholinomimetic	Tachycardia or bradycardia†	Agitation, delirium, coma; bronchorrhea, bronchospasm; diaphoresis; fasciculations; lacrimation; miosis; urination; diarrhea, vomiting; seizures	Carbamates, cholinesterase inhibitors (e.g., physostigmine, neostigmine, edrophonium), *Inocybe* or *Clitocybe* mushroom sp, nerve gases (e.g., soman, sarin), organophosphorus compounds
Opiate, opioid	Bradycardia, bradypnea or apnea, hypotension (rare), hypothermia	CNS depression; hypotonia; miosis; mydriasis (dextromethorphan, meperidine, pentazocine)	Codeine, fentanyl, designer fentanyls, heroin, opioids (e.g., hydrocodone, oxycodone, meperidine, morphine), propoxyphene, central α_2-agonists (e.g., clonidine, imidazolines)
Sedative-hypnotic	Bradypnea or apnea, hypotension, hypothermia	Ataxia, CNS depression, hyporeflexia, slurred speech, stupor, or coma	Barbiturates, benzodiazepines, bromides, chloral hydrate, ethanol, ethchlorvynol, etomidate, glutethimide, meprobamate, methaqualone, methyprylon, propofol, zolpidem

*Reflex bradycardia can occur as a result of a pure α-adrenergic agonist effect.
†Tachycardia can occur early as a result of a preganglionic nicotinic effect; as toxicity progresses, postganglionic muscarinic effects predominate, and bradycardia develops.
CNS = central nervous system.

Vital Signs

Tachycardia can occur with numerous toxicants and with anxiety and other nontoxicologic conditions and is not a helpful finding. The limited differential diagnosis for toxicant-induced *bradycardia* includes baclofen, β-adrenergic receptor antagonists, L-type calcium-channel antagonists (diltiazem or verapamil), cardiac glycosides, α-adrenergic receptor agonists (e.g., phenylpropanolamine, whose effects are mediated by baroreceptor reflexes), γ-hydroxybutyric acid, opioids, some sedative-hypnotics, central α_2-agonists, organophosphorus compounds, carbamates, cyanide, muscarine-containing mushrooms (*Clitocybe, Inocybe* sp), plant- and animal-derived toxins (aconitine, andromedotoxin, ciguatoxin, veratridine), therapeutic cholinesterase inhibitors (e.g., physostigmine), cyclic antidepressants (bradycardia is a preterminal sign), and some antiarrhythmic drugs (e.g., procainamide, flecainide, other class IA and IC drugs such as amiodarone, sotalol).

Many toxicants cause *hypotension* (Chapter 7). The primary mechanisms are decreased peripheral vascular resistance, decreased myocardial contractility, hypovolemia secondary to vomiting or loss of intravascular volume, and, occasionally, arrhythmias. Common causes of *hypertension* (Chapter 67) include amphetamines, cocaine, ephedrine and similar agents, ergots, phencyclidine, nicotine, phenylpropanolamine, thyroid hormones, chronic yohimbine use, and chronic lead toxicity. Blood pressure can rise early in poisoning with cyclic antidepressants, central α_2-adrenergic agonists, and monoamine oxidase inhibitors.

Hyperthermia (Chapter 109) occurs with toxicants that cause agitation or excessive motor activity (e.g., cocaine, phencyclidine, monoamine oxidase inhibitors, strychnine), uncouple oxidative phosphorylation (e.g., salicylates, 2,4-dinitrophenol), increase the metabolic rate (thyroid hormones), impair sweating (e.g., first-generation antihistamines, anticholinergics, cocaine, phenothiazines, zonisamide), cause vasoconstriction (e.g., amphetamines, ephedrine), or impair vasodilation and alter perception of heat (cocaine). Other toxicant-induced states associated with hyperthermia include malignant hyperthermia, neuroleptic malignant syndrome, serotonin syndrome, metal fume fever, and hydrocarbon aspiration. Toxicant-induced *hypothermia* is typically due to sedative-hypnotics, opioids, barbiturates, ethanol, phenothiazines, or hypoglycemic agents such as insulin, sulfonylureas, meglitinides, or unripe akee fruit. Oxygen saturation (Figure 161-2 in Chapter 161) as measured by *pulse oximetry*, decreases with true hypoxemia (Figure 104-1 in Chapter 104) or methemoglobinemia (Chapter 161) but remains normal or may be increased in carbon monoxide poisoning (Chapter 94).

Eyes, Ears, Nose, and Throat

Toxicant-induced bilateral miosis (Fig. 110-1) has a limited differential diagnosis that includes central α_2-agonists such as clonidine, guanfacine, and the imidazolines; olanzapine; opioids; organophosphorus compounds or carbamates; therapeutic cholinesterase inhibitors (e.g., physostigmine); topical miotic ophthalmic drugs (e.g., pilocarpine, carbachol); and, variably, phencyclidine, phenothiazines, ethanol, and some sedative-hypnotics (Chapter 432). Pontine hemorrhage is the major nontoxicologic diagnosis to consider in a comatose patient with miotic pupils (Chapter 415). Mydriasis is a nonspecific finding. A unilateral dilated pupil may be due to topical ocular application of sympathomimetics (e.g., phenylephrine), antihistamines, or anticholinergic agents (e.g., inhaled anticholinergics such as ipratropium or tiotropium, dust or sap from *Datura* sp) and can be caused by a postauricular scopolamine patch. Failure of topical 4% pilocarpine ophthalmic drops to constrict the pupil supports the diagnosis of pupillary dilation from a topical mydriatic agent. Visual disturbances, including partial or total blindness as a result of systemic toxicity, have been reported with anticholinergic agents, carbon monoxide, digitalis, ethambutol, methanol, methyl bromide, quinine, and agents that are associated with pseudotumor cerebri, including antimicrobials (e.g., ampicillin, metronidazole, nalidixic acid, nitrofurantoin, sulfa drugs, tetracycline), glucocorticosteroids, lead, lithium, oral contraceptives, phenothiazines, phenytoin, and vitamin A. Nonarteritic anterior ischemic optic neuropathy has developed after the use of sildenafil and other related drugs (Chapter 242); the causal relationship is unknown.

Acute hearing loss (Chapter 436) can occur as a toxic effect of aminoglycosides, bromates, chloroquine, cisplatin, carboplatin, high-dose loop diuretics, nitrogen mustard, quinine, salicylates, vinblastine, and vincristine. Nasal septal erosions and perforations may be due to chronic exposure to intranasal cocaine (Chapter 33) or inhalation of fumes from chromium and nickel (Chapters 93 and 94).

Neurologic Signs

Many toxicants affect the central nervous system (CNS) and can produce agitated delirium, depression, or seizures (Table 110-2). Distinguishing features of various toxicants may assist in making the correct diagnosis. Patients withdrawing from opioids are alert and oriented, whereas patients withdrawing from alcohol, barbiturates, benzodiazepines, and other sedative-hypnotics can be disoriented. Initial CNS depression can also develop with large ingestions of acetaminophen or ibuprofen. Isoniazid and theophylline are noted for producing seizures refractory to the usual doses of benzodiazepines and barbiturates. Pyridoxine treats isoniazid-induced seizures by increasing CNS γ-aminobutyric acid; phenytoin is relatively ineffective for theophylline-induced seizures. Plant or mushroom ingestion can also produce CNS depression (e.g., *Rhododendron* sp, *Solanum* [bittersweet], *Taxus* [yew], *Sophora* [mescal bean]), CNS stimulation (e.g., *Catha edulis* [khat], *Strychnos nux vomica* [contains strychnine], *Cicuta* sp [water hemlock], *Ephedra* [Mormon tea]), atropine-like effects (e.g., *Atropa belladonna* [deadly

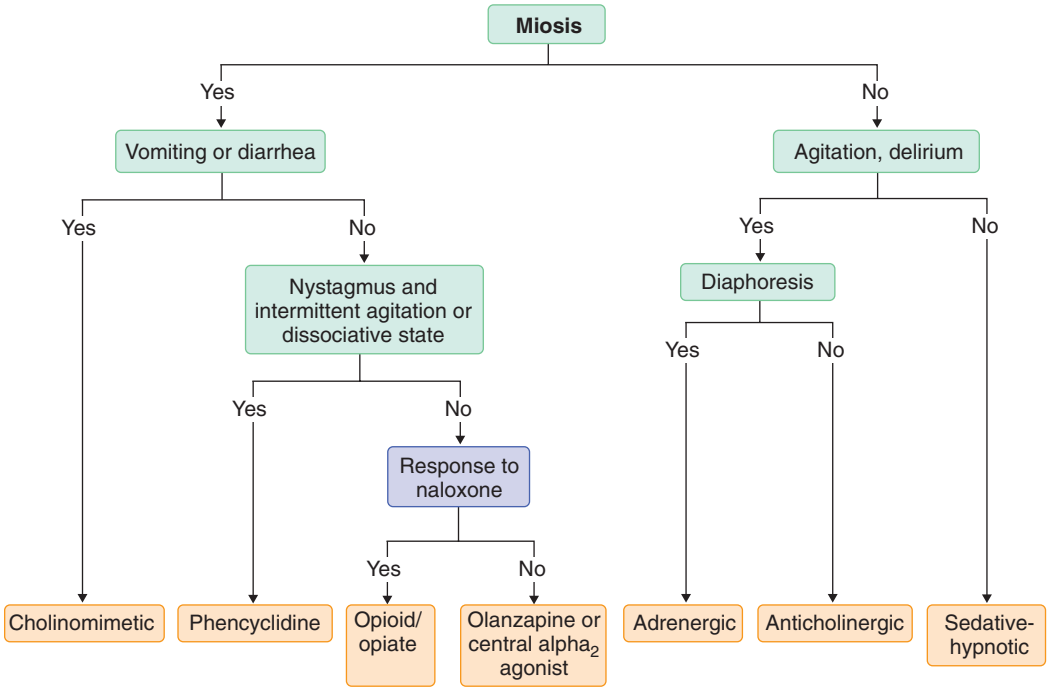

FIGURE 110-1. Diagnostic algorithm using the size of the pupils.

TABLE 110-2 CENTRAL NERVOUS SYSTEM EFFECTS OF TOXICANTS

TOXICANT CATEGORIES/AGENTS	*CNS Effects*		
	AGITATED DELIRIUM	DECREASED LEVEL OF CONSCIOUSNESS	SEIZURES
CATEGORIES			
Adrenergic agonists	•		•
Anticholinergic agents	•	•	•
Anticonvulsants		•	• (paradoxical with some agents)
Antipsychotic drugs	•	•	•
β-Adrenergic receptor antagonists		•	•
Hallucinogenic agents	•		•
Monoamine oxidase inhibitors	•	•	•
Opioids	• (propoxyphene, normeperidine, tramadol)	•	• (propoxyphene, normeperidine, tramadol)
Sedative-hypnotics		•	• (rare)
Serotonin agonists	•	•	•
AGENTS			
Amphetamines, cocaine	•	•	•
Antidepressants	•	•	• (can be delayed with bupropion)
Antihistamines (first generation, e.g., diphenhydramine)	•	•	•
Barbiturates		•	
Benzodiazepines		•	
Cytochrome oxidase inhibitors (e.g., carbon monoxide, cyanide, hydrogen sulfide, azides)		•	•
Ephedra alkaloids and similar agents			•
Ethylene glycol, methanol	•	•	•
γ-Hydroxybutyrate and precursors	•	•	• (rare)
Lithium	•	•	•
Organophosphorus compounds, carbamates (e.g., diazinon, malathion, fenthion, carbaryl)		•	•
Salicylates	•	•	•
SSRIs/SRIs	•	•	• (uncommon)
Withdrawal from alcohol, barbiturates, benzodiazepines, other sedative-hypnotics	•	•	•
Withdrawal from opioids			• (reported only in neonates)

CNS = central nervous system; SRIs = serotonin re-uptake inhibitors; SSRIs = selective serotonin re-uptake inhibitors.

nightshade], *Datura* sp [jimsonweed]), and cholinomimetic effects (e.g., *Nicotiana* genus [tobacco], *Conium maculatum* [poison hemlock], *Inocybe* and *Clitocybe* mushrooms). Seizures can also occur with many of these plants and with mushrooms that contain gyromitrins (e.g., *Gyromitra* sp) and muscimol (e.g., *Amanita muscaria*, *Amanita pantherina*).

Distal axonopathy, a primary degeneration of peripheral nervous system axons with secondary degeneration of the myelin sheath, is the predominant type of toxicant-induced peripheral neuropathy. Common causative agents include acrylamide monomer, allyl chloride, arsenic (inorganic), capsaicin, carbon disulfide, chloramphenicol, cisplatin, colchicine, cyanate, dapsone, dideoxycytidine (ddC), dideoxyinosine (ddI), disulfiram, ethambutol, ethanol, ethylene oxide, gold salts, hexachlorophene, *n*-hexane, hydralazine, interferon, isoniazid, lead, linezolid, mercury, methyl bromide, methyl *n*-butyl ketone, metronidazole, nitrofurantoin, nitrous oxide, some organophosphorus compounds, phenol, platinum, podophyllotoxin, polychlorinated biphenyls, pyridoxine, tacrolimus, taxoids, thalidomide, thallium, vidarabine, vinca alkaloids, and vinyl chloride. Amiodarone, arsenic, and trichloroethylene can produce a demyelinating neuropathy, whereas pyridoxine can produce a sensory neuronopathy.

Neuronal transmission can be altered by aminoglycosides; the venom of *Latrodectus* species (widow spiders), scorpions (only the bark scorpion, *Centruroides exilicauda*, in the United States), and crotaline (e.g., rattlesnakes) and elapid snakes; brevetoxin (shellfish) and ciguatoxin (various fish); neuromuscular blocking drugs; nicotine and related alkaloids; paralytic shellfish toxins; saxitoxin (shellfish); organophosphorus compounds and carbamates; tetrodotoxin (puffer fish [fugu], blue-ringed octopus, salamanders, newts, and others); and veratridine (e.g., false hellebore). Cranial nerves can be affected by carbon disulfide, ciguatoxin, domoic acid (shellfish), elapid venom, ethylene glycol metabolites, paralytic shellfish toxins, bark scorpion, saxitoxin, tetrodotoxin, thallium, and trichloroethylene. Mononeuropathies and vasculitic neuropathies are unlikely to be induced by toxicants (Chapters 113 and 114).

Cardiopulmonary Effects

The examination should focus on blood pressure, heart rate, electrocardiographic abnormalities (e.g., rhythm, conduction, depolarization, repolarization), and pulmonary findings, including pulse oximetry. Drugs and other toxicants that can cause arrhythmias or conduction abnormalities include β-adrenergic receptor antagonists, butyrophenones (e.g., droperidol), L-type calcium-channel antagonists, cardiac glycosides (e.g., digoxin; bufadienolides, found in toxic toad venom and incorporated into some illicit aphrodisiacs; cardenolides, found in plants such as oleander and lily of the valley), chloral hydrate, chloroquine, cocaine, cyclic antidepressants, ethanol, halogenated hydrocarbons (e.g., halothane, trichloroethylene), magnesium, potassium, propoxyphene, thioridazine or mesoridazine, and antiarrhythmics and other agents that affect the myocardial voltage-gated sodium channels (e.g., bupivacaine, chloroquine, cocaine, cyclic antidepressants, flecainide, mexiletine, quinidine, procainamide, propafenone) and potassium channels (e.g., astemizole, cisapride, citalopram, erythromycin [especially when taken concomitantly with cytochrome P-450 A inhibitors; see Chapter 28], quinidine, sotalol, terfenadine). Bedside echocardiography may reveal depressed myocardial contractility as a result of agents that block the

myocardial voltage-gated sodium channel, β-adrenergic receptor antagonists, calcium-channel antagonists, cyclic antidepressants, magnesium, arsenic, ciguatoxin, cyanide, ethanol, iron, scorpion venom, and tetrodotoxin.

Toxicants can produce myriad pulmonary effects, including airway irritation; parenchymal, pleural, and vascular diseases; and barotrauma. Immediate life-threatening toxic effects include acute lung injury and pulmonary edema, acute respiratory distress syndrome (ARDS; Chapter 104), and rapidly developing pulmonary fibrosis or bronchiolitis obliterans. Typical syndromes and etiologic agents include pulmonary edema (β-adrenergic receptor antagonists, calcium-channel antagonists, antiarrhythmics, daunorubicin, doxorubicin), acute lung injury or ARDS (amphetamines, cadmium, chlorine, cocaine, ethchlorvynol, methotrexate, opioids, heroin, paraquat, salicylates; inhalation of smoke, zinc chloride, methyl bromide, methyl chloride), and rapidly developing pulmonary fibrosis or bronchiolitis obliterans (nitrogen dioxide, paraquat).

Gastrointestinal Effects

Symptoms of nausea, vomiting, diarrhea, and abdominal pain are nonspecific and must be interpreted in the context of other findings. Agents that produce severe or life-threatening toxicity with early gastrointestinal findings include acid or large alkali ingestions; cardiac glycosides, colchicines, and other microtubular toxicants; iron; metals such as arsenic, acute high-level lead, mercury salts, or thallium; mushrooms containing amanitine (*Amanita phalloides*, *Amanita virosa*, *Amanita verna*, *Lepiota chlorophyllum*), gyromitrins (*Gyromitra esculenta*), orellanines (*Cortinarius orellanus*), or allenic norleucine (*Amanita smithiana*); nicotine; organophosphorus compounds; and theophylline. Severe abdominal pain and rigidity can occur with envenomation by *Latrodectus* species (widow spiders). Right upper quadrant tenderness develops with toxic hepatitis. Hepatotoxicity can occur as an adverse effect of the therapeutic use of many drugs; in the United States, acetaminophen and ethanol are the most common causes of toxicant-induced hepatotoxicity (Chapter 152). Other notable hepatotoxicants include aflatoxins (in food contaminated with *Aspergillus flavus*), arsenicals, carbon tetrachloride, copper sulfate, cyclopeptide mushrooms (e.g., *Amanita phalloides*), *Ephedra* species (e.g., ma huang), iron, methamphetamine, pennyroyal oil, pyrrolizidine alkaloids (various plant species used in herbal teas), and vitamin A in chronic excessive doses.

Dermatologic Signs

The skin, hair, nails, and mucous membranes should be examined for evidence of intravenous drug use; the presence or absence of skin and mucous membrane moisture; abnormal skin coloration, including erythema and cyanosis; alopecia; and nail abnormalities. Bullous skin lesions have been reported with chronic barbiturate use, glutethimide, carbon monoxide, meprobamate, methadone, and valproic acid. Cyanosis may reflect hypoxemia or methemoglobinemia. Commonly used agents that can cause methemoglobinemia include aniline dyes, benzocaine and other amide anesthetics, dapsone, naphthalene, nitrates, nitrites, phenazopyridine, rifampin, and sulfonamides. Skin erythema or flushing occurs with anticholinergic agents, boric acid ingestion, monosodium glutamate, niacin, scombroid toxicity as a result of the ingestion of inadequately refrigerated fish with a high histidine content (e.g., tuna, mahi-mahi, amberjack), vancomycin, and interactions between ethanol and numerous agents that produce disulfiram or disulfiram-like reactions (e.g., carbon disulfide, some cephalosporins, *Coprinus atramentarius* mushroom, disulfiram, griseofulvin, metronidazole, thiuram herbicides, trichloroethylene).

Specific Toxicants

Some common toxicants can be suspected from their characteristic manifestations (Table 110-3). These suspicions should guide specific diagnostic and therapeutic strategies that complement general decontamination and supportive treatments.

Diagnostic Tests

Drug testing should be guided by the history and physical examination, with emphasis on tests that can influence management. Rapid qualitative urine drug screening tests are readily available in most hospitals, but their clinical value is limited by the number of drugs that can be tested and the reliability of the tests themselves. A positive test result may be unrelated to the patient's condition because drug analytes may be detectable within hours to more than 30 days after drug use, depending on the drug, dose, and frequency of use. False-positive and false-negative results occur (Table 110-4), and the screening result must be verified with a second method, such as gas chromatography–mass spectrometry. The type of drug use in a population should be considered when determining the drugs to be screened to decrease the incidence of false-positive results. A test with 99% specificity for a drug with a prevalence of 0.1% in a population would produce 10 false-positive results for every true-positive result. Clinically irrelevant true-positive findings also occur, such as when poppy seeds produce a positive opiate test. Failure to consider these limitations of drug screens can result in misdiagnosis.

For a limited number of drugs and toxicants, levels in blood or urine are useful for diagnosis, therapy, or monitoring (Table 110-5). Threshold levels of certain toxicants indicate the need for specific therapies: acetaminophen (*N*-acetylcysteine), ethylene glycol (fomepizole and hemodialysis), iron (deferoxamine), methanol (fomepizole and hemodialysis), methemoglobin (methylene blue), salicylates (urine alkalinization and hemodialysis), and theophylline (hemoperfusion or hemodialysis). In chronic poisoning with some drugs, such as salicylates or theophylline, these therapies may be indicated at lower drug levels. In general, any end-organ toxicity that is evident or anticipated (based on the toxicant, amount ingested, and time required to produce toxic effects) is more important than a specific level in determining the need for treatment.

Occult acetaminophen ingestion with toxic serum levels occurs in 0.3 to 1.9% of intentional ingestions. Given that these patients may be asymptomatic until hepatotoxicity develops and that administration of an antidote can prevent this hepatotoxicity, the current recommendation is to test for acetaminophen in all patients with intentional ingestions.

Other Blood Tests

Anion gap metabolic acidosis resulting from primary lactic acidosis can be caused by cyanide, hydrogen sulfide, iron, isoniazid, metformin, nucleoside reverse transcriptase inhibitors, phenformin, sodium azide, and, rarely, acetaminophen with high serum levels. Anion gap metabolic acidosis not related to lactic acidosis occurs with diethylene glycol, ethylene glycol, nonsteroidal anti-inflammatory drugs (NSAIDs), methanol, salicylates, theophylline, and toluene. In poisonings resulting from ibuprofen, methanol, propylene glycol, and salicylates, lactic acid can also be produced, but the level is insufficient to account for the anion gap. Anion gap metabolic acidosis can also develop in patients with ongoing agitation, hyperthermia, and muscle rigidity, such as in neuroleptic malignant syndrome (Chapter 442), or in some cases of rhabdomyolysis (Chapter 115) secondary to toxicants such as doxylamine, phencyclidine, strychnine, cocaine, and amphetamines. Elevated serum creatinine and blood urea nitrogen levels indicative of declining renal function may be seen with numerous toxicants. Direct toxicity occurs with acetaminophen, aminoglycosides, cadmium, Chinese weight-loss botanicals (containing *Stephania tetrandra* or *Magnolia officinalis*), chromium, *Crotalus durissus* venom, diethylene glycol, diquat, ethylene glycol, fluorinated anesthetics, gold, heroin, lithium (diabetes insipidus), mercury salts, mushrooms (*Amanita smithiana* and *Cortinarius* sp), paraquat, radiocontrast agents, solvents (e.g., carbon tetrachloride, trichloroethylene, tetrachloroethylene, toluene), and sulfonamides. Agents that decrease glomerular perfusion by reducing renal blood flow include amphotericin, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, cocaine, cyclosporine, mannitol (excessive chronic doses), methotrexate, and NSAIDs.

Imaging

A computed tomographic scan of the head can detect life-threatening cerebral edema secondary to toxicant-induced hepatic failure, ethylene glycol, and methanol. It also detects intracranial bleeding caused by anticoagulant drugs and rodenticides, scorpion venom, and sympathomimetics (e.g., amphetamines, cocaine, phenylpropanolamine). An abdominal radiograph can reveal radiopaque ferrous sulfate tablets or metals such as arsenic, lead, mercury, and thallium.

Diagnostic Syndromes

Given the myriad combinations of signs, symptoms, and laboratory findings, making the correct diagnosis in a noncommunicative patient can be daunting. A thorough history from bystanders, friends, and prehospital medical personnel may yield crucial information. Additionally, the diagnostic possibilities can be narrowed by noting a finding to limit that list. For example, consider a patient with sudden loss of consciousness, anion gap metabolic acidosis, and bradycardia without hypoxemia. Among the possible causes of anion gap metabolic acidosis (see earlier) and sudden loss of consciousness

TABLE 110-3 PATHOPHYSIOLOGY, CLINICAL EFFECTS, AND MANAGEMENT OF SPECIFIC DRUGS AND TOXICANTS

DRUG OR TOXICANT	PATHOPHYSIOLOGY	CLINICAL EFFECTS	LABORATORY	SPECIFIC THERAPY
Acetaminophen	NAPQI (toxic metabolite) binds hepatic and renal tubular cells; acetaminophen itself induces transient decrease in functional factor VII	Initial: nausea, vomiting, coma, lactic acidosis in severe cases Days 1-3: elevated INR, aminotransferase, and bilirubin levels; RUQ tenderness; increased creatinine level in severe cases Days 4-14: gradual recovery or continued increase in INR and creatinine, lactic acidosis, coma, cerebral edema, death	Potentially toxic level ≥ 150 μg/mL 4 hr after ingestion* INR may be transiently elevated in first 24 hr because of decrease in functional factor VII; further increases indicate hepatic necrosis; elevated aminotransferase and bilirubin levels not predictive of hepatic failure Creatinine elevated in severe cases	NAC (see dosing guidelines in Table 110-6); NAC can increase INR but not aPTT†
Amphetamines	Increased release of presynaptic norepinephrine and dopamine Increased serotonin release (especially MDMA, PMA, DOB, other synthetic amphetamines)	Mild: euphoria, decreased appetite, repetitive behavior Moderate: vomiting, agitation, hypertension, tachycardia, mydriasis, bruxism, diaphoresis Severe: hypertension or hypotension, arrhythmias, hyperthermia, seizures, coma, hepatotoxicity, rhabdomyolysis, DIC, hyponatremia (SIADH), renal failure, cerebral infarction or hemorrhage	Not helpful; many false-positives and false-negatives on screening tests (see Table 110-4)	IV crystalloids External cooling Benzodiazepines or barbiturates to control agitation or seizures Benzodiazepines or nitroprusside for hypertension See SSRIs/SRIs for features and treatment of serotonin syndrome
β-Adrenergic receptor antagonists	Blocks catecholamines from β-adrenergic receptors α- and β-adrenergic receptor antagonism: carvedilol, labetalol Delayed rectifier potassium-channel blockade: sotalol	Bradyarrhythmias, decreased myocardial contractility, hypotension, respiratory depression, decreased consciousness with seizures or coma (lipophilic agents, e.g., propranolol), prolonged QT interval (sotalol)	ECG No specific tests	IV glucagon, 3.5-5 mg over 2-min period; if no increase in BP or HR, can repeat up to 10 mg; if effective, immediately start continuous infusion at 2-10 mg/hr; if still unstable, options include (1) regular insulin, 1 U/kg by IV bolus, followed by 1 U/kg/hr, plus dextrose to maintain euglycemia; (2) norepinephrine or dobutamine infusion titrated to desirable BP and HR; (3) IV milrinone, 50 μg/kg over 10-min period, then 0.375-0.75 μg/kg/min based on hemodynamic status‡ Electrical pacing and IABP in refractory cases
L-type calcium-channel antagonists	Blocks L-type voltage-sensitive calcium channels, thereby decreasing calcium entry into myocardial and vascular smooth muscle cells Decreases pancreatic insulin release and increases insulin resistance	Bradyarrhythmias (verapamil, diltiazem), hypotension, hyperglycemia	ECG No specific tests	IV 10% calcium chloride, 10-20 mg/kg (0.1-0.2 mL/kg); can repeat once; if BP improves, continuous infusion at 0.2-0.5 mL/kg/hr (20-50 mg/kg/hr) Ionized Ca^{2+} levels should not exceed 2× normal (severe cases will be refractory to calcium therapy) Glucagon, high-dose insulin and dextrose, catecholamines, and milrinone (as for β-adrenergic antagonists)
Cardiac glycosides, including digoxin, bufadienolides (toxic toad venom), or cardenolides (e.g., oleander, lily of the valley, dogbane)	Inhibits Na^+,K^+-ATPase Decreased CNS sympathetic output Decreased baroreceptor sensitivity Increased vagal acetylcholine discharge	Bradyarrhythmias, including second- and third-degree AV block and asystole Ventricular ectopy, tachycardia, fibrillation Junctional tachycardia, paroxysmal atrial tachycardia with block Weakness, visual disturbances, nausea, vomiting	Serum digoxin level Serum potassium (hyperkalemia occurs in acute poisoning; hypokalemia may be present in chronic poisoning), magnesium, and creatinine levels	Correct hypokalemia and hypomagnesemia; do not give calcium Digoxin-specific antibody fragments (Fab) indicated if patient has hemodynamically significant arrhythmias, serum potassium ≥5 mg/L, Mobitz II or third-degree AV block, ingestion of bufadienolide- or cardenolide-containing agents, or renal insufficiency Empirical dose Chronic: 2-5 vials Acute: 10-20 vials Calculated dose Chronic: number of vials = 2 × serum digoxin level (ng/mL) × 5.6 × weight (kg)/1000 Acute: number of vials = 2 × oral digoxin dose (mg) × 0.8
Cyclic antidepressants	Myocardial sodium- and potassium-channel blockade Blockade of α-adrenergic and cholinergic muscarinic receptors Inhibition of norepinephrine re-uptake	Decreased level of consciousness (can develop rapidly), myoclonus, seizures, coma Anticholinergic toxidrome (see Table 110-1) Sinus tachycardia, ventricular conduction delays, ventricular arrhythmias, asystole Hypotension	Serum levels not helpful in management	Intermittent IV boluses of $NaHCO_3$ (1 mEq/kg) to maintain arterial pH at 7.5 because acidemia can worsen cardiovascular complications Intubation and neuroparalytic drugs may be useful to ameliorate acidemia from muscular hyperactivity while seizures are being treated Contraindicated drugs: types IA and IC antiarrhythmic agents, physostigmine, flumazenil

TABLE 110-3 PATHOPHYSIOLOGY, CLINICAL EFFECTS, AND MANAGEMENT OF SPECIFIC DRUGS AND TOXICANTS—cont'd

DRUG OR TOXICANT	PATHOPHYSIOLOGY	CLINICAL EFFECTS	LABORATORY	SPECIFIC THERAPY
Ethylene glycol, methanol (e.g., antifreeze, window cleaners, camping stove fuels)	Ethylene glycol: toxic metabolites produce cytotoxicity in CNS, kidneys, lungs, heart, liver, muscles; metabolic acidosis is due to glycolate accumulation; oxalate complexes with calcium, so hypocalcemia can develop Methanol: metabolized to formic acid, which is responsible for metabolic acidosis and inhibition of cytochrome aa_3; target organs include retina, optic nerve, CNS	Ethylene glycol: CNS depression, cerebral edema, seizures, anion gap metabolic acidosis, renal failure with acute tubular necrosis, pulmonary edema, myositis Methanol: nausea, vomiting; cerebral edema, hemorrhage, infarcts; necrosis of thalamus and putamen; anion gap metabolic acidosis; visual disturbances, papilledema, hyperemic optic disc, nonreactive pupils	Serum ethylene glycol and methanol levels; levels may be low or undetectable if significant metabolism has occurred Ethylene glycol: serum calcium, creatinine, BUN levels; examine urine for calcium oxalate crystals; false hyperlactatemia occurs with certain analyzers using L-lactate oxidase, which cross-reacts with glycolic and glyoxylic acids	For both: fomepizole (which inhibits alcohol dehydrogenase and blocks formation of toxic metabolites), 15 mg/kg IV loading dose, then 10 mg/kg IV for 4 doses during the next 48 hr, then 15 mg/kg for subsequent doses; interval dosing is q12h (q4h during hemodialysis, with dosing interval adjustments at start and finish); continue until ethylene glycol or methanol is no longer detectable Use of ethanol is no longer recommended Hemodialysis: initiate if level is ≥50 mg/dL or metabolic acidosis with end-organ toxicity; continue until acidosis resolves and serum level of ethylene glycol or methanol is undetectable Monitor for cerebral edema with possible herniation Ethylene glycol: IV calcium for symptomatic hypocalcemia Methanol: folinic acid, 50 mg IV q4h until methanol not detectable and acidosis cleared
γ-Hydroxybutyrate (GHB) and its precursors (γ-butyrolactone and 1,4-butanediol [1,4-BD])	Agonist effect on CNS GHB receptors; indirect action with opioid receptors (may increase proenkephalins); metabolized to GABA, interacts with $GABA_B$ receptors; decreases dopamine release	CNS: rapid loss of consciousness, with recovery typical within 2-4 hr; myoclonus (possible seizures) Respiratory depression; bradycardia; nausea, vomiting	No specific tests	Supportive care, including respiratory support as needed Withdrawal resembles sedative-hypnotic withdrawal and can be treated with benzodiazepines or pentobarbital
Lithium	Decreases brain inositol; alters CNS serotonin, dopamine, and norepinephrine; inhibits adenylate cyclases, including those that mediate vasopressin-induced renal concentration and thyroid function	Chronic toxicity usually more severe than acute toxicity: tremor, hyperreflexia, drowsiness, incoordination, clonus, confusion, ataxia; in severe cases, seizures, coma, death; recovery may take weeks, and CNS deficits may persist Sinus node dysfunction, QT prolongation, T wave abnormalities, U waves Nephrogenic diabetes insipidus, hypothyroidism, hyperthyroidism, hypercalcemia, pseudotumor cerebri Acute toxicity: nausea, vomiting, diarrhea, and milder neurologic findings	Peak serum levels: Normal dose 2-3 hr; up to 5 hr for sustained-release lithium Acute overdose Peak may be delayed ≥4-12 hr	Replenish intravascular volume, maintain urinary output at 1-2 mL/kg/hr Consider GI decontamination with oral polyethylene glycol electrolyte solution within 1-2 hr after acute overdose of sustained-release drug Hemodialysis[§] in patients with altered mental status, ataxia, seizures, or coma or in patients with mild symptoms in the setting of acute overdose or renal insufficiency Ineffective or contraindicated therapies include oral activated charcoal, diuretics, and aminophylline
Opioids (e.g., heroin, morphine, oxycodone, fentanyl)	Agonist effect at CNS μ, κ, and δ opioid receptors; result is cell hyperpolarization and decreased neurotransmitter release	CNS depression, respiratory depression, miosis (see Table 110-1) Dextromethorphan increases CNS serotonin and inhibits NMDA receptors, which causes hallucinations Propoxyphene and its metabolite norpropoxyphene block sodium channels and can cause seizures and wide-complex arrhythmias similar to cyclic antidepressants; $NaHCO_3$ treats arrhythmias Seizure risk with tramadol, meperidine, propoxyphene Rapid, powerful heroin-like effect when sustained-release oxycodone is crushed before ingestion, snorting, or smoking QTc prolongation and torsades de pointes with methadone	Rapid urine drug screens detect morphine and codeine but may not detect semisynthetic and synthetic opioids; some interferents/irrelevants (see Table 110-4)	IV naloxone, 0.4-2 mg; can repeat up to 10 mg if no response Continuous infusion for recurrent symptoms or sustained-release opioid ingestion; give 50% of dose that produces desired effect 15 min after initial effect is obtained, then infuse two thirds of this dose every hr; infusion rate can be increased or decreased to maintain normal respiration and avoid withdrawal symptoms Contraindicated therapies: nalmefene and naltrexone should not be used for acute opioid reversal

TABLE 110-3 PATHOPHYSIOLOGY, CLINICAL EFFECTS, AND MANAGEMENT OF SPECIFIC DRUGS AND TOXICANTS—cont'd

DRUG OR TOXICANT	PATHOPHYSIOLOGY	CLINICAL EFFECTS	LABORATORY	SPECIFIC THERAPY
Organophosphorus compounds and carbamates (e.g., diazinon, mevinphos, fenthion, aldicarb)	Inhibits acetylcholinesterase, resulting in excessive acetylcholine stimulation of nicotinic and muscarinic receptors in autonomic and somatic motor nervous systems and CNS	Nicotinic-mediated effects: tachycardia, mydriasis, hypertension, delirium, coma, seizures, muscle weakness, fasciculations Muscarinic-mediated effects: salivation, lacrimation, urination, vomiting, defecation, miosis, bronchorrhea, bronchospasm, bradycardia	Serum (butyrylcholinesterase) or RBC (acetylcholinesterase) activity <50% of normal (see Table 110-6) Clinical recovery occurs before serum cholinesterase levels normalize	Atropine, 1-2 mg by initial IV bolus; double the dose every 5 min (2 mg, 4 mg, 8 mg, 16 mg, etc) until drying of bronchial secretions, adequate oxygenation, pulse >80 bpm, systolic blood pressure >80 mm Hg achieved; continuous infusion at 10- 20% of total stabilizing dose per hr; stop infusion if patient develops any signs or symptoms of anticholinergic toxidrome (see Table 110-1); restart infusion at lower rate when signs or symptoms abate Pralidoxime[‖] chloride 30 mg/kg (maximum 2 g) IV bolus over 30 min, then 8-10 mg/kg/hr (maximum 650 mg/hr) continuous infusion; administer as soon as possible after poisoning; continue 12-24 hr after atropine no longer required and symptoms resolve■
Salicylates	Inhibits cyclooxygenase; decreases formation of prostaglandins and thromboxane A_2; stimulates CNS medullary respiratory receptor and chemoreceptor trigger zone; impairs platelet function; disrupts carbohydrate metabolism; uncouples oxidative phosphorylation; increases vascular permeability	Acute toxicity Mild: nausea, vomiting, diaphoresis, tinnitus, decreased hearing, hyperpnea, tachypnea Moderate–severe: confusion, delirium, coma, seizures, hyperthermia, ALI; death can occur within hours of overdose Chronic toxicity: same as acute, but may not have diaphoresis or vomiting Consider diagnosis in patients with new-onset confusion, anion gap metabolic acidosis, or ALI	Serum salicylate level: toxic ≥30 mg/dL; level ≥100 mg/dL indicates life-threatening toxicity with possible sudden, rapid clinical deterioration; in chronic toxicity, levels may be minimally elevated (>30 mg/dL), and clinical evaluation is more reliable for gauging degree of toxicity Arterial blood gases: respiratory alkalosis with metabolic acidosis Anion gap metabolic acidosis Prolonged PT and PTT, ketonuria, ketonemia	Multidose activated charcoal q2-3h in acute overdose with progressive symptoms or rising salicylate level
SSRIs/SRIs	Inhibits re-uptake of serotonin SRIs have additional effects (e.g., duloxetine inhibits norepinephrine re-uptake, nefazodone inhibits serotonergic 5-HT2 receptors, trazodone inhibits peripheral α-adrenergic receptors, venlafaxine inhibits norepinephrine and dopamine re-uptake)	Vomiting, blurred vision, CNS depression, tachycardia Seizures and coma rare Torsades de pointes reported with citalopram Serotonin syndrome: clonus, agitation, tremor, diaphoresis, hyperreflexia; hyperthermia and hypertonicity in severe cases	No specific tests If serotonin syndrome suspected: electrolytes, BUN, glucose, liver enzymes, coagulation panel, blood gases, chest radiograph	Respiratory support as needed Benzodiazepines for agitation or seizures Serotonin syndrome: consider cyproheptadine, 12 mg PO initial dose, then 2 mg PO q2h (to a maximum of 32 mg/day) until symptoms resolve Critical care therapies for hyperthermia, rhabdomyolysis, DIC, ARDS, renal and hepatic dysfunction, torsades de pointes

*A nomogram to evaluate the potential toxicity of levels drawn more than 4 hours after ingestion is provided in Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. *Pediatrics.* 1975;55:871-876. The nomogram is valid only for levels drawn after a single acute ingestion.
†NAC can be discontinued in patients with uncomplicated disease after a loading dose plus six maintenance doses if hepatic aminotransferase levels are normal and acetaminophen is not detected; otherwise, the full regimen should be administered.
‡Adjust infusion for reduced renal function.
§Continue hemodialysis until the serum lithium level is less than 1 mEq/L. Recheck the level 8 hours after dialysis, and restart hemodialysis if the level is higher than 1 mEq/L. Repeat this cycle until the serum lithium level remains lower than 1 mEq/L.
‖A double-blind, randomized, placebo-controlled trial of pralidoxime in acute organophosphorus poisoning found no significant difference in mortality rates or need for intubation.■
ALI = acute lung injury; aPTT = activated partial thromboplastin time; ARDS = acute respiratory distress syndrome; AV = atrioventricular; BP = blood pressure; bpm = beats per minute; BUN = blood urea nitrogen; CNS = central nervous system; DIC = disseminated intravascular coagulation; DOB = 4-bromo-2,5-dimethoxyamphetamine; ECG = electrocardiogram; GABA = γ-aminobutyric acid; GI = gastrointestinal; HR = heart rate; IABP = intra-aortic balloon counterpulsation; INR = international normalized ratio; IV = intravenous; MDMA = 3,4-methylenedioxymethamphetamine; Na^+,K^+-ATPase = sodium, potassium adenosine triphosphatase; NAC = *N*-acetylcysteine; NAPQI = *N*-acetyl-p-benzoquinone imine; NMDA = *N*-methyl-D-aspartate; PMA = paramethoxyamphetamine; PT = prothrombin time; PTT = partial thromboplastin time; RBC = red blood cell; RUQ = right upper quadrant (abdomen); SIADH = syndrome of inappropriate antidiuretic secretion; SRI = serotonin re-uptake inhibitor; SSRI = selective serotonin re-uptake inhibitor.

are hydrogen sulfide, cyanide, and severe poisoning with sodium azide; however, sinus bradycardia in the absence of acute ischemic injury is typical only of cyanide poisoning.

TREATMENT

Initial Stabilization

Intubation and Respiratory Support

Appropriate airway management should be instituted to correct hypoxemia and respiratory acidosis and to protect against pulmonary aspiration (Fig. 110-2); intubation should be considered if the patient has depressed consciousness and a decreased gag reflex. Rapid-sequence intubation facilitates airway management. Anatomic difficulties should be anticipated in patients with caustic ingestions (hypopharyngeal burns that may perforate); angioedema caused by angiotensin-converting enzyme inhibitor therapy or envenomation by some rattlesnakes, such as the canebrake (*Crotalus horridus atricaudatus*) and eastern diamondback (*Crotalus adamanteus*) (Chapter 113); and swelling secondary to direct tissue injury (e.g., huffing Freon, snakebite on the tongue) or secondary to anaphylactoid and anaphylactic reactions. Endotracheal intubation via flexible fiberoptic nasopharyngoscopy may be indicated in these cases. Hypoxemia can occur with toxicants that produce CNS depression, such as antidepressants, barbiturates, sedative-hypnotics, and central α_2-adrenergic receptor agonists (clonidine), or agents causing peripheral neuromuscular impairment, such as nicotine, organophosphorus

TABLE 110-4 QUALITATIVE URINE DRUG SCREENS: CAUSES OF ERRONEOUS RESULTS*

DRUG/TOXICANT	INTERFERENTS/IRRELEVANTS†	COMMENTS
Amphetamines	Amantadine, bupropion, chlorpromazine, ephedrine, pseudoephedrine, desoxyephedrine, *Ephedra* sp, mexiletine, phenylephrine, phenylpropanolamine, selegiline, trazodone	Vicks nasal inhaler (desoxyephedrine) and selegiline also cause positive GC-MS findings; chiral confirmation is required; newer immunoassays have eliminated false-positive results from desoxyephedrine Interferents in older assays include labetalol and ranitidine
Benzodiazepines	Oxaprozin, sertraline	Poor detection of parent drugs with absent or low concentration of oxazepam metabolite (e.g., alprazolam, lorazepam, triazolam)
Cocaine	Coca leaf teas	Urine is most reliable for detecting true positives
Opiates, opioids	Dextromethorphan, poppy seeds, quinine, quinolones, rifampin	Does not detect semisynthetic or designer opioids (e.g., fentanyls, meperidine, methadone, propoxyphene)
Phencyclidine	Dextromethorphan, diphenhydramine, doxylamine, ibuprofen, ketamine, meperidine, mesoridazine, thioridazine, tramadol, venlafaxine	
Tetrahydrocannabinol	Dronabinol, efavirenz, proton pump inhibitors	Positive result is seldom clinically relevant; synthetic cannabinomimetics are not detected
Tricyclic antidepressants	Carbamazepine, cyclobenzaprine, cyproheptadine, diphenhydramine, phenothiazines, quetiapine	

*Advances in drug screening and variability in immunoassay results should be considered by the clinician when interpreting qualitative drug screening results. Consultation with the testing laboratory is advised. Positive screening results are considered presumptive and should be verified by GC-MS.
†Irrelevants are agents causing true-positive but clinically irrelevant results on laboratory screening tests; they vary, depending on the screening method.
GC-MS = gas chromatography–mass spectrometry.

TABLE 110-5 CLINICALLY IMPORTANT QUANTITATIVE DRUG LEVELS

	Levels	
DRUG OR TOXICANT	**THERAPEUTIC**	**TOXIC**
SOURCE: BLOOD OR SERUM		
Acetaminophen*	10-30 µg/mL	≥150 g/mL 4 hr after ingestion†
Carbamazepine	4-12 µg/mL	>15 g/mL
Carboxyhemoglobin	Nonsmoker: 0.5-1.5% Smoker: 4-9%	>20%‡
Cholinesterase§		
Serum (butyrylcholinesterase)	3100-6500 U/L	<50% of normal value
Red blood cell (acetylcholinesterase)	26.7-49.2 U/g of hemoglobin	<50% of normal value
Digoxin (≥12 hr after dose for long-term therapy)	0.8-2.0 ng/mL‖	>2.0 ng/mL
Ethanol	None measured	>80-100 mg/dL
Ethylene glycol	None measured	>25 mg/dL
Iron	50-175 µg/dL	>350 g/dL
Lead	<10 µg/dL	>25 g/dL
Lithium	0.6-1.2 mEq/L	>1.2 mEq/L¶
Methanol	None measured	>20 mg/dL
Methemoglobin	1-2%	>15%
Phenobarbital	15-40 µg/mL	>40 g/mL
Phenytoin	10-20 µg/mL	>20 g/mL
Salicylates	≤30 mg/dL	>30 mg/dL
Theophylline	8-20 µg/mL	>20 g/mL
Valproic acid	50-100 µg/mL	>100 g/mL
SOURCE: URINE		
Arsenic	None measured	>100 g/24-hr urine¶
Mercury	None measured	>20 g/L¶
Thallium	None measured	>200 g/L¶

*False-positive levels of 16-28 µg/mL have been reported in patients with bilirubin levels greater than 17 mg/dL.
†Levels drawn more than 4 hours after ingestion should be plotted on the nomogram provided by Rumack and Matthew (Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. *Pediatrics.* 1975;55:871-876) to assess the potential for toxicity.
‡Lower levels may be toxic in pregnant patients and in those with prolonged exposure to carbon monoxide.
§Consult a reference laboratory for normal values; results are assay dependent.
‖Some patients may require levels above the therapeutic range to control symptoms.
¶Lower values may indicate toxicity if appropriate clinical findings are present.

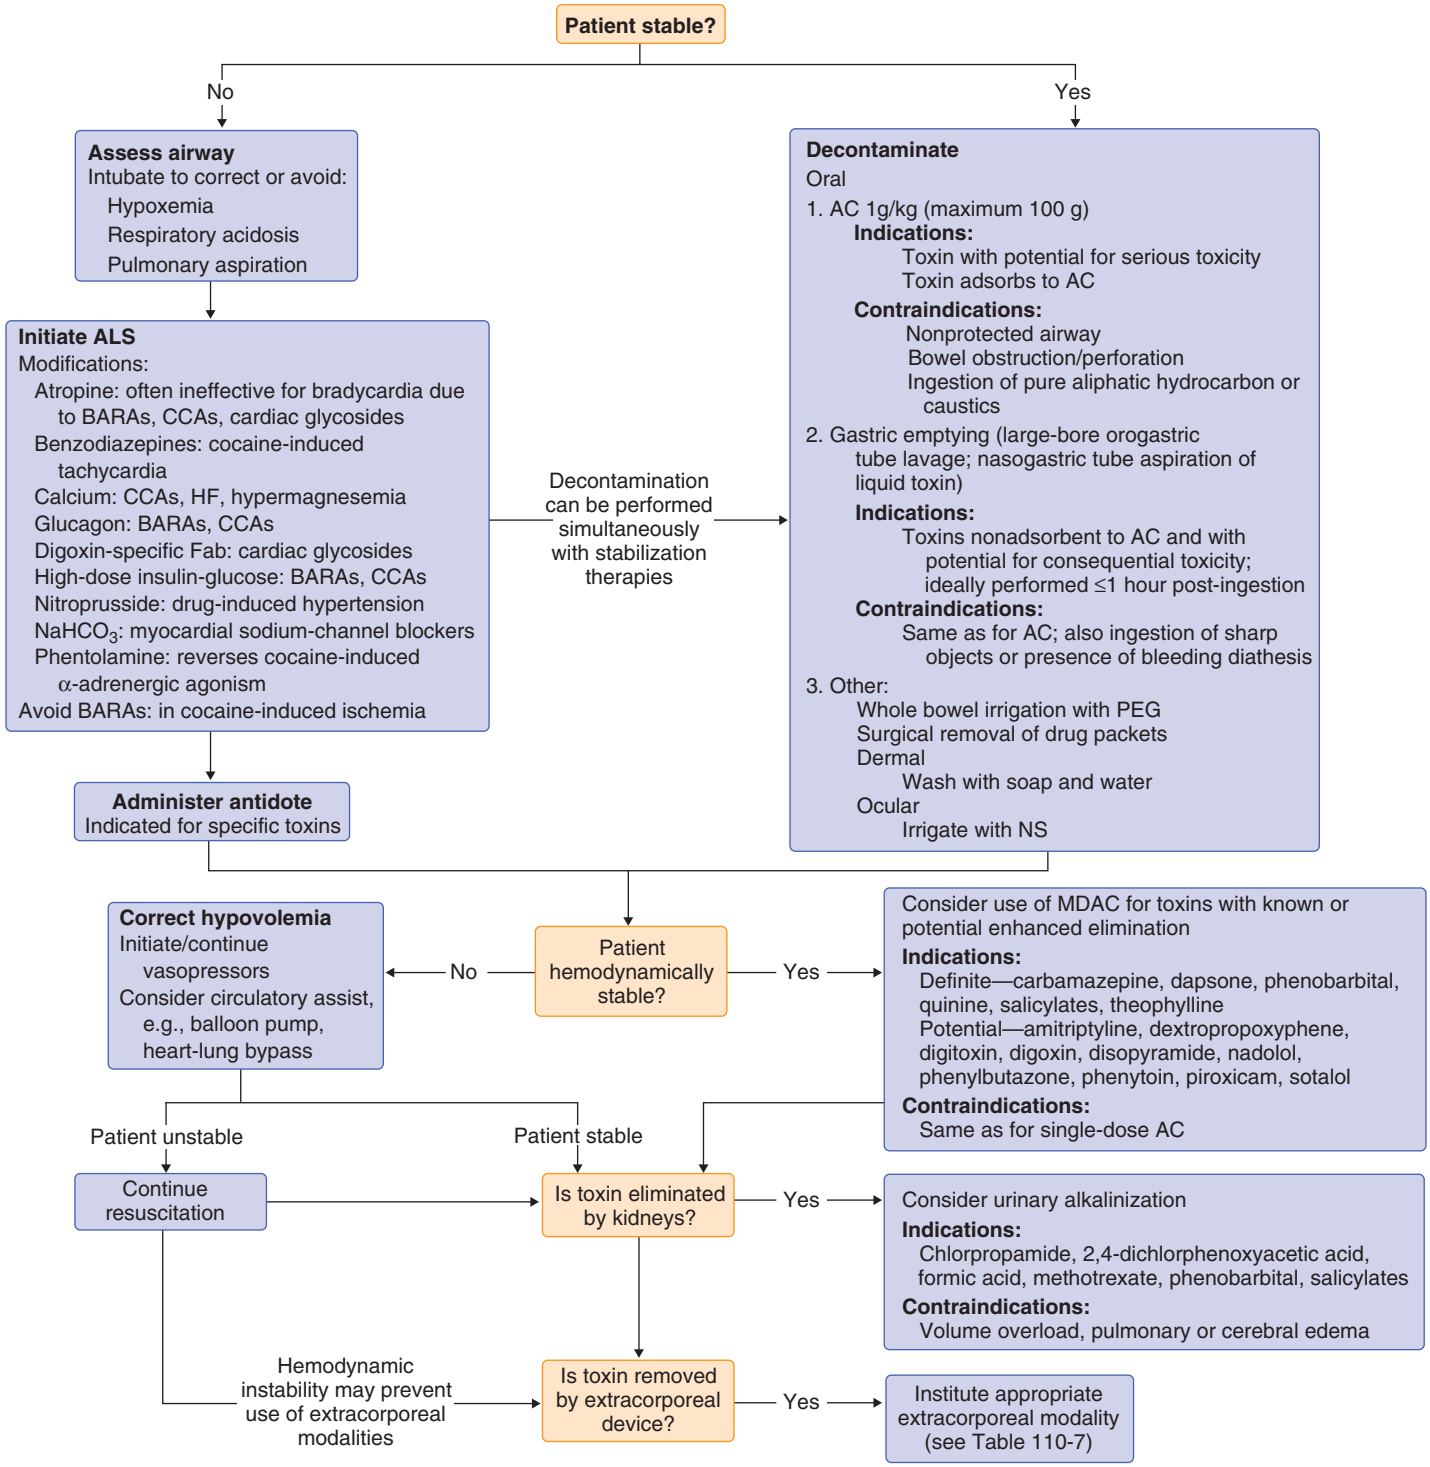

FIGURE 110-2. Algorithm for the management of acute poisoning. AC = activated charcoal; ALS = advanced life support; BARAs = β-adrenergic receptor antagonists; CCAs = L-type calcium-channel antagonists; HF = hydrofluoric acid; MDAC = multidose activated charcoal; NS = 0.9% saline solution; PEG = nonabsorbable polyethylene glycol solution.

compounds, strychnine, tetrodotoxin (puffer fish, blue-ringed octopus), botulinum, or envenomation from elapids (coral snake), Mojave rattlesnakes, or certain coelenterates (box jellyfish, Portuguese man-of-war) (Chapters 113 and 114).

Respiratory acidosis can rapidly worsen the toxicities of cyclic antidepressants and salicylates; sedation of these patients should be accompanied by immediate airway support. Intoxicated patients may have an increased risk for pulmonary aspiration because of concomitant CNS depression, attenuated airway reflexes, full stomachs, and delayed gastric emptying.

Succinylcholine can cause prolonged paralysis in patients with organophosphorus poisoning and can exacerbate hyperkalemia from cardiac glycosides, hydrofluoric acid, or rhabdomyolysis (Chapter 115). Rhabdomyolysis has been reported with adrenergic agents, doxylamine, phencyclidine, heroin, *Tricholoma equestre* mushrooms, and envenomation by crotaline snakes, scorpions, or widow spiders (*Lactrodectus* sp); short-acting nondepolarizing agents, such as vecuronium and rocuronium, are preferable in these cases.

Advanced Life Support

Standard emergency cardiovascular care algorithms (Chapter 63) must be modified for effects caused by specific poisons. Atropine often does not reverse bradycardia secondary to β-adrenergic receptor antagonists, L-type calcium-channel antagonists, or cardiac glycosides. In these cases, more specific therapy with intravenous calcium (calcium-channel antagonists), high doses of glucagon (β-adrenergic receptor antagonists, calcium-channel antagonists), or digoxin-specific Fab antibody (cardiac glycosides) is indicated. High-dose insulin-glucose therapy can successfully reverse myocardial depression and conduction abnormalities in humans poisoned with β-adrenergic receptor antagonists and calcium-channel antagonists. Intravenous sodium

bicarbonate may reverse cardiac conduction delays caused by antiarrhythmic drugs with sodium-channel blockade recovery rates of greater than 1 second (Vaughn-Williams classification IA and IC), cocaine, cyclic antidepressants, diphenhydramine, propoxyphene, and quinine. β-Adrenergic receptor antagonists are contraindicated in patients with cocaine-induced myocardial syndromes, but phentolamine can reverse the agonistic effects of cocaine on α-adrenergic receptors. Benzodiazepines can reverse significant sinus tachycardia from sympathomimetic agents. Calcium may also be life-saving in systemic hydrofluoric acid poisoning and severe hypermagnesemia, and it is indicated for symptomatic hypocalcemia caused by ethylene glycol toxicity. Drug-induced hypertension may be transitory; nitroprusside should be used if treatment is clinically indicated. In patients with toxicant-induced circulatory collapse refractory to maximal therapy, including vasopressors, circulatory assist devices may support the patient until sufficient toxicant is eliminated (Chapter 107).

Decontamination

Activated Charcoal

Single-dose activated charcoal without prior gastric emptying has been the preferred method of treatment for the ingestion of substances that have the potential to cause moderate to life-threatening toxicity and are known to adsorb to activated charcoal. The absence of clinical signs and symptoms does not preclude administering activated charcoal, because drug absorption and toxicity can be delayed. Activated charcoal can also be administered when the ingested toxicant cannot be identified but significant toxicity is a concern. Activated charcoal consists of pyrolysis products that have been specially cleaned to produce an internal pore structure to which substances can reversibly adsorb, thus preventing their absorption by the gastrointestinal tract. Activated charcoal can be administered with antiemetic drugs or given through a nasogastric tube, when necessary. The oral dose is approximately 1 g/kg body weight, with a maximum single dose of 100 g. Efficacy in preventing toxicant absorption declines with time, so activated charcoal should be given as soon as possible after ingestion. A large randomized trial in Sri Lankan hospitals showed no benefit of activated charcoal in reducing mortality,■ but 87% of the study patients had ingested a pesticide or yellow oleander (which contains a cardiac glycoside); the applicability of this study's findings to populations in which other toxicants are more commonly ingested is unknown. Activated charcoal should not be used in patients with CNS depression until the airway is secure to minimize aspiration; the patient's head should also be elevated unless contraindicated. Activated charcoal is contraindicated in patients with a perforated bowel, functional or mechanical bowel obstruction, ingestion of a pure aliphatic hydrocarbon such as gasoline or kerosene (no benefit and increased risk for aspiration), and ingestion of caustic acid and alkali (no benefit and obscures endoscopy). Certain agents, such as lithium, iron, metals, and ethanol, do not adsorb significantly to activated charcoal, but its use is not precluded if the patient has ingested other toxicants that do adsorb to activated charcoal. Pulmonary aspiration and bowel obstruction from inspissated activated charcoal are the most common complications; both occur more frequently when multidose activated charcoal is administered, but they can be avoided by withholding treatment in patients who have suboptimal bowel function or decreased fecal elimination.

Gastric Emptying

Two methods of gastric emptying, syrup of ipecac and orogastric lavage via a large-bore tube, are no longer routinely used. Both are relatively ineffective therapies that potentially increase the risk for aspiration. No well-designed study has documented any benefit of gastric emptying, either by lavage or by syrup of ipecac, when compared with the use of activated charcoal alone. Gastric emptying via lavage or, rarely, by syrup of ipecac may be of benefit and should be performed in patients who have ingested toxicants that do not adsorb to activated charcoal and are known to produce significant morbidity, or for which aggressive decontamination may offer the best chance for survival (e.g., colchicine, sodium azide, sodium fluoroacetate). Removal of a liquid toxicant, such as ethylene glycol, may be accomplished by aspiration of gastric contents via a nasogastric tube. Contraindications to gastric emptying include those for activated charcoal, a bleeding diathesis, and the ingestion of sharp objects. Placement of an endotracheal tube before gastric lavage may be necessary to protect the airway in patients who have a decreased level of consciousness and impaired gag reflex; major complications of gastric emptying include pulmonary aspiration, esophageal tears and perforations, and laryngospasm (with lavage).

Whole Bowel Irrigation

Whole bowel irrigation with a nonabsorbable polyethylene glycol solution has been recommended for iron and sustained-release medications, for agents not adsorbed to activated charcoal, and for body packers (smugglers who swallow packets of illicit drugs). The most common complication is vomiting, and whole bowel irrigation is contraindicated in patients with bowel perforation, obstruction, hemorrhage, or hemodynamic or respiratory instability. The initial recommended dose is 500 mL/hour given orally or via nasogastric tube, with titration to 2000 mL/hour as tolerated; treatment continues until the rectal effluent clears. Rarely, surgery may be necessary to remove packets in smugglers who have symptoms of drug toxicity; endoscopic removal of these packets should never be attempted because of the risk of packet rupture.

Antidotes

Few toxicants have specific therapies (Table 110-6). Although antidotes may be essential in treating patients exposed to certain toxicants, their use does not preclude the need for ongoing supportive care and, in some cases, extracorporeal elimination.

Enhanced Elimination

Three methods are used to accelerate the elimination of toxicants or drugs from the body: (1) multiple doses of oral activated charcoal, (2) urinary alkalinization, and (3) extracorporeal removal. A fourth method using the oral ion exchange resins sodium polystyrene sulfonate and cholestyramine has experimentally enhanced the elimination of lithium, digoxin, digitoxin, and organochlorines but has limited clinical usefulness.

Multiple Doses of Oral Activated Charcoal

The rationale for administering multiple doses of oral activated charcoal includes the adsorption of any toxic agent remaining in the gastrointestinal tract (e.g., sustained-release drugs, drugs that retard their absorption); interference with the enterohepatic and enteroenteric recirculation of toxicants; and enhancement of the elimination of drugs with a long half-life, a volume of distribution less than 1 L/kg body weight, and low protein binding. The existing evidence shows enhanced elimination of carbamazepine, dapsone, phenobarbital, quinine, salicylates, and theophylline, but multiple doses of activated charcoal may also be effective for amitriptyline,

TABLE 110-6 ANTIDOTES AND INDICATIONS FOR USE

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Antivenom (Fab)†	Crotalines	4-6 vials; repeat for persistent or worsening clinical condition; repeat doses of 2 vials at 6, 12, and 18 hr after initial antivenom dose(s) are recommended	Halt in progression of circumferential and proximal swelling Resolving systemic effects	Better safety profile than equine-derived antivenom Repetitive dosing indicated for recurrent soft tissue swelling
Antivenom, *Latrodectus* (equine)†	Black widow spider (*Latrodectus* sp)	1 vial diluted in 100 mL NS, infused over 1 hr; can repeat	Resolution of symptoms, vital signs normal	Dilution and slow infusion rate are **critical** to avoid anaphylactoid reaction Indications include severe pain unresponsive to opioids and severe hypertension Serum sickness can occur IV calcium is ineffective
Atropine	Carbamates Nerve agents Organophosphorus compounds	2 mg IV; double the dose every 5 min to achieve atropinization and hemodynamic stability; then start continuous infusion of 10-20% of total stabilizing dose per hr	Cessation of excessive oral and pulmonary secretions, >80 bpm, systolic blood pressure >80 mm Hg	Doubling of the dose every 5 min (e.g., 2 mg, 4 mg, 8 mg, 16 mg) estimated to achieve atropinization within 30 min Stop infusion if patient develops any signs or symptoms of anticholinergic toxidrome (see Table 110-1); restart infusion at lower rate when signs or symptoms abate

TABLE 110-6 ANTIDOTES AND INDICATIONS FOR USE—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Calcium‡	Calcium-channel antagonists	Calcium chloride 10%, 20-50 mg (0.2-0.5 mL)/kg/hr	Reversal of hypotension; may not reverse bradycardia	*All indications:* Monitor ionized calcium levels IV extravasation causes tissue necrosis, especially with calcium chloride Can administer at faster than stated rates for immediate life-threatening conditions Taper infusions and monitor for relapse of toxicity when discontinuing therapy Calcium chloride contains three times more elemental calcium than calcium gluconate does Calcium-channel antagonists: may be ineffective in severe toxicity
	Hydrofluoric acid	Systemic toxicity: calcium gluconate 10%, 1-3 g (10-30 mL) per dose IV over 10-min period; repeat as needed every 5-10 min	Reversal of life-threatening manifestations of hypocalcemia and hyperkalemia	Can dilute and give intra-arterially or IV with a Bier block for extremity exposures and burns
	Hyperkalemia (except cardiac glycosides)	Calcium gluconate 10%, 1 g (10 mL) per dose IV over 10-min period; repeat as needed every 5-10 min	Reversal of myocardial depression and conduction delays	May precipitate ventricular arrhythmias
	Hypermagnesemia	Calcium gluconate 10%, 1-2 g (10-20 mL) per dose IV over 10-min period; repeat as needed every 5-10 min	Reversal of respiratory depression, hypotension, and cardiac conduction blocks	Simultaneous therapies to increase magnesium elimination should be instituted
	Hypocalcemia (e.g., ethylene glycol)	Calcium gluconate 10%, 0.5-1.0 g (5-10 mL) per dose over 10-min period; repeat as needed every 10 min	Reversal of tetany	Correct symptomatic hypocalcemia; avoid excessive administration that may increase production of calcium oxalate crystals in ethylene glycol poisoning
L-Carnitine	Valproate-induced hyperammonemia or hepatotoxicity	100 mg/kg (maximum 6 g) IV over 30 min, then 15 mg/kg IV over 30-min period q4h (max 6 g/day)	Treat until clinical improvement occurs	Levocarnitine is active form Adjust dose for end-stage renal disease
Cyanide antidote kit Amyl nitrite Sodium nitrite Sodium thiosulfate	Cyanide	Amyl nitrite: 0.3-mL pearls, crush and inhale over 30-sec period Sodium nitrite 3%: 10 mL IV over 10-min period Sodium thiosulfate 25%: 50 mL (12.5 g) IV over 10-min period	Resolution of lactic acidosis and moderate to severe clinical signs and symptoms: seizures, coma, dyspnea, apnea, hypotension, bradycardia	Coordinate amyl nitrite with continued oxygenation and give only until sodium nitrite infusion is begun; nitrites may produce hypotension and excess methemoglobinemia Sodium nitrite dose must be adjusted if patient has hemoglobin <12 g/dL Sodium thiosulfate dosing can be repeated
Deferoxamine	Iron	15 mL/kg/hr IV (max 8 g/day) Mild to moderate: administer for 6-12 hr Severe toxicity: administer 24 hr	Resolution of clinical signs and symptoms Do not use urine color, which is an unreliable marker for iron clearance	Indications: symptomatic patients with lethargy, severe abdominal pain, hypovolemia, acidosis, shock; any symptomatic patient with peak serum iron level >350 g/dL Prolonged therapy can cause pulmonary toxicity
Digoxin-specific antibody fragments (Fab)	Digoxin Digitalis Other cardiac glycosides (e.g., bufodienalides [Bufo toads], oleander)	Unknown digoxin dose or serum level or for plant or toad source: acute toxicity—10-20 vials; chronic toxicity—3-6 vials Digoxin dose known: number of vials = (mg ingested × 0.8) ÷ 0.5 Digoxin serum level known: number of vials = [serum level (ng/mL) × weight (kg)] ÷ 100	Resolution of hyperkalemia, symptomatic bradydysrhythmias, ventricular arrhythmias, Mobitz II or third-degree heart block	Each vial binds 0.5 mg of digoxin or digitoxin Monitor ECG and potassium levels Digoxin serum levels unreliable after antidote administered unless test is specific for free serum digoxin

TABLE 110-6 ANTIDOTES AND INDICATIONS FOR USE—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Dimercaprol (BAL)	Arsenic Lead Mercury, elemental and inorganic salts	Arsenic: 3-5 mg/kg IM q4h Lead: 75 mg/m^2 (4 mg/kg) IM q4h for 5 days Inorganic mercury: 5 mg/kg IM, then 2.5 mg/kg IM q12h for 10 days or until patient clinically improved	Arsenic: 24-hr urinary arsenic <50 µg/L Lead: encephalopathy resolved, blood lead level <100 µg/dL, and succimer therapy can be started Mercury, elemental and inorganic: 24-hr urinary mercury <20 µg/L	Maximum adult dose is 3 g/day BAL started 4 hr before initiation of concomitant $CaNa_2EDTA$ for lead encephalopathy Dosing not well established for arsenic and elemental or inorganic mercury toxicity; not used for organic mercury poisoning Adverse effects: painful injections, fever, diaphoresis, agitation, headache, salivation, nausea and vomiting, hemolysis in G6PD-deficient patients, chelation of essential metals Check essential metal levels if chelation is prolonged Succimer is replacing BAL for many indications except lead encephalopathy Treatment end points for arsenic and mercury include improving clinical condition
Edetate calcium disodium ($CaNa_2EDTA$)	Lead	1500 mg/m^2/24 hr (max 3 g) by continuous infusion	Treat for 5 days, followed by 2-day hiatus; repeat until encephalopathy resolved, lead level <100 µg/dL, and succimer therapy can be started	Use in patients with lead encephalopathy or lead level >100 g/dL Administer BAL 4 hr before initiating $CaNa_2EDTA$ Hydrate patient and establish good urinary output before starting therapy Avoid thrombophlebitis by diluting in NS or D_5W to a concentration ≤0.5% Substitution of Na_2EDTA can cause fatal hypocalcemia
Flumazenil	Benzodiazepines Venlafaxine	0.1 mg/min IV to a total dose of 1 mg	Reversal of respiratory depression	Limit use to reversal of inadequate respiration in benzodiazepine-toxic patients Increases intracranial pressure and risk for seizures in presence of underlying seizure disorder or ingestion of seizure-producing toxicants Monitor for resedation up to 2 hr after last dose
Folinate (tetrahydrofolic acid [leucovorin])	Methanol Methotrexate	Methanol: 50 mg IV q4h Methotrexate: 100 mg/m^2 IV q3-6h	Methanol: methanol undetectable, metabolic acidosis cleared Methotrexate: serum level <1 × 10^{-8} mol/L	Essential therapy for both toxicants Methotrexate: large ingestions may require increased dose Glucarpidase administered 2-4 hr before or after folinate
Fomepizole	Ethylene glycol Methanol	Dose 1: 15 mg/kg IV Doses over next 48 hr: 10 mg/kg IV All subsequent doses: 15 mg/kg IV Administer q12h, except when HD performed: HD initiation: ½ next dose if >6 hr since last dose HD ongoing: q4h End of HD (based on time of last dose): <1 hr, no dose; 1-3 hr, ½ next dose; >3 hr, next dose	For both: serum level <20 mg/dL and metabolic acidosis resolved	Start immediately if toxic alcohol suspected, without waiting for confirmatory levels Dose amount is not affected by interval timing of doses
Glucagon	β-Adrenergic receptor antagonists Calcium-channel antagonists	Bolus of 3.5-5 mg IV; can repeat to achieve clinical effect, then infusion of 2-10 mg/hr	Reversal of hypotension and bradycardia; taper infusion	Can precipitate vomiting; be prepared to protect airway Mild hyperglycemia occurs Maximum dosing amounts unknown; bolus doses up to 30 mg reported Duration of effect is 15 min; thus infusion must be started immediately
Hydroxocobalamin	Cyanide	Initial: 5 g IV over 15-min period Second dose: 5 g IV over 15 min-2 hr; maximum total dose is 10 g Follow each hydroxocobalamin dose with sodium thiosulfate 25%: 50 mL (12.5 g) IV over 10-min period	Resolution of lactic acidosis and moderate to severe clinical signs and symptoms: seizures, coma, dyspnea, apnea, hypotension, bradycardia	Can be administered IV push if patient is in cardiac arrest Do not give hydroxocobalamin and sodium thiosulfate through the same IV line Adverse effects: red discoloration of plasma, urine, mucous membranes, skin; transient hypertension Interference with laboratory colorometric assays: Levels increased: bilirubin; creatinine; glucose; hemoglobin; magnesium; co-oximetry total Hb, COHb%, MetHb% Levels decreased: AST, ALT, creatinine, co-oximetry O_2Hb%

TABLE 110-6 ANTIDOTES AND INDICATIONS FOR USE—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Hyperbaric oxygen (HBO)	Carbon monoxide Experimental: carbon tetrachloride, cyanide, hydrogen sulfide	3.0 atm pressure for 60 min (25 min O_2, 5 min air, 25 min O_2, 5 min air), then 2.0 atm for 65 min (30 min O_2, 5 min air, 30 min O_2), then "surface" to 1.0 atm	One treatment Second treatment rarely administered (controversial)	Carbon monoxide: treatment protocols may vary HBO indicated for loss of consciousness; seizures; cerebellar dysfunction; impaired cognition; headache, nausea/vomiting persisting after 4 hr O_2 therapy regardless of carboxyhemoglobin level Experimental indications: treatment protocols not established
Insulin-glucose	Calcium-channel antagonists β-Adrenergic receptor antagonists	Regular insulin, 1 U/kg bolus, followed by 0.5-1 U/kg/hr Titrate 50% dextrose IV to avoid hypoglycemia	Reversal of myocardial depression	Beneficial in case series and reports Initiate if glucagon and vasopressor or inotropic drugs fail to reverse myocardial depression; more effective if used before onset of cardiogenic shock Monitor glucose and potassium; hypoglycemia can occur during and after therapy Hyperglycemia results from toxicant-induced insulin resistance, and initial dextrose requirements may be less than anticipated. Recovery may be heralded by normalization of glucose levels, with increased dextrose required to avoid hypoglycemia
Intralipid	Cardiac toxicity from local anesthetics (e.g., bupivacaine, ropivacaine) Experimental: verapamil, diltiazem, tricyclic antidepressants, bupropion, propranolol	Use 20% formulation Initial bolus: 1.5 mL/kg IV over 1 min, followed immediately by infusion of 0.25 mL/kg/min for 30-60 min Can repeat bolus for asystole	Return of hemodynamic stability	Use based on animal experiments and human case reports; numerous dosing regimens have been used Use if advanced life support measures fail; continue CPR as needed during drug administration
Methylene blue	Methemoglobin-producing agents	1-2 mg/kg body weight (0.1-0.2 mL/kg) of 1% methylene blue is administered over 5-min period; repeat dose for persistent or recurrent symptoms or signs	Resolution of dyspnea and altered mental status	Use if patient is symptomatic (i.e., dyspneic, altered mental status) Maximum dose should not exceed 7 mg/kg (0.7 mL/kg) Contraindicated in G6PD-deficient patients; may cause hemolysis Some toxicants (e.g., dapsone) may require prolonged therapy
N-acetylcysteine (NAC)	Acetaminophen Experimental: carbon tetrachloride, chloroform, pennyroyal oil	Oral: Load—140 mg/kg Maintenance (starting 4 hr after load)—70 mg/kg q4h IV: Load—150 mg/kg over 1-hr period Maintenance infusion—12.5 mg/kg over 4-hr period, then 6.25 mg/kg per hour as continuous infusion	Administer 24 hr of NAC and repeat AST and APAP levels: if AST normal and APAP not detected, stop NAC; if AST normal and APAP detected, continue NAC for 12 hr, then reassess AST and APAP levels; if AST elevated, continue NAC for total of 72 hr of therapy After 72 hr of therapy, if INR <2.0, stop NAC After patient has received 72 hr of therapy, if INR ≥2.0 or severe hepatotoxicity present, continue NAC until INR <2.0	Most effective if initiated within 8 hr after ingestion; may be started any time after ingestion and is beneficial in severe hepatotoxic states Use IV in patients unable to tolerate PO or with severe hepatotoxicity; the dose and timing differ from the oral regimen Dosage and administration of FDA-approved IV formulation assumes early treatment of acute overdose without hepatotoxicity; longer duration of treatment required in patients with hepatotoxicity Treatment end points simplified for ease of use INR result not valid indicator if FFP recently administered
Naloxone	Opioids	Bolus: 0.4-2 mg via IV, sublingual injection, or endotracheal instillation; 0.4-0.8 mg SC Continuous infusion: establish bolus dose required to reverse respiratory depression Begin infusing two thirds of reversal dose every hour, and titrate to maintain adequate respirations Rebolus with half of reversal dose 15 min after reversing respiratory depression	Initial: reversal of respiratory depression with resolution of hypoxia and hypercapnia Final: resolution of CNS and respiratory depression	Preventilate patients with respiratory depression by bag-valve mask or intubation before administration Use smaller doses in opioid-dependent patients; some opioids (e.g., propoxyphene, pentazocine, fentanyls) may require larger doses of naloxone; use continuous infusion for recurrent symptoms and prolonged action of some formulations (e.g., sustained-release morphine, methadone) Resedation can occur Do not use nalmefene or naltrexone to reverse acute toxicity
Octreotide	Sulfonylureas	50 mg SC q6h	Resolution of hypoglycemia and dextrose not required	Maintain dextrose infusion as needed

TABLE 110-6 ANTIDOTES AND INDICATIONS FOR USE—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Physostigmine	Anticholinergic agents (e.g., diphenhydramine, jimsonweed [*Datura* sp], scopolamine)	1-2 mg IV over 5-min period; can repeat once after 10-15 min if no effect	Reversal of anticholinergic effects	Duration of effect is 60-90 min Benzodiazepine used for subsequent treatment of agitation and seizures; additional physostigmine used rarely (e.g., refractory seizures or agitation) Adverse effects include seizures, excessive oral secretions, bradyarrhythmias; contraindicated in cyclic antidepressant toxicity
Pralidoxime chloride	Organophosphorus compounds Nerve agents—sarin, VX	30 mg/kg IV bolus (max 2 g) over 30 min, followed by continuous infusion of 8-10 mg/kg/hr (max 650 mg/hr)	Resolution of signs and symptoms, atropine no longer required	Can give initial dose over 2-min period for life-threatening clinical effects Administer early when diagnosis known or strongly suspected Efficacy variable, depending on the organophosphate Fat-soluble organophosphates may require prolonged treatment
Pyridoxine	Ethylene glycol (theoretical efficacy) Isoniazid Monomethylhydrazine mushrooms	100 mg IV 5 g IV, repeat for refractory seizures	One dose Resolution of seizures	Efficacy theoretical Pyridoxine may stop seizures, but patient can remain comatose (isoniazid, mushrooms); use benzodiazepines and phenobarbital concomitantly to manage seizures Excessive dosing can cause neuropathy
Sodium bicarbonate ($NaHCO_3$)	Reversal of myocardial sodium-channel blockers (e.g., cyclic antidepressants, cocaine, propoxyphene, sodium-channel-blocking antiarrhythmics with $\tau_{recovery}$ >1 sec, piperidine phenothiazines (thioridazine, mesoridazine)	1-2 mEq $NaHCO_3$/kg via intermittent bolus; repeat as needed	Narrowing of prolonged QRS, resolution of ventricular arrhythmias, reversal of hypotension	Monitor blood pH (optimal pH approximately 7.50); avoid pH > 7.55
	Altered tissue distribution or enhanced elimination of salicylates; may be used in chlorophenoxy herbicides, chlorpropamide, formic acid, methotrexate, phenobarbital	1-2 mEq $NaHCO_3$/kg, followed by 3 ampules (150 mL) $NaHCO_3$ (44 mEq per 50 mL) in 850 mL of D_5W, infused at 2-3 times normal maintenance fluid rate	Serum salicylate <30 mg/dL and patient clinically stable	Monitor urinary pH hourly; adjust infusion to maintain urine pH of 7.5-8.0 (avoid blood pH >7.55) Monitor ABGs Maintain normokalemia
Succimer (DMSA)	Arsenic Lead Mercury, all forms	10 mg/kg/dose q8h for 5 days, followed by q12h for 14 days Drug holiday for 2 wk; repeat if treatment end point not reached	Arsenic: 24-hr urinary arsenic <50 µg/L Lead: resolution of encephalopathy, gastrointestinal symptoms, neuropathy, nephropathy, arthralgias, myalgias, and blood lead level <70 µg/dL Mercury, elemental and inorganic: 24-hr urinary mercury <20 µg/L Mercury, organic: end point not well established	Oral chelator; adverse effects include rash, transient AST and alkaline phosphatase elevations, and gastrointestinal distress; minimal chelation of essential metals occurs Dosing for arsenic and mercury not well established Therapeutic end point for organic mercury not established; neurotoxicity not responsive to chelation therapy; suggest chelation until blood mercury level within normal value range for reference laboratory
Vitamin K	Anticoagulants (e.g., warfarin, long-acting anticoagulant rodenticides [LAARs])	Subcutaneous: AquaMEPHYTON (K_1), 10-25 mg, repeat every 6-12 hr until oral vitamin K_1 started Oral: 25-50 mg q6h; larger doses may be required	INR is normal 48-72 hr after stopping vitamin K_1 therapy Can also monitor factor VII activity	Anaphylactoid reaction can occur with IV administration Severe bleeding may also require FFP or factor concentrates Base decision to treat on finding of elevated INR; do not administer prophylactic vitamin K_1 Oral therapy has been required for months with LAAR poisoning because of lipophilicity of toxicant, with slow body clearance

*Dose concentrations and infusion times are not given. Drug dosages may require adjustment in patients with renal or hepatic failure.
†Administer antivenom in a monitored setting; antivenom must be reconstituted and then diluted; initially infuse at a rate of 2 to 5 mL/hr, and double the infusion rate every 5 minutes as tolerated to administer antivenom over a 1-hour period.
‡Ten percent calcium chloride solution = 100 mg/mL (27.2 mg/mL elemental calcium); 10% calcium gluconate solution = 100 mg/mL (9 mg/mL elemental calcium).
ABG = arterial blood gas; ALT = alanine aminotransferase; APAP = acetyl-para-aminophenol (acetaminophen); AST = aspartate aminotransferase; BAL = British antilewisite; bpm, beats per minute; CNS = central nervous system; COHb% = percent carboxyhemoglobin; CPR, cardiopulmonary resuscitation; D_5W = 5% dextrose in water; DMSA = 2,3-dimercaptosuccinic acid; ECG = electrocardiogram; FDA = Food and Drug Administration; FFP = fresh-frozen plasma; G6PD = glucose-6-phosphate dehydrogenase; Hb = hemoglobin; HD = hemodialysis; IM = intramuscular; INR = international normalized ratio; IV = intravenous; MetHb% = percent methemoglobinemia; NS = normal saline; PO = per os (by mouth); SC = subcutaneous; ; $\tau_{recovery}$ = drug blockade recovery rate.

TABLE 110-7 COMMON TOXICANTS REMOVED BY HEMODIALYSIS

TOXICANT	INDICATIONS	COMMENTS
Ethylene glycol	Serum level ≥50 mL/dL, or lower levels with concomitant metabolic acidosis and evidence of end-organ toxicity	May not be required in a patient with normal creatinine clearance and acid-base status who is receiving fomepizole
Lithium*	Clinical indications	Clinical indication is CNS toxicity (e.g., decreased mental status, ataxia, coma, seizures) Use dialysate containing bicarbonate to decrease Na^+/K^+ antiporter intracellular sequestration of lithium
Methanol	Serum level ≥50 mL/dL, or lower levels with concomitant metabolic acidosis and evidence of end-organ toxicity	Usually required because of slow elimination half-life in presence of fomepizole (mean, 52 hr; range, 22-87 hr), even in patients with no metabolic acidosis or evidence of end-organ toxicity
Phenobarbital	Clinical indications	Rarely necessary except when a patient is hemodynamically unstable despite aggressive support
Salicylates	Acute toxicity: serum level ≥100 mL/dL or <100 mg/dL in the presence of a clinical indication Chronic toxicity: any clinical indication	Serum protein binding decreases with increasing toxic levels, increasing the amount of free salicylate available for HD removal; clinical indications are one or more of the following: altered mental status, seizures, pulmonary edema, intractable acidosis, renal failure
Theophylline	Acute toxicity: serum level ≥90 µg/mL or <90 µg/mL plus any clinical indication Chronic toxicity: serum level ≥40 µg/dL and not declining despite MDAC; any clinical indication	Clinical indications for HD: seizures, hypotension, ventricular arrhythmias
Valproic acid	Severe intoxication with serum concentration >850 mg/L	Clinical indications include hepatic dysfunction; coma, especially with hyperammonemia; deteriorating clinical status despite aggressive support

*Hemodiafiltration removes lithium; the clinical benefit of this technique is unknown.
CNS = central nervous system; HD = hemodialysis; MDAC = multidose activated charcoal.

dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol. Whether enhanced elimination translates into decreased morbidity and mortality has not been examined in controlled clinical trials. The usual recommendations are an average dose of 12.5 g of activated charcoal (after the initial dose) administered every 1, 2, or 4 to 6 hours after the previous dose. The contraindications to single-dose activated charcoal also apply to multidose activated charcoal. Reported complications include pulmonary aspiration, bowel obstruction, and fluid and electrolyte imbalance from multiple doses of a simultaneously administered cathartic.

Urinary Alkalinization

Alkalinization of the urine, which increases the renal elimination of weak acids, is used primarily to enhance the elimination of salicylates, but the elimination of chlorpropamide, 2,4-dichlorophenoxyacetic acid, formic acid, methotrexate, and phenobarbital may be increased with this method. Urinary alkalinization is accomplished by an intravenous bolus of 1 to 2 mEq of sodium bicarbonate per kilogram body weight, followed by three ampules (150 mL) of sodium bicarbonate (44 mEq/50 mL) in 850 mL of 5% dextrose in water infused at two to three times the normal maintenance fluid rate. Urinary pH should be checked hourly, and the infusion should be adjusted to maintain a urine pH of 7.5 to 8.0. Potassium should be administered simultaneously to avoid hypokalemia, which would result in urinary acidification because the distal tubule excretes hydrogen ion in exchange for potassium (Chapter 112). Serum pH should be monitored to avoid excessive alkalemia. Contraindications to this therapy include volume overload and cerebral or pulmonary edema. Urinary acidification is no longer recommended to enhance the elimination of weak bases, such as amphetamines, because of the danger of precipitating tubular myoglobin in patients with rhabdomyolysis.

Extracorporeal Removal

Extracorporeal techniques enhance the elimination of a few drugs and toxicants that exhibit single-compartment kinetics, a volume of distribution less than 1 L/kg, and endogenous clearance of less than 4 mL/minute/kg (Table 110-7). For hemodialysis, the toxicant must be water soluble, have a molecular weight less than 500 D, and exhibit low protein binding. For hemoperfusion, the toxicant must adsorb to activated charcoal. For continuous renal replacement therapy, the toxicant must have a molecular weight less than the permeability limit of the filter membrane. Rarely, extracorporeal removal has been used for aminoglycosides, atenolol, bromide, carbamazepine, diethylene glycol, isopropanol, magnesium, metformin, methotrexate, *N*-acetylprocainamide, phenobarbital, procainamide, sotalol, and trichloroethanol (chloral hydrate).

PROGNOSIS

Almost all patients who reach the hospital alive survive with appropriate care. Inpatient mortality rates are 0.2 to 0.5%.

ELECTRIC INJURY

BASIL A. PRUITT JR.

ELECTRIC CURRENT INJURY

DEFINITION

The tissue damage caused by electric current ranges from a transient increase in cell membrane permeability to immediate coagulation necrosis of large volumes of tissue. The clinical consequences include disturbances in the physiologic electrical conduction systems, which may cause cardiopulmonary arrest; tetanic muscle contractions, with resulting compression fractures of vertebrae; and delayed tissue damage, such as cataract formation.

EPIDEMIOLOGY

As the use of electricity has increased worldwide, the number of electric injuries has increased. The precise incidence of electric injury is unknown,

but the National Centers for Health and Centers for Disease Control and Prevention have estimated that each year in the United States there are 52,000 trauma admissions for electric injuries. During a recent 86-month period, 5.3% of patients admitted to the U.S. Army Burn Center had an electric injury; at other burn centers, the percentage of admissions related to electric injury ranges from 0.04 to 6.7% in developed countries and as high as 32 to 42% in developing countries.

PATHOBIOLOGY

Environmental conditions, duration of contact, pathway of the current, type of current (and, if alternating current, its frequency), and voltage all influence the effects of electricity on tissue. Voltage greater than 40 is potentially dangerous, and the likelihood of sudden death and remote tissue injury increases as voltage increases to 1000. Voltages greater than 1000 are considered to be high tension and are associated with immediate severe tissue damage. Alternating current is more dangerous than direct current because of its likelihood to produce cardiac arrest or cessation of respiration and its tetanic effect, which may prevent the patient from breaking contact with the source of electricity. As the frequency of alternating current increases to greater than 60 cycles per second, tissue injury decreases. The path of the current through the body between the points of contact is important in determining tissue damage; a course through the heart or the respiratory center of the brain is especially dangerous. Ventricular fibrillation can be produced by current flow of only 100 mA from a hand to the feet. Rapid separation from the source of electricity is crucial, because tissue damage increases in proportion to the duration of contact. Resistance to current flow at the point of contact is influenced by environmental conditions; dry and thickened palmar or plantar skin is more resistant to the passage of current than is skin moistened by perspiration or other liquid.

Heat is the principal mediator of tissue damage in electric injury, the severity of which is related to voltage and duration of contact. Tissue-specific differences in resistance to the flow of current (neural tissue least; blood vessels, muscle, and skin intermediate; bone greatest) may explain differences in tissue injury caused by low-voltage current. Because all body tissues and fluids are conductive, the soft tissues between bone and skin can be viewed as a volume conductor. Heat is produced in tissues as a function of voltage drop and current flow per unit of cross-sectional area (i.e., density of the current). The inverse relationship between the density of the current and the tissue's cross-sectional area accounts for the frequency of severe injury to the digits and extremities and the rarity of major injury to the trunk in patients with high-tension electric injury (Fig. 111-1). Contact with less than 1000 V causes injuries that are self-limited because at the contact points, where the density of the current is greatest, the skin is severely injured and chars, which results in a rapid increase in resistance and reduction in the passage of current. When the source is greater than 1000 V, arcing is so intense that tissue destruction is increased markedly as relatively constant levels of current are maintained. Arcing, which may occur across the flexor surfaces of joints, can char the skin in these areas and ignite the patient's clothing. After cessation of the flow of current, the heated tissue acts like a volume radiator and cools unevenly, with the superficial portions cooling more rapidly than the deeper portions; deeper tissues are therefore more prone to severe injury.

Tissue damage can also be caused by low-voltage direct current (e.g., contact with automobile battery terminals or with defective or inappropriately used medical equipment, such as electrosurgical devices, external pacing devices, or defibrillators). Direct-current injuries are reportedly common during laparoscopy with high-voltage coagulation.

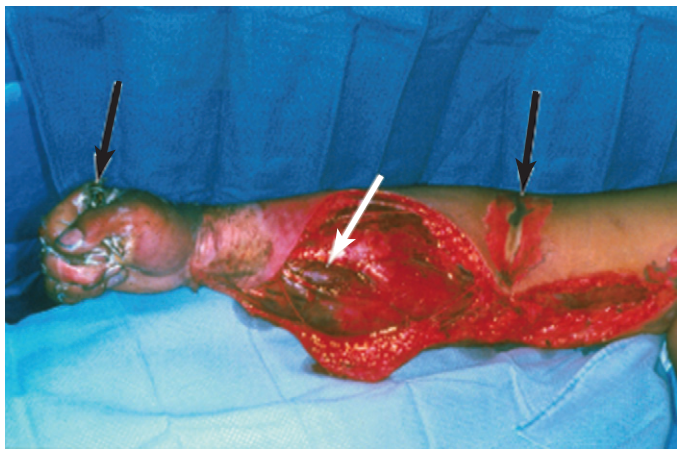

FIGURE 111-1. Charring at the contact site in the first web space and at the site of arcing in the antecubital space *(black arrows)* of a victim of electric injury. The fixed flexion deformity of the thumb and other digits is characteristic of severe high-voltage injury to the hand and forearm. The severity of the injury is indicated by the marked edema of the forearm muscles, bulging above the cut edges of the fasciotomy incision, and by the patchy dark discoloration of the muscles of the arm and the forearm, particularly the deeper muscle exposed in the central portion of the forearm incision *(white arrow)*.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cardiopulmonary arrest can be caused by low-voltage electric injury but is more common with high-voltage electric injury. Extensive tissue necrosis may also liberate enough potassium to cause cardiac dysfunction. Because cardiac arrhythmias may recur after resuscitation or develop 24 to 48 hours after injury, all patients who have sustained high-voltage electric injury should undergo continuous electrocardiogram (ECG) monitoring for at least 48 hours after the last ECG-documented arrhythmia. Early imaging of the heart with technetium-99m tetrofosmin has been proposed as a means of detecting myocardial perfusion defects requiring cardiac monitoring and predicting the possibility of long-term cardiac effects. Renal failure may occur in patients with high-voltage electric injury if inapparent deep tissue injury with accompanying occult edema results in an underestimation of fluid requirements, inadequate resuscitation, and oliguria. Additionally, the destruction of muscle and red blood cells liberates hemochromes, which may precipitate in the renal tubules unless adequate urinary output is maintained (Chapter 122).

Muscle Damage

High-voltage electric injury commonly causes edema beneath the investing fascia of the involved muscle compartments, thereby compromising nutrient blood flow to muscles within the compartments and to distal unburned tissue. Clinical indications for the surgical release of intracompartmental pressure by fasciotomy and surgical exploration of a limb include impaired capillary refilling of distal unburned skin or nails, cyanosis of distal unburned skin, stony hardness of a muscle compartment on palpation, and diminished or absent pulsatile flow in the distal arteries as assessed by Doppler ultrasound. Tissue pressures 30 mm Hg or higher above atmospheric pressure, as measured by a catheter placed in the compartment, indicate the need for immediate decompression. If clinical signs are consistent with deep tissue injury but large-vessel pulses are intact, arteriography can determine the need for operative intervention, including amputation of the affected limb. "Pruning" of the arterial tree, with a decrease in the density of nutrient branches in the muscles of an involved limb, identifies the level of amputation required to remove muscle that has been irreversibly damaged. Muscle blood flow of 1 mL/minute/100 g of tissue, as determined by xenon-133 "washout," has been proposed as the minimum level required for ultimate tissue viability. In patients with high-voltage electric injury, myoglobinemia and elevation of serum creatine phosphokinase reflect significant muscle damage, and myoglobinuria is a strong predictor of the need for fasciotomy in the first 24 hours after injury.

Neurologic Examination

On admission and at scheduled intervals thereafter, a detailed neurologic examination must be performed on all patients with high-voltage electric injury; all nerve deficits should be documented fully. Central nervous system or peripheral nerve dysfunction may be apparent immediately after electric injury or may appear later. Recovery of function after direct electrical nerve damage is rare. Conversely, the spontaneous resolution of immediate and early functional deficits of nerves not injured directly (motor nerves are more sensitive to nondestructive injury than are sensory nerves) is common. A polyneuritic syndrome of relatively late onset can cause deficits in the function of peripheral nerves far removed from the points of contact. Direct nerve damage of the spinal cord causes immediate deficits, which are more likely to be transient than are deficits with a later onset. Delayed-onset spinal cord deficits can manifest as quadriplegia, hemiplegia, localized nerve deficits with signs of ascending paralysis, transverse myelitis, and even an amyotrophic lateral sclerosis–like syndrome. The cause of delayed paresthesias and nerve dysfunction after electric injury is unknown, but an increase in permeability of the cell membrane and an associated loss of cell contents induced by exposure to a millivoltage electric field (electroporation) have been implicated. Children have greater improvement in neurologic function than adults do, owing to their greater neurologic plasticity. Children with electric injuries

that cause full-thickness destruction of the calvaria may have direct brain injury, with affective and/or cognitive difficulties that can persist for a year or longer.

Remote Organ Injury

Direct liver injury, focal pancreatic and gallbladder necrosis, and intestinal perforation have been reported after electric injury, but all are uncommon. Delayed hemorrhage from moderate to large blood vessels has been ascribed to an arteritis caused by the electric injury, but this hemorrhage seems to be related to inadequate débridement of injured tissue or to vascular wall necrosis as a consequence of exposure after débridement.

Compression fractures of vertebral bodies may be produced by tetanic contractions of the paraspinous muscles. Fractures of the skull and the long bones of both the upper and lower extremities may be caused by falls after the electric shock.

TREATMENT

Rx

Cardiopulmonary arrest must be treated by immediate institution of cardiopulmonary resuscitation (Chapter 63). In patients with high urinary hemochrome concentrations, a urinary output of 75 to 100 mL/hour should be maintained (Chapter 115). If the hemochromes do not clear promptly or the patient remains oliguric despite the administration of resuscitation fluids at more than twice the required rate, as estimated based on the extent of the burn and the patient's weight (Chapter 112), 25 g of mannitol should be given as an intravenous bolus, and 12.5 g of mannitol should be added to each liter of intravenous fluid until the pigment has cleared from the urine. Hyperkalemia is treated as in any other patient (Chapter 119).

If the electric injury is limited to the skin and subcutaneous tissue, an antibacterial cream such as Sulfamylon should be applied twice daily to the burned tissue until débridement is performed. The antimicrobial (mafenide acetate) in Sulfamylon readily diffuses into the nonviable tissue to limit microbial proliferation. As soon as resuscitation has restored hemodynamic stability, severely damaged limbs or other areas of tissue necrosis should be surgically explored. The viability of vital structures and the extent of deep tissue damage are assessed to determine the need for amputation. If amputation is not required, all necrotic tissue is débrided to eliminate the source of hyperkalemia and reduce the risk for infection. It is imperative to examine the periosseous muscles, which may be necrotic because of delayed heat dissipation but overlain by more superficial viable muscles. After débridement or amputation, the operative wound is dressed but not surgically closed, and the patient is scheduled for re-exploration of the wound 24 to 72 hours later. At that time, residual necrotic tissue is débrided, and the wound is closed by skin grafts, tissue transfer, or biologic dressings, depending on the condition, extent, and site of the wound. An exception to early excision of questionably viable tissue is the conservative removal of only obviously necrotic tissue from low-voltage oral commissure wounds that result from a child's biting or sucking on exposed wires or house current outlets (Fig. 111-2).

PROGNOSIS

Cardiopulmonary and fluid resuscitation combined with monitoring of limb tissue pressure and wound care have maximized tissue salvage, reduced renal failure, and increased the survival of patients with electric injuries. Overall, current treatment is associated with a 96% survival rate.

Among the patients with serious high-voltage electric injuries hospitalized at the U.S. Army Burn Center over the past decade or so, about 8% died and another 22% had permanent neurologic deficits at discharge. High-voltage electric injury has been associated with the subsequent formation of cataracts, most frequently when the contact site was on the head or neck. Cataracts may form rapidly, but they more commonly develop 3 years or more after the injury. Rarely, exfoliative debris may be evident in the anterior chamber of the eye immediately after injury. Cholelithiasis and gastrointestinal dysfunction have been reported after high-voltage injury, but they appear to be rare.

Most patients with low-voltage injuries, many caused by electric flash burns, develop long-term sequelae. The neurologic symptoms (memory loss, numbness, headache, chronic pain, weakness), psychological symptoms (depression, insomnia, post-traumatic stress syndrome, nightmares, anxiety), and musculoskeletal symptoms (pain, reduced range of motion, contracture) often have a delayed onset (1.6 to 29.5 months), persist on average for 300 days after injury, and limit return to work in more than 40% of patients.

LIGHTNING INJURY

An estimated 300 to 350 persons are struck by lightning each year, and about 30% of them die. The duration of a lightning bolt is $\frac{1}{100}$ to $\frac{1}{1000}$ of a second, but it may have a voltage of approximately 1 billion V and induce currents ranging from 12,000 to 200,000 A. The temperature in a lightning bolt, which may be 30,000 K, dissipates in a few microseconds.

CLINICAL MANIFESTATIONS

Cardiopulmonary arrest, which can be secondary to either asystole or ventricular fibrillation, is common in patients struck by lightning. Cardiopulmonary resuscitation (Chapter 63) must be instituted immediately; recovery has been reported in some patients who were apparently without life signs for 15 minutes or longer. Although signs of acute myocardial damage may become evident later, persistent or recurrent ECG abnormalities are uncommon. Coma is common immediately after injury and typically resolves in a few hours. Abdominal signs of peritonitis with free air in the peritoneal cavity should alert one to the possibility of intestinal perforation, which must be treated by prompt primary closure. Keraunoparalysis (lightning paralysis), which is characterized by paresthesias and paralysis, usually involves the lower limbs, often develops over a period of several days after lightning injury, is typically associated with vasomotor disorders, and is usually transient. Myoglobinuria is uncommon; when present, it is treated as described earlier for other electric injuries. Tympanic membrane rupture and hearing loss may

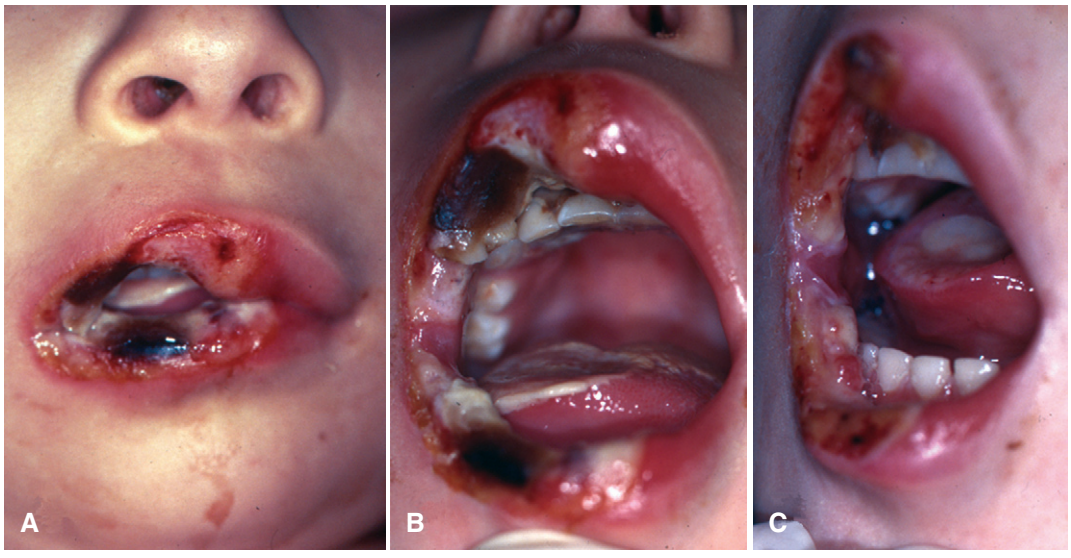

FIGURE 111-2. **A,** This child sustained a potentially disfiguring injury by biting on wires carrying house current. **B,** Note the extent of the injury, with black areas of necrotic tissue on each lip and the white plaque of nonviable tissue on the upper surface of the tongue. **C,** Spontaneous separation and removal of only unequivocally dead tissue minimizes disfigurement and reduces the magnitude of surgical reconstruction required to restore lip function.

FIGURE 111-3. The arborescent current markings on the face, neck, and anterior trunk of this young patient, which are characteristic of lightning injury, healed without the need for grafting. Note the focal lesions on the right arm, indicating the spread of the current that produced the marks on the right anterolateral aspect of the chest wall.

also be caused by lightning injury. Cutaneous burns of the trunk and proximal areas of the limbs caused by lightning injury, called *Lichtenberg figures*, typically have a "splashed on" arborescent and spidery appearance and are generally superficial (Fig. 111-3). Small, circular, full-thickness burns of the tips of the toes are also common and have been termed the *tiptoe sign*. Mottling of the skin and other signs of vasoconstriction previously considered specific to lightning injury generally resolve with adequate resuscitation.

TREATMENT AND PROGNOSIS

Rx

Current treatment, which emphasizes immediate cardiopulmonary resuscitation, has decreased mortality significantly, and two thirds of lightning-injured patients now survive. Persistent nerve deficits and long-term problems are relatively uncommon in survivors. However, Guillain-Barré syndrome, with neurologic deficits persisting beyond hospital discharge, has been reported.

MEDICAL ASPECTS OF TRAUMA AND BURN CARE

ROBERT H. DEMLING AND JONATHAN D. GATES

MEDICAL ASPECTS OF TRAUMA

EPIDEMIOLOGY

Trauma is the third leading cause of death in people of all ages in the United States, surpassed only by cancer and atherosclerosis. Trauma is the leading cause of death in children, adolescents, and young adults aged 1 to 44 years.

More than 140,000 deaths and twice as many permanent disabilities occur annually in the United States from injuries. Fatal injuries have a trimodal distribution. Half of all fatalities occur within minutes of the injury as a result of massive hemorrhage from the heart, lacerations of large blood vessels, or catastrophic neurologic injury. In such cases, there is insufficient time for medical intervention to alter the outcome; the only method to reduce this category of trauma-related morbidity and mortality is through prevention and education programs. Of the fatalities, 30% occur within a few hours after injury from airway obstruction, shock, or neurologic dysfunction. This interval represents an opportunity during which appropriate and timely medical or surgical intervention is most likely to influence outcome. Fatalities within this second peak occur as a result of epidural and subdural hematomas, chest injuries, liver lacerations, splenic rupture, pelvic fractures, or the accumulation of multiple injuries resulting in significant blood loss. The third peak of trauma fatalities is due to multisystem organ dysfunction or overwhelming infection weeks later. This delayed systemic response is related to the degree of the initial insult, the individual response to the injury, and the cumulative effect of any additional complications that arise after injury.

Motor vehicle crashes, firearms, and falls are major contributors to injury in the United States. In 2008, an estimated 2.35 million people were injured in motor vehicle traffic crashes, which resulted in approximately 38,000 fatalities. About 50% of all traffic deaths in 15- to 34-year-olds are alcohol related (Chapter 32). About 35,000 gun-related deaths, unintentional and intentional, occur annually. Of all injury deaths, 8% are related to falls, and fall from a height is responsible for one third of all injury-related hospitalizations.

PATHOBIOLOGY

Mechanism of Injury

Trauma produces a structural or physiologic alteration as a result of an external force, whether it is mechanical, chemical, electrical, or thermal energy. The force that initiated the motion of an object must be absorbed or dissipated in an effort to decelerate that object. When an automobile traveling at a given speed strikes an immobile object, a tremendous amount of energy in the moving vehicle is transmitted to the immobile object and the structure of the vehicle, deforming both until the automobile stops. These same forces are imparted to the occupants of the vehicle with potentially dire consequences. In a head-on impact, the driver continues to move forward until impeded by objects inside the automobile or until the energy is dissipated by the restraint of a seat belt or air bag. Deceleration forces are imparted to individual organs. These same physical principles apply to injury after a fall from a height. Compression, shear, and overpressure from these and other forces injure internal organs.

Penetrating injuries, which are described as either low velocity or high velocity, result from the kinetic energy of the missile. In the case of a bullet discharged from a gun, the tissue immediately contacted by the bullet is crushed to create a permanent cavity. Transfer of energy farther away from the bullet path creates a temporary cavity beyond the boundary of the permanent tract, the so-called blast effect. A simple stab wound from a knife or sharp object is considered a low-velocity injury in which the wound is confined to the tract itself. Virtually no temporary cavity is created, but the consequences may be just as devastating as a high-velocity injury if a vital structure is affected.

Pathophysiology of Injury

Shock (Chapter 106) results in inadequate organ perfusion and subsequent failure to deliver sufficient oxygen to maintain aerobic metabolism. Poor peripheral perfusion results in cellular hypoxia and slowing of oxidative phosphorylation, with the accumulation of H^+ ion in the extracellular fluid, resulting in metabolic acidosis. The initial step in managing shock associated with trauma is to recognize inadequate organ perfusion. The second step is to identify and treat the probable cause. The four general categories of shock in trauma are hemorrhagic, compressive, neurogenic, and cardiogenic; however, most shock is hypovolemic in nature. Adrenal insufficiency (Chapter 234), anaphylaxis (Chapter 261), and septic shock (Chapter 108) are less common but may occur during the recovery period. The goal of treatment is restoration of cellular and organ perfusion with adequately oxygenated blood volume.

Hemorrhagic Shock

Hemorrhagic shock results from a decline in cardiac filling pressure as blood is lost (Chapter 106). Cardiac output is preserved through compensatory

mechanisms when the loss of blood is about 10% of blood volume. Endogenous neurogenic and endocrine responses result in peripheral vasoconstriction and shunting of blood from the nonessential areas of skin, muscle, and abdominal viscera to maintain perfusion to the heart and brain. Cardiac output decreases with a blood volume loss of 20 to 40%, with a resultant decrease in systolic blood pressure. Additional compensatory mechanisms to maintain perfusion pressure in the face of a sudden decrease in intravascular volume result in a shift of proteins and fluids from the extracellular space to the intravascular compartment. The relative decrease in volume and increase in osmolarity of the extracellular space stimulate movement of fluid out of the cells to replace it.

It is imperative to identify a patient in shock or compensated shock. A normal systemic arterial blood pressure or absence of tachycardia may lead an inexperienced physician to believe that the patient is hemodynamically stable when in fact the patient may be in the precarious situation of partially compensated shock. A high index of suspicion and early aggressive diagnostic evaluation and treatment minimize the possibility that occult blood loss may be missed and lead to appropriate volume resuscitation and possible surgical correction.

Compressive Shock

Compressive shock arises when external compression of the lungs or heart from air, fluid, or blood either compromises diastolic filling of the right ventricle or prevents adequate ventilation and oxygenation. The two most notable forms of compressive shock are tension pneumothorax (Chapter 99) and pericardial tamponade (Chapter 77).

In tension pneumothorax, air within the pleural space impedes expansion of the ipsilateral lung and shifts the mediastinum. Compression of the inferior and superior vena cava leads to inadequate filling of the right atrium and ventricle, which decreases cardiac output. Identification of the injury is paramount; typical findings include absence of breath sounds in the ipsilateral chest, jugular venous distention, and tracheal deviation to the opposite side. Appropriate intervention involves release of air under tension in the pneumothorax by means of needle or tube thoracentesis.

Cardiac tamponade occurs because of extrinsic compression of the chambers of the heart from blood within the pericardial space, which is normally a potential space filled with less than 50 mL of pericardial fluid (Chapter 77). An external chest wound that penetrates the pericardium and the heart may create a rent in the pericardium too small to vent the accumulated blood; as a result, blood collects in the noncompliant pericardial sac, and pressure is directed inward toward the hollow chambers of the heart. The external compression inhibits diastolic filling of the chambers and reduces stroke volume. Pericardial tamponade should be suspected in patients who have wounds in the vicinity of the precordium and epigastrium, hypotension, tachycardia, jugular venous distention, and muffled heart sounds. Treatment is immediate evacuation of the pericardial space by needle pericardiocentesis, followed by sternotomy or left thoracotomy.

Neurogenic Shock

Complete injury to the cervical or upper thoracic spinal cord may result in sympathetic denervation manifested as loss of vasomotor tone in the periphery. Neurogenic shock should be considered in any trauma patient who is hypotensive but not actively bleeding. Only about 20% of patients with a complete high spinal cord injury have neurogenic shock, however, and patients with incomplete motor or sensory deficits (or both) rarely have hypotension directly caused by neurologic injury.

Cardiogenic Shock

Cardiogenic shock (Chapter 107) implies inadequate peripheral perfusion as a result of pump failure. It may be caused by arrhythmias, valvular dysfunction, or failing myocardial contraction. The latter may be seen with cardiac contusion or ischemic dysfunction of a previously damaged myocardium with marginal reserve.

DIAGNOSIS AND TREATMENT Rx

An organized approach to a trauma patient is mandatory to avoid confusion or missing life-threatening injury. A randomized trial found no benefit in advanced prehospital life support, whereby paramedics in the field perform endotracheal intubation and administer intravenous therapy, compared with basic prehospital life support and rapid transfer to a trauma center.■ The American College of Surgeons Advanced Trauma Life Support (ATLS) guidelines divide management into the primary survey for rapid diagnosis and treatment of life-threatening injuries and the secondary survey for a more complete, in-depth evaluation of the whole patient for definitive therapy.

The initial management of a trauma patient requires immediate intravenous access for volume resuscitation. The type and rapidity of solution delivered are determined by the patient's hemodynamic stability, as reflected by the degree of intravascular depletion or blood loss. Four classes of hemorrhage are widely accepted (Table 112-1). Intravenous access also allows the administration of analgesics, sedatives, and antibiotics. The rapidity of volume resuscitation with isotonic crystalloid and blood products is determined by the initial degree or class of shock. The guidelines are based on the "three-to-one" rule, which derives from the empirical observation that most patients in hemorrhagic shock require 300 mL of electrolyte solution for each 100 mL of blood loss because crystalloid equilibrates in the entire extracellular space.

More recently, the experience of the U.S. military had led to the concept of damage control resuscitation, which focuses on the strategy of transfusing blood products (red cells, plasma, and platelets) early and often in the exsanguinating patient while limiting the use of crystalloids to avoid hemodilution of coagulation products. Despite the absence of randomized trials, a 1:1 ratio of plasma and platelets to packed red blood cells appears to result in higher survival among patients with exsanguinating injury. Use of leukoreduced blood provides no advantage over standard blood products.■ Tranexamic acid (loading dose 1 g over 10 minutes then infusion of 1 g over 8 hours), which inhibits thrombolysis, beginning within 8 hours of injury reduces mortality by 9% in trauma patients who require blood transfusions.■

Primary Survey

The primary survey (airway, breathing, circulation) is the same whether the mechanism of injury was blunt, penetrating, or thermal. Evaluation of the airway is paramount. Supplemental oxygen is given to all trauma patients to maximize delivery of oxygen to the periphery. If the patient is hemodynamically unstable or is unable to maintain a patent airway because of mental status changes or airway debris, endotracheal intubation should be performed. There is little role for the use of oral airways or nasal trumpets in a trauma patient. Care must be taken to avoid movement of the cervical spine during intubation so that exacerbation of an undiagnosed cervical spine fracture or ligamentous disruption is avoided. Inability to perform endotracheal intubation in a trauma patient should lead to rapid surgical control of the airway by cricothyroidotomy. Tracheostomy is a poor second choice because

TABLE 112-1 CATEGORIZATION AND INITIAL TREATMENT OF HEMORRHAGIC SHOCK*

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (mL)	≤750	750-1500	1500-2000	≥2000
Blood loss (% of blood volume)	≤15	15-30	30-40	≥40
Pulse rate	<100	>100	>120	≥140
Blood pressure	Normal	Normal	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respiratory rate	14-20	20-30	30-40	>35
Urine output (mL/hr)	≥30	20-30	5-15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

*Based on a 70-kg adult.

it is more time-consuming and potentially bloody, especially if the landmarks are obscured by trauma.

The primary survey should observe the symmetry of chest wall movement, determine whether breath sounds are equal bilaterally and adequate, and assess the chest wall for crepitus, instability, or tenderness. If a tension pneumothorax or massive hemothorax is suspected (and the findings are not caused by intubation of the right mainstem bronchus), a large-bore chest tube is placed in the ipsilateral anterolateral fifth intercostal space. Chest tube insertion is diagnostic and therapeutic. Return of greater than 1500 mL of blood suggests a significant injury within the ipsilateral hemothorax; this magnitude of initial output or ongoing hourly blood loss of 200 to 250 mL through the chest tube may warrant urgent thoracic surgical exploration.

Adequacy of the circulation is determined clinically by noting the presence of carotid, radial, and femoral pulses. Brisk capillary refill, as elicited by transient compression of the nail bed, and a warm, well-perfused patient suggest good peripheral perfusion. A patient in extremis may have a barely palpable carotid pulse, mental status changes, and mottled, cold, clammy skin. During this evaluation, simultaneous insertion of short, large-caliber intravenous catheters into the antecubital veins is recommended for the initial administration of lactated Ringer's solution.

The primary survey should include an evaluation of neurologic function. The Glasgow Coma Scale (Chapter 406) grades the patient's eye movement, best motor response, and best verbal response on a scale from 1 to 5, with a total score of 15 indicating the best function. For patients with brain trauma (Chapter 406), resuscitation with a saline solution provides better outcomes than using albumin.

The patient should be assessed for all evidence of traumatic injury. This assessment should include an examination of the back with the patient log-rolled under cervical spine precautions.

Secondary Survey

The secondary survey is the head-to-toe physical examination of the patient to evaluate the airway, reassess the adequacy of breathing and circulation, and look for any injuries or underlying conditions that were not immediately apparent during the primary survey. At this stage, pertinent radiographs, blood tests, and other tests (e.g., an electrocardiogram) are obtained, and a Foley catheter can be inserted if needed.

Head and Neck

Evaluation of neurologic function should determine whether there is evidence of closed head injury (Chapter 406). Physical examination should assess for skull and facial fractures and eye and ear injuries. The physician should have a low threshold for performing computed tomography (CT) of the head, which is preferred over magnetic resonance imaging in this situation.

The management of neck injuries that penetrate the platysma is dependent on the anatomic level of injury. The neck is divided into threes zones. Zone I injury, including the thoracic inlet up to the level of the cricothyroid membrane, is treated as an upper thoracic injury. In a stable patient, injuries in zone I require an arteriogram or CT angiography to define the injury and plan the surgical approach; hemodynamically unstable patients should undergo immediate surgical exploration.

Zone III injury, from the angle of the mandible to the base of the skull, is treated as a head injury. Most patients with injuries in this region are hemodynamically stable. Arteriography, bronchoscopy, esophagoscopy, and sometimes direct laryngoscopy should be performed to evaluate the type and extent of injury.

Zone II injuries, which are in the most exposed area of the neck between the other two zones, must be evaluated locally to determine whether the platysma muscle has been penetrated. Both selective operative management and mandatory exploration of penetrating injuries to zone II of the neck appear to be equally justified and safe. Selective operative management of a patient with penetrating wounds deep to the platysma requires nonoperative evaluation with arteriography and diagnostic upper endoscopy and bronchoscopy, with operative intervention reserved for situations in which the evaluation reveals pathology. Spiral CT with intravenous contrast material can define arterial injuries and has replaced angiography except where CT cannot define the arterial anatomy. Hemodynamically unstable patients should be resuscitated and explored surgically without further testing.

Chest

Life-threatening injuries of the chest include tension pneumothorax, massive hemothorax, cardiac tamponade (see earlier), flail chest, open pneumothorax, and disruption of the thoracic aorta. Flail chest implies an unstable segment of the chest wall as a result of multiple rib fractures. The negative pleural pressure required for inspiration pulls the unstable segment of the chest wall inward while the remainder of the chest moves in the opposite direction. An open pneumothorax implies air entering the pleural space through an external chest wound. The wound should be covered with a partially occlusive dressing, and a chest tube should be inserted to prevent the accumulation of air and the development of tension pneumothorax. Large open chest wounds require endotracheal intubation, operative débridement, chest tube drainage, chest wall stabilization, and closure. Although not usually considered life-threatening, there are a myriad of chest injuries, including simple pneumothorax, pulmonary contusions (Fig. 112-1), rib fractures, and minor to moderate hemothorax, that may play a major role in the duration of lung dysfunction or the need for ventilatory support, or both.

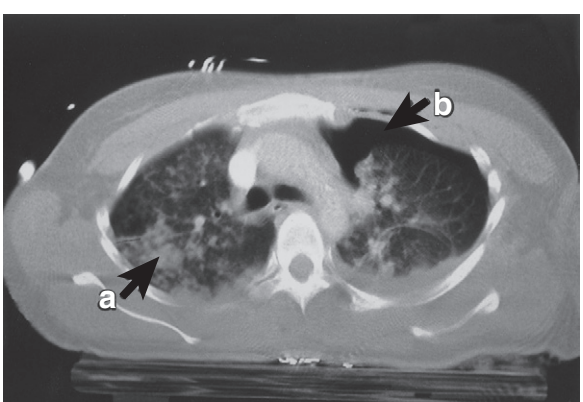

FIGURE 112-1. Chest evaluation. A chest computed tomographic scan shows bilateral pulmonary contusions *(arrow a)* and effusions with a small pneumothorax on the left *(arrow b)*.

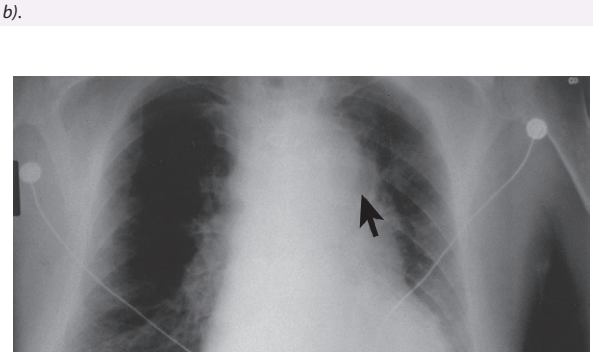

FIGURE 112-2. Widened superior mediastinum on an upright chest radiograph. Note the loss of normal contour of the aortic knob *(arrow)*.

All trauma patients should have a supine chest radiograph taken to examine the lung fields, the mediastinal contour, and the chest wall. Thoracic aortic injury, which is a feared complication of severe acceleration-deceleration injury, results in the immediate death of 90% of persons with this injury. Survivors who reach medical care often have a contained mediastinal hematoma that appears as a widened superior mediastinum or loss of the aortic contour on the chest radiograph, or both (Fig. 112-2). These patients have historically been evaluated by arteriography (Fig. 112-3), but now chest CT is used to screen for this injury. A contained mediastinal hematoma is an unstable condition that demands timely evaluation and possible endovascular or open operative intervention.

Myocardial Injury

Myocardial contusion results from transmission of force to the myocardium in the form of compression, blast, or sudden deceleration. The true incidence is difficult to define given the absence of consensus on a reliable test to identify myocardial contusion. A high degree of suspicion is needed because there are no specific clinical signs of myocardial injury. Sternal fracture, anterior rib fractures, and aortic injuries are all examples of trauma that may suggest underlying cardiac contusion. Life-threatening myocardial contusion (5%) is manifested within the first 6 to 12 hours after injury as malignant arrhythmias or, if enough of the left ventricle is damaged, cardiogenic shock. Myocardial rupture is uncommon and typically involves the right ventricle because of the thin muscular wall and close proximity to the sternum. More commonly, arrhythmias or conduction disturbances may occur with elevation of cardiac biomarkers. Electrocardiographic findings include ST-T wave anomalies, supraventricular and ventricular arrhythmias, and atrioventricular nodal dysfunction. The echocardiogram may show left ventricular wall motion abnormalities, valvar dysfunction, or pericardial effusion. There is no evidence to support prophylactic treatment of arrhythmias, and emergency surgery for other injuries does not appear to carry a risk for increased morbidity or mortality in the presence of minor abnormalities.

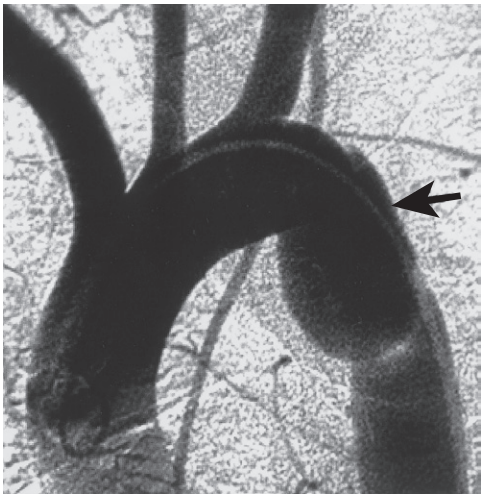

FIGURE 112-3. Arteriography of the chest. An arteriogram shows thoracic aortic disruption *(arrow)* beyond the left subclavian artery in the patient depicted in Fig. 112-2.

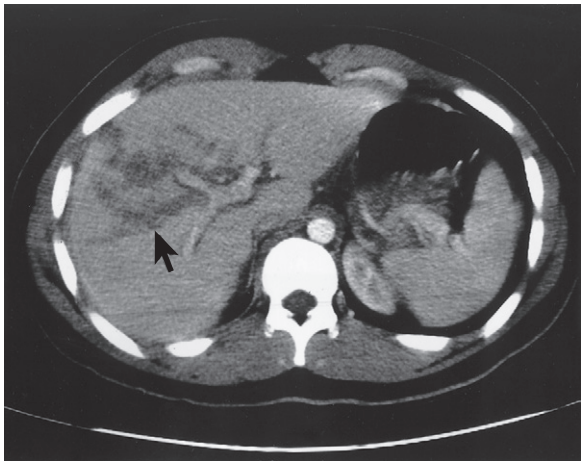

FIGURE 112-4. Abdominal injury. An abdominal computed tomographic scan shows an injury to the right lobe of the liver *(arrow)*.

Commotio cordis is sudden cardiac arrest after acute blunt trauma to the chest. The so-called concussion to the heart is one of the more common causes of sudden death in youth sports. By definition, there is no preexisting cardiac disease or identifiable morphologic change in the heart. The precordial impact, most commonly from softballs, baseballs, and hockey pucks, presumably occurs during an electrically vulnerable period between 30 and 15 msec before the T wave peak and produces ventricular fibrillation. The mortality rate is 90%, and nearly all survivors require resuscitation (Chapter 63) initiated within 1 minute of the insult. Education, improved chest protective equipment, and personnel competent in the use of automatic external defibrillators at youth sporting events may reduce the incidence of this infrequent but feared injury.

Injuries to the coronary arteries are uncommon. Potential vascular injuries include laceration, intimal disruption with dissection, and vasospasm. The sequelae and treatment are similar to those for myocardial ischemia from atherosclerotic occlusion (Chapter 73).

Back

Palpation of the thoracic and lumbar spine combined with a thorough history is sufficient to exclude a thoracolumbar spine fracture in an alert patient. Ongoing back discomfort or a mechanism suggestive of the possibility of injury should lead to radiographic examination of the spine.

Abdomen

The abdominal contents may be injured by blunt or penetrating mechanisms. The ability to identify intra-abdominal injury is limited on physical examination. If the patient is hemodynamically stable, has a normal abdominal examination, and has sustained no other injuries that warrant operative repair, serial abdominal examination, a complete blood count, and amylase and lipase levels suffice. If there is any question about the normality of the abdominal examination or the ability to monitor the patient reliably, further evaluation is warranted.

Abdominal CT has proved a reliable determinant of intra-abdominal injury in a stable patient (Fig. 112-4). It identifies both intraperitoneal and retroperitoneal injury (Fig. 112-5). CT evaluation can identify sources of blood loss and help decide whether the problem requires operative exploration.

The most frequently injured intra-abdominal organ is the spleen. Left-sided rib fractures, left upper quadrant pain or tenderness, and pain referred to the left shoulder secondary to diaphragmatic irritation are suggestive of splenic injury. CT allows definition of the grade of splenic injury and detection of free intraperitoneal blood. Hemodynamic instability, ongoing blood loss, and CT findings of a high-grade injury to the spleen are all indications for splenectomy or, preferably, splenorrhaphy for salvage of the damaged spleen with preservation of splenic function.

Blunt injury to the liver is often associated with right-sided rib fractures and right upper quadrant tenderness with or without peritonitis. An abdominal CT scan with intravenous contrast material allows classification of the liver injury according to the location, depth, and extent of the hematoma or laceration. Currently, most (85%) blunt liver injuries are managed successfully nonoperatively if other intra-abdominal injuries do not require surgery.

Focused abdominal sonography in trauma (FAST) has a sensitivity of 95% for detecting free blood in the abdomen (Fig. 112-6). FAST sequentially surveys for the presence or absence of blood in the pericardial sac and dependent abdominal regions, including the right upper quadrant, left upper quadrant, and pelvis. Evaluation of the pericardial sac also allows the operator to identify tamponade physiology (Chapter 77). FAST is limited in its ability to identify the

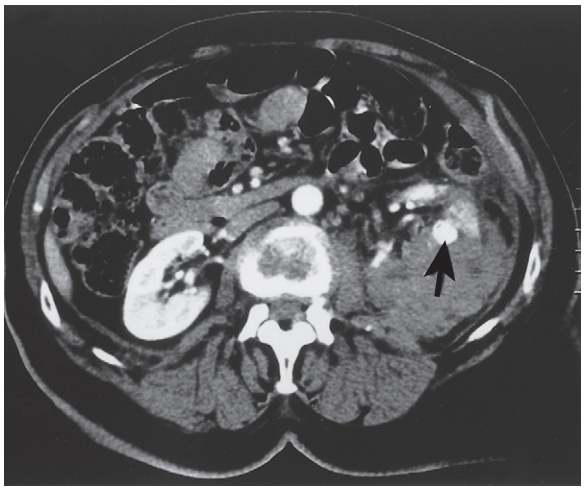

FIGURE 112-5. Intraperitoneal and retroperitoneal injury. An abdominal computed tomographic scan shows blood in the retroperitoneum surrounding a shattered left kidney, with pooling of contrast *(arrow)* in the kidney parenchyma. These findings are consistent with a pseudoaneurysm of a branch of the left renal artery.

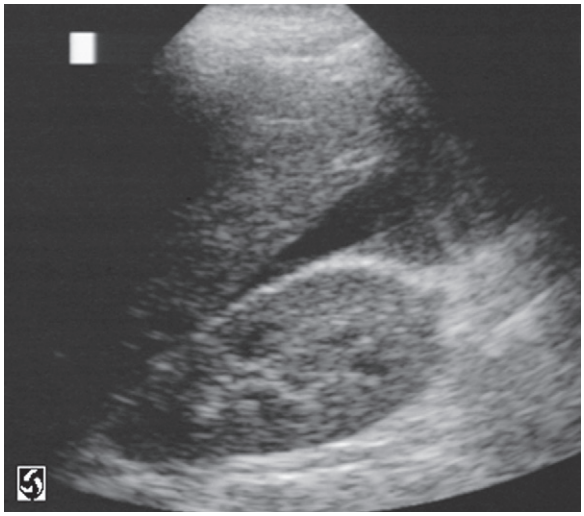

FIGURE 112-6. Positive focal abdominal sonography in trauma (FAST) study. There is a collection of fluid that shows up as a black strip between the liver and kidney. The white appearance is fat around the kidney. These findings are consistent with a fluid collection in Morrison's pouch.

source of bleeding and the retroperitoneal structures. It is effective in a pregnant trauma patient and allows evaluation of the fetus.

An alternative to FAST is diagnostic peritoneal aspiration or lavage. In this approach, a small midline infraumbilical incision is made in the peritoneum to allow sampling of fluid in the peritoneal cavity. If blood is found, laparotomy is necessary to identify and correct the source.

Wounds that penetrate the anterior abdominal region are further divided into low-velocity stab wounds and gunshot wounds, each of which has a different management algorithm. Because mandatory laparotomy for stab wounds results in a high number of negative explorations, many institutions have adopted a selective approach. An unstable victim of an abdominal stab wound should be explored immediately in the operating room. In contrast, a stable patient can undergo local exploration of the wound to determine the depth of penetration. If the wound is superficial, it is irrigated and the patient is observed; if the wound extends beneath the fascia, the patient should undergo exploratory laparotomy to exclude intra-abdominal injury. All gunshot wounds to the anterior abdominal region, except injuries with tangential trajectories, are now routinely explored, but this approach may change in the future.

In an unstable patient or a patient with clinical signs of peritonitis, penetrating wounds to the flanks and posterior abdominal region require exploratory laparotomy. In a stable patient without peritoneal signs, a CT scan with oral, intravenous, and occasionally rectal contrast material may help identify injury to retroperitoneal structures, the ascending and descending colon, the duodenum, the pancreas, and the kidneys.

Pelvis, Perineum, and Buttocks

Clinical evaluation of the pelvis is accomplished through compression of the lateral and anterior aspect of the pelvis to elicit tenderness or bony instability. Rectal examination is essential to exclude bony fragments or blood. Bladder catheterization can identify hematuria and monitor urinary output as a reflection of intravascular volume. Scrotal hematoma, meatal blood, or a high-riding boggy prostate indicates potential urethral injury and requires a urethrogram before insertion of a Foley catheter. All patients with major trauma require an anteroposterior plain film of the pelvis to exclude pelvic or hip fractures. A wound in the perineum in the presence of a pelvic fracture represents an open fracture until proven otherwise.

Penetrating wounds of the buttocks should not be overlooked or underestimated. The likelihood of concomitant peritoneal penetration is 25%, with a mortality rate of 5%. Structures at risk include the retroperitoneal rectum, bladder, ureters, and major arterial and venous structures within the pelvis.

Extremities

Palpation of the long bones is performed to determine whether there is any tenderness or deformity. Range of motion should be assessed in all joints of the upper and lower extremities. Areas of concern on examination should be evaluated radiographically. If there is any suspicion of vascular injury, angiographic examination should be performed.

The compartments of the lower part of the leg are most prone to intracompartmental swelling from direct trauma, long bone fracture, or arterial injury with ischemia or bleeding. Palpation of rigid compartments suggests elevated compartment pressures, which may be measured directly; if pressures are elevated, four-compartment fasciotomies should be performed.

Penetrating wounds to an extremity require operative exploration if they are associated with an enlarging hematoma, active arterial bleeding, or absent arterial pulses. Penetrating wounds resulting in diminished or fluctuating pulses require arteriography to document arterial injury. Otherwise, extremity wounds in proximity to major arterial structures do not require an arteriogram, but the vascular territory should be observed for 24 hours.

MEDICAL ASPECTS OF BURNS

EPIDEMIOLOGY

The National Fire Prevention and Control Administration estimates that 2.6 million fires are reported annually in the United States. About 500,000 burn injuries occur per year and result in about 4000 deaths. About 75% of these deaths occur at the scene of the incident or during initial transport. The most common age groups involved are toddlers (2 to 4 years), for whom scalding is the most common cause, and young adults (17 to 25 years), usually male, for whom the most common cause is a flammable liquid. Structural fires account for less than 5% of hospital admissions but are responsible for more than 45% of burn-related deaths.

Burns can be categorized as scalds, contact burns, and flame burns. Scald burns are the predominant injury in children, whereas contact and flame burns are most common in adults. The major cause of the injury to the skin is exposure to high temperature, which destroys surface tissue. Flames result in temperatures of several thousand degrees Fahrenheit, especially in a closed space. Because water can conduct heat 1000 times better than air, a much lower temperature (about 48 to 55° C, or 120 to 130° F) is required to produce a deep burn from hot liquid.

Chemical and electrical burns (Chapter 111), although often severe, account for less than 5% of burn admissions. The mechanism of a chemical burn is protein coagulation of skin caused by the acid or alkali. The injury progresses until the chemical is removed by aggressive water lavage. An electrical burn produces tissue coagulation along the course of passage of the current. This deeper injury is hidden from view and must be anticipated to make an early diagnosis and initiate effective treatment.

PATHOBIOLOGY

The skin is the largest organ of the body and ranges from 0.25 m^2 in a newborn to more than 2 m^2 in an adult (Chapter 443). The outermost layer of the epidermis is composed of dead, cornified cells that act as a tough protective barrier against the environment. The second, thicker layer, the corneum (0.06 to 0.12 mm), is composed chiefly of fibrous connective tissue. The dermis contains the blood vessels and nerves to the skin and the epithelial appendages of specialized function. The nerve endings that mediate pain are found in the dermis. Partial-thickness injuries are extremely painful because the nerve endings are exposed. Full-thickness burns are usually anesthetic because of destruction of the nerves.

The skin is also the barrier that prevents loss of body heat and fluids by evaporation. Sweat glands help maintain body temperature by controlling the amount of heat lost by evaporation. Increased loss of water and heat through burned skin is a major problem early after a burn. In addition, the skin is the primary protective barrier against invasive infection. The skin also detects the sensations of touch, pressure, pain, cold, and heat; loss of this function leads to long-term impairment.

TREATMENT Rx

A burned patient undergoes many dramatic physiologic and metabolic changes over the course of the injury. The burn injury is divided into four phases, each of which has many different physiologic and metabolic characteristics: (1) resuscitation phase (0 to 36 hours), (2) postresuscitation phase (2 to 6 days), (3) inflammation and infection phase (7 days to wound closure), and (4) rehabilitation and wound-remodeling phase (admission to 1 year afterward).

Resuscitation Phase (0 to 36 hours)

Life-threatening airway and breathing problems are of major immediate concern, with the effects of smoke inhalation injury being the most concerning problem (Chapter 94). The initial phase is also characterized by hypovolemia as plasma volume is lost into the burned tissue. The burn itself is of less immediate concern except for initial assessment regarding its severity and depth and the selected need for escharotomy. Wound management becomes a higher priority in later phases. The adequacy of initial treatment of pulmonary and circulatory abnormalities sets the stage for subsequent management.

Smoke Inhalation Injury

The first priority in managing a burn victim is recognition and treatment of smoke exposure. Inhalation injury can be divided into three components based on the onset of symptoms and pathophysiology (Table 112-2).

Carbon Monoxide Toxicity

Carbon monoxide and sometimes cyanide toxicity is evident immediately, with peak symptoms occurring at the scene of the inhalation (Chapter 94). Carbon monoxide rapidly displaces oxygen from hemoglobin and produces carboxyhemoglobin, which impairs oxygen delivery to tissues. The peak level

TABLE 112-2 SMOKE INHALATION COMPLEX

CARBON MONOXIDE (CYANIDE) TOXICITY
Onset of peak symptoms is immediate Symptoms are systemic
SUPRAGLOTTIC INJURY
Onset of peak symptoms is delayed (hours) Problem is upper airway edema
INFRAGLOTTIC INJURY
Onset of peak symptoms is delayed (days) Problem is lower airway mucosal injury

of carboxyhemoglobin also occurs at the scene of the burn; its half-life is about 20 minutes. Treatment is 100% oxygen. Symptoms, which range from confusion to coma, resolve with oxygen therapy unless the patient also suffered severe anoxic injury. The use of hyperbaric oxygen remains controversial in this situation.

Cyanide, which is present in smoke, is absorbed rapidly through the lung and causes systemic toxicity. Cyanide levels are difficult to obtain, but an unexplained base deficit can be assumed to be due to cyanide mitochondrial toxicity; treatment consists of oxygen along with sodium thiosulfate and hydroxocobalamin.

Supraglottic Injury

Smoke injures the mucosa above the glottis because of the combination of superheated air and the toxins in smoke. Mucosal edema, which usually develops over a period of several hours, impedes and potentially obstructs the upper airway. Early endotracheal intubation is indicated if significant edema is evident on direct laryngoscopy, especially if the edema is increasing on subsequent examinations. Upper airway edema generally resolves in 3 to 4 days.

Infraglottic Injury

Toxins in the inhaled air or coating the inhaled soot particles damage the tracheobronchial mucosa, but heat does not usually reach this level. The extent of damage depends on the toxicity of the chemicals and the duration of exposure. Symptoms vary from transient bronchospasm to sloughing of the airway mucosa, which results in plugging and infection. Bronchoscopic evidence of erythema and edema indicates that an injury has occurred but does not predict the degree of injury or time course to recovery.

Endotracheal intubation and positive-pressure ventilation are indicated if symptoms increase, especially if there is an early and progressive impairment in gas exchange. Aggressive pulmonary toilet is necessary to avoid respiratory failure. The time course to resolution may be days or weeks.

Burn Shock and Resuscitation

Adequate volume resuscitation is crucial to survival of the victim of a major body burn. Hypovolemia can also rapidly lead to conversion of viable burned tissue to a nonviable, full-thickness burn, thus further increasing mortality. With modern treatment in burn centers, the failure rate of initial volume restoration is less than 5%, even for large burns involving greater than 85% of the total body skin surface.

Two processes lead to postburn hypovolemia: an increase in microvascular permeability in the burn wound and an increase in the osmolarity of surface burn tissue. A large intravascular-to-extravascular plasma shift occurs. The phase of rapid loss of intravascular fluid persists for about 24 to 36 hours.

Isotonic crystalloid, preferably lactated Ringer's solution, is used in the first 24 hours. Normal saline in large amounts predictably leads to hyperchloremic metabolic acidosis. A volume of 4 mL/kg is given for each percent of body surface burned, with 50% given in the first 8 hours and 50% in the subsequent 16 hours. Isotonic crystalloid is used for the first 24 hours in view of the change in skin capillary permeability for protein. Albumin can be added to the resuscitation fluid to maintain a serum albumin level greater than 2.5 g/dL. After the acute injury, the major fluid loss is water from the injured skin surface, which is no longer able to act as a barrier to the evaporation of water.

Burn Wound

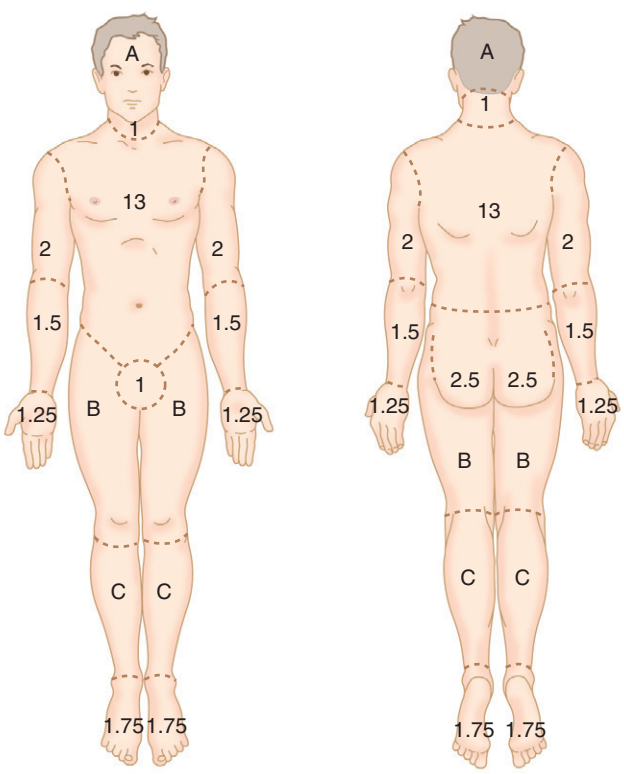
The initial management of a burn wound is based on knowledge of the anatomy of the skin and the functional losses with injury. The major objectives are to decrease the potential for further local damage and the systemic abnormalities that can be produced by loss of the barrier function. Early treatment focuses on neutralizing the source of burn injury, avoiding excess heat loss, determining the extent of the injury, cleaning and débriding the wound, controlling infection with topical antibiotics, and maintaining tissue perfusion.

Assessment of Burn Depth and Size

Burns are categorized as partial thickness or full thickness. A partial-thickness burn is defined by destruction of the epidermis and a portion of the dermis; a superficial partial-thickness burn is confined to the upper third of the dermis, a mid partial-thickness burn involves the middle third, and a deep partial-thickness burn leaves only a portion of the dermis viable. For management purposes, a deep partial-thickness burn is managed similarly to a full-thickness burn: wound excision and skin grafting are required. The approach to superficial partial-thickness burns is to provide for optimal healing, which is initiated by the remaining viable epidermal cells in the hair follicles. Burn size in older children and adults is determined by the percentage of total skin surface area that is involved by the burn (Fig. 112-7).

Postresuscitation Phase (2 to 6 days)

The early postresuscitation phase is a period of transition from the shock phase to the hypermetabolic phase. In general, cardiopulmonary stability is optimal during this period because wound inflammation and infection have not yet developed. Early wound excision and grafting are initiated during this period. Operative risks, especially blood loss and septicemia, are substantially less than later, when inflammation and infection are common.



Relative percentages of areas affected by growth

Area	Age		
	10	15	Adult
A = half of head	5.5	4.5	3.5
B = half of one thigh	4.25	4.5	4.75
C = half of one leg	3	3.25	3.5

FIGURE 112-7. Assessment tool for assessing burn size as a percentage of total body surface area.

Pulmonary Support

Continued upper airway maintenance with an endotracheal tube may be required. Placement of the patient with the head elevated 30 to 45 degrees allows faster resolution of edema. Deciding when to extubate is difficult, and the degree of lower airway injury dictates the timing. Laryngoscopy to determine the presence of cord edema is helpful. Extubation should not be performed unless reintubation is feasible. Lower airway injury is managed by aggressive pulmonary toilet for increased sputum production and microbial overgrowth. Progressive tracheobronchitis and bronchopneumonia are common. The predicted extravascular-to-intravascular fluid shift results in an increased risk for pulmonary edema. Increased levels of antidiuretic stress hormones can prevent appropriate diuresis.

Hemodynamic Stability

The postresuscitation period is characterized by major fluid shifts mainly from the extravascular to the intravascular fluid space. Edema in burned tissue is maximum between 24 and 30 hours after injury in patients with well-controlled fluid resuscitation. The red blood cell mass continues to decrease. Electrolyte and acid-base changes are prominent.

Evaporation from the surface of the burn is a major source of water loss that persists until the wound is closed. The loss is measured in terms of water vapor pressure at the surface. In normal skin, vapor pressure is 2 to 3 mm Hg, whereas the pressure is about 32 mm Hg in a full-thickness burn in which the eschar is soft and hydrated. The rate of loss is increased with increasing surface blood flow. A reasonable estimate of the average loss per hour can be obtained from the following formula: evaporative water loss (mL/hr) = (25 + % total body surface burn) × body surface area (m^2).

Burn Wound

The wound undergoes dramatic changes during the next several days as inflammation develops. Of particular importance is the potential for change in the zone of injured, but still viable, tissue. Changes in local wound microcirculatory blood flow as a result of vasoactive inflammatory agents or local infection can convert this zone of ischemia to a zone of necrosis.

TABLE 112-3 MOST COMMON ORGANISMS IN BURN INFECTIONS

	STAPHYLOCOCCUS AUREUS	*PSEUDOMONAS AERUGINOSA*	*CANDIDA ALBICANS*
Wound appearance	Loss of wound granulation	Surface necrosis, patchy black	Minimal exudates
Course	Slow onset, 2-5 days	Rapid onset, 12-36 hr	Slow onset, days
Central nervous system	Disorientation	Modest changes	Often no change
Temperature	Marked increase	High or low	Modest changes
White blood cells	Marked increase	High or low	Modest changes
Hypotension	Modest	Often severe	Minimal change
Mortality	5%	20-30%	30-50%

Hypermetabolic-Sepsis Phase (7 Days to Recovery)

The generalized inflammation of the final phase alters organ function and magnifies any preexisting organ dysfunction. The burn wound is now colonized with bacteria, so wound sepsis is of prominent concern. Infection, whether in the lung or burn wound, becomes increasingly difficult to diagnose because of the continued presence of a non-infection-induced hyperdynamic state. Multisystem organ failure, if it is to occur, is seen during this period.

Burn Wound Infection

Burn wounds are never sterile, even with the administration of topical agents or systemic antibiotics. The presence of bacteria just on the wound surface is termed *colonization*. Colonization may be with a single type of organism or with multiple types. Infection of the wound (Table 112-3) indicates invasion of the underlying viable tissue; this process is diagnosed by eschar biopsy and quantitative culture showing greater than 10^5 organisms per gram of tissue. With progression, viable tissue and its blood vessels are invaded, and septicemia develops. Wound infections require systemic antibiotics. Because all patients have a hyperdynamic state with an elevated temperature and leukocytosis, it is difficult to make a diagnosis of infection based on systemic symptoms. Optimally, most of the eschar should be removed in the first week to avoid burn wound sepsis. *Staphylococcus aureus* is the most common organism isolated from the burn, especially during the first week.

Hypermetabolic State

Beginning at day 5 or 6, there is a gradual increase in the metabolic rate from a normal of 35 to 40 cal/m^2/hr (25 cal/kg/day) to levels twice this value at about 10 days. The increase in metabolic rate after burns is far in excess of that seen after any other severe injury, including sepsis. The magnitude of the increase is related to the size of the burn. The hypermetabolic state is characterized by increased oxygen consumption, increased heat production, increased body temperature, and increased protein catabolism. Body temperature increases from normal to 38 to 38.5° C (100 to 101° F) because of resetting of the hypothalamic temperature center as a result of the altered hormonal environment (Chapter 288).

Marked and sustained increases in circulatory catecholamines lead to hypermetabolism, and treatment with β-blockers (e.g., propranolol titrated to reduce the resting heart rate by 20%) may reduce muscle catabolism. Sustained increases in glucagon and glucocorticoids result in excessive gluconeogenesis and an insulin-resistant state. Increased glucocorticoids also lead to a severe catabolic state, especially because anabolic hormones (growth hormone and testosterone) are decreased after a burn injury.

Nutritional Support

Optimal nutritional support is essential and can decrease net catabolism by about 50%. Currently, there is no recognized ideal nutritional program because of evolving changes with new research findings on postburn nutrient processing. Decreasing stress by wound closure and control of pain, heat loss, and hypovolemia further controls the hypermetabolism. Caloric requirements can be measured with indirect calorimetric techniques. Because more than 95% of the energy generated requires oxygen, there is a direct relationship between oxygen consumption and the metabolic rate. Caloric needs can be estimated by the formula whereby energy requirements = basal metabolic rate × 1.25 × stress factor; the stress factor is 1.2 for a 10% burn, 1.5 for a 20% burn, 1.7 for a 30% burn, 1.8 for a 40% burn, and 2.0 for a 50% or greater burn. If the activity level is increased markedly or additional stress (e.g., severe pain) is present, the metabolic rate can be increased further.

Nutrients Required

Carbohydrate is the preferred fuel for most tissues, but there is a limit to the amount that is used, especially in a hypermetabolic or septic patient (Chapters 221, 223, and 224). Current recommendations are that carbohydrate infusions not exceed 5 to 7 mg/kg per minute, or approximately 1800 to 2200 carbohydrate calories per day. Excess carbohydrate results in the formation of fat, which requires energy rather than produces energy. Approximately 50% of the estimated calorie requirements is usually given as glucose to spare nitrogen. Fat is used as a calorie source, but fat should account for no more than 30% of the total calories. Protein represents 20 to 25% of infused calories. A standard estimate of 1.5 to 2 g of protein per kilogram of body weight can be used for all major burns. Necessary vitamins and trace elements should be provided in the form of high-potency multivitamin-mineral pills or liquid.

Route of Administration of Nutrition

Nutritional support is best managed during this period by the enteral route, generally through a combination of balanced tube feeding and voluntary intake (Chapter 223). Parenteral hyperalimentation (Chapter 224) through a central vein is occasionally required if for some reason the gastrointestinal tract is not functioning adequately, as sometimes occurs in a patient on a ventilator or a patient with sepsis.

Use of Anabolic Agents

An increase in anabolic activity can decrease the catabolic response to burns, thereby preserving lean body mass, which improves all aspects of wound healing. Glutamine, a conditionally essential amino acid, is invariably deficient several days after a burn because of increased utilization and decreased intake. Glutamine supplementation in major burns, at a dose of 0.4 g/kg body weight, improves wound healing and decreases infections and mortality. Endogenous levels of anabolic human growth hormone and testosterone are decreased after burn surgery, and insulin resistance often develops. These intrinsic changes are all detrimental to wound healing. Supplemental human growth hormone significantly decreases the rate of muscle loss and increases wound healing. Similarly, insulin infusion with glucose in burn patients increases lean mass loss and improves outcome.

The only anabolic steroid approved by the U.S. Food and Drug Administration to treat weight loss and catabolism is oxandrolone, which is given orally (10 mg twice a day), is excreted by the kidney, and has no effects on metabolism other than protein synthesis. Oxandrolone acts on androgenic receptors in lean mass, especially on skin fibroblasts. A number of studies have demonstrated its ability to preserve lean mass after burn injury and thereby improve local healing. In addition, several recent studies have demonstrated direct wound-healing properties.

Rehabilitation after burns is critical to recovery. An augmented exercise program can effectively treat deconditioning and improve subsequent aerobic capacity.

113 VENOMOUS SNAKE BITES

STEVEN A. SEIFERT, JAMES O. ARMITAGE, AND G. RALPH COREY

About 500 of the approximately 2900 species of snakes are venomous, and more than 200 species have caused fatal envenomation in humans. It has been estimated that, worldwide, there are up to 5 million snake bites annually, causing up to 125,000 deaths.

EPIDEMIOLOGY

The incidence of venomous snake bites varies enormously throughout the world. Snake-free areas consist primarily of islands, and Europe continues to be the continent with the lowest incidence of venomous snake bites. In the United States, it is estimated that up to 8000 venomous bites by native species occur each year, mostly by pit vipers (rattlesnakes, copperheads, cottonmouths), with fewer than 100 bites by coral snakes, the only native elapid. Fortunately, the number of fatalities, primarily caused by rattlesnakes, is less than 10 per year. Children and possibly pregnant women are at highest risk for complications. In addition, there are approximately 50 venomous snake bites a year in the United States by non-native (exotic) species; most of these snakes are in private collections, but also in zoos and academic institutions. In the past 10 years, human envenomation by more than 90 different nonnative species has occurred. The majority of bites are by viperids, with about 40% by elapids, mostly cobras. The case-fatality rate of exotic envenomation is an order of magnitude higher than that of native species, because of both the number of highly venomous animals that are kept and the logistical issues of management. Most bites occur on extremities when snakes are threatened by being trod on, by someone reaching without looking, or by intentional handling of venomous snakes. Because the crotaline antivenom in the United States is effective against all U.S. crotaline species (and because coral snakes are easily identifiable), there is no need to capture or kill the offending snake for purposes of genus or species identification; such actions only increase the risk of a second envenomation or additional victims. Prevention of snake bite is better than therapy.

Venomous snakes belong to one of five families: Viperidae, with its two subfamilies—Viperinae, or Old World vipers, and Crotalinae, or pit vipers (e.g., rattlesnakes, copperheads, cottonmouths [water moccasins]); Elapidae (e.g., cobras, mambas, kraits, coral snakes); Hydrophiidae (e.g., sea snakes); Atractaspididae (e.g., asps); and Colubridae (e.g., garter snakes, corn snakes, boomslangs). Although all five families contain venomous species, the two responsible for more than 90% of venomous bites are Viperidae and Elapidae. In North America, pit vipers, named for the heat-sensitive organ between the eye and nostril used for hunting warm-blooded prey, are responsible for the majority of venomous snake bites. Fatalities are rare because of a well-developed health care system and the ready availability of antivenom.

In Europe, the only snake of importance is the adder, a viperid snake. Bites are uncommon and rarely fatal. Australia is home to numerous very dangerous Elapidae, including the taipan, death adder, tiger snake, and eastern brown snake. As a result, there are many serious bites each year, despite the low-density population. Fatalities are infrequent, however.

In Central and South America, pit vipers are the primary subfamily responsible for human envenomation; rattlesnakes (Crotalinae, *Sistrurus*) and the *Bothrops* species (*Bothrops jararaca,* fer-de-lance) are responsible for the high morbidity and mortality. The largest venomous snake in the Americas is the bushmaster (*Lachesis muta muta*).

Africa is home to a large number of venomous species. Elapids (cobras and mambas) and the Old World vipers (e.g., saw-scaled viper, puff adder) are among the most prevalent and dangerous of all the world's snakes.

Asia produces the largest number of fatalities from snake envenomation. In India and its eastern neighbors, elapids and viperids are prominent. Cobras, kraits, pit vipers, saw-scaled vipers, and Russell's viper inflict most of the injuries. Although antivenoms are available for most African and Asian snakes of clinical importance, mortality remains high because the health care system is less well developed in these regions.

PATHOBIOLOGY

Snake venoms are complex poisons and often consist of dozens of components that immobilize and digest prey. The effects of venom may be neurotoxic, cardiotoxic, hemotoxic, or myotoxic. Particular species generally produce a characteristic envenomation profile, but the presence or absence of particular components may be variable even within a single species.

Local swelling and bruising after a bite are caused by increased vascular permeability as a result of endothelial cell damage and are mediated by hydrolases, proteases, phospholipase A_2, polypeptide toxins, metalloproteinases, and the release of endogenous autacoids such as bradykinin and histamine. Snakes from the Viperidae and Elapidae families are primarily responsible for these effects.

Hemostatic abnormalities are frequent and varied. Pro-coagulants activate factors V, IX, and X, protein C (Russell's viper), and prothrombin (vipers) and cleave fibrinopeptide A from fibrinogen. Fibrinolytic activators result in a disseminated intravascular coagulation (DIC)–like picture, although there are key differences from true DIC, including the absence of thrombin formation and the failure of heparin therapy in snake evenomation. Snake venom hemorrhagins damage endothelium and increase the potential for serious bleeding, especially after viper bites. Intravascular hemolysis, which can occur after bites by *Bothrops* (e.g., fer-de-lance) and other species, results in severe anemia and acute renal failure.

Paralysis is the primary function of many types of venom of the Elapidae and Hydrophiidae families and of some Viperidae snakes. Presynaptic neurotoxins (e.g., β-bungarotoxins, crotoxin, taipoxin) prevent acetylcholine release, and postsynaptic toxins (e.g., α-bungarotoxins, cobrotoxin) bind to acetylcholine receptors on the motor end plate.

Rhabdomyolysis (Chapter 115) occurs most commonly from the presynaptic neurotoxins of sea snakes, but myotoxins have also been found in Australasian elapids, Russell's viper, and selected rattlesnakes. Acute renal failure, hyperkalemia, and death often result. Other mechanisms of renal failure after envenomation include a direct renal toxin, hemoglobinuria after massive intravascular hemolysis, hypotension, and DIC-like defects.

Toxins that do not immobilize prey through neurotoxins may immobilize by causing hypotension. Some snakes (primarily vipers) produce an acute hypotensive syndrome within minutes after envenomation through the release of vasodilating autacoids. *Bothrops* species inhibit the breakdown of bradykinin and angiotensinogen (angiotensin-converting enzyme inhibitors). Vasodilation, diffuse vascular permeability, myocardial depression, and atrioventricular block all play roles in the hypotension caused by crotalines and elapids. Individuals who handle snakes or who have been bitten previously may develop an immunoglobulin (Ig) E–mediated anaphylactic reaction. A non-IgE-mediated anaphylactoid response may be seen with the rapid introduction of foreign proteins into circulation; nonspecific effects, such as vagal reactions and hypovolemia secondary to massive tissue fluid accumulation as a result of local venom injury, may also produce hypotension.

CLINICAL MANIFESTATIONS

Pit Viper Envenomation

Swelling and pain are the first and most important findings of early pit viper envenomation. These symptoms often occur within minutes and are followed by progressive proximal swelling and ecchymosis in the bitten extremity, although onset of the latter may be delayed for hours. Local swelling, usually extracompartmental, may be massive, and elevated tissue or compartmental pressures may occur from tension created by the skin's limited elasticity. Necrosis may develop as a consequence of direct venom-related tissue injury or possibly as a result of pressure-mediated vascular compromise. Necrosis typically occurs over a period of several days, with the potential for permanent tissue loss. Progression of local injury usually ceases within 24 to 36 hours. Secondary infection of snake bites is rare, but the presence of necrosis increases its likelihood. The development of systemic symptoms such as

nausea, diaphoresis, paresthesias, metallic taste, and dizziness may indicate more severe envenomation. Hypotension and bleeding manifestations (e.g., distant petechiae; hematuria; gingival, gastrointestinal, central nervous system bleeding) may also occur early and pose the greatest risk for death. During the first 24 hours, the white blood cell count is often increased. Various coagulation abnormalities, alone or in combination, may be seen, including thrombocytopenia; elevated D-dimer or fibrin-fibrinogen degradation products, with or without hypofibrinogenemia; and prolongation of the international normalized ratio or activated partial thromboplastin time. Hematologic effects are more common with rattlesnake bites but can occur with copperhead or cottonmouth envenomation as well. Spontaneous bleeding is more likely with combined and severe coagulation system abnormalities. In patients with persistent hypotension, the presence of coma, acidosis, and oliguric renal failure presages death.

Progression of local injury may recur in the first 24 hours, particularly in patients treated with a Fab antivenom. This occurs as protective levels of circulating antivenom decline rapidly secondary to their larger volume of distribution compared with IgG or $F(ab')_2$ antivenoms and the renal clearance of unbound antivenom. This recurrence is not associated with a recurrence of detectable blood venom antigens and appears to be the result of a lack of adequate amounts of neutralizing antivenom at the leading margin of envenomated tissue. Coagulation system disorders may persist despite antivenom and may also recur. Recurrence of coagulation defects typically occurs several days after treatment with a Fab antivenom and is associated with the loss of protective circulating antivenom secondary to renal clearance, thereby allowing unneutralized venom still entering the circulation to exert its toxic effects. This recurrence is associated with detectable blood venom antigens. The specific hematologic abnormalities (e.g., thrombocytopenia) seen early in the course tend to recur, with similar degrees of severity ("like predicts like in kind and degree"). The ultimate severity of envenomations treated within 1 to 2 hours may have been masked, and such patients are also at risk of severe recurrence, despite apparently mild early effects. Recurrent coagulation abnormalities may persist or continue to recur following additional treatment, for up to 3 weeks.

Coral Snake Envenomation

Unlike the pit vipers, local symptoms after coral snake bites are often confined to paresthesias around the bite and mild swelling in a minority of patients. Systemic symptoms are often delayed for 1 to 6 hours. Because of species differences, coral snake bites in Florida (*Micrurus fulvius*) tend to be more severe than those in Texas (*Micrurus tener*). In the bordering states (Louisiana, Alabama), which may have either species, the risk of toxicity may be difficult to determine. Coral snake bites in Arizona and New Mexico (*Micruroides euryxanthus*) do not produce significant clinical effects. With severe envenomation, perioral paresthesias, nausea, vomiting, hypersalivation, and euphoria give way to cranial nerve paralysis (e.g., ptosis, diplopia, dysphagia) and respiratory failure. Respiratory failure may develop within minutes of the onset of neurologic signs.

TREATMENT

Rx

Expert assistance in managing a snake bite of any kind can be obtained by contacting the regional poison center at 1-800-222-1222.

Snake bite is primarily a medical rather than a surgical condition. On a patient's arrival at an emergency care facility, primary attention should be given to assessing and establishing the airway, breathing, and circulation. Management might include antivenom administration, management of type I hypersensitivity reactions to snake venom or antivenom (e.g., epinephrine, H_1- and H_2-blockers), intravenous fluids, tetanus toxoid, airway protection, mechanical ventilation, pressors, pain medications, radiographs of the wound to rule out retained foreign bodies (fangs or teeth), and, later, physical therapy. Late surgical débridement of necrotic tissue, if any, may be required. Surgical treatment of elevated tissue or compartment pressures is very rarely indicated. Because of the inability of prophylactic antibiotics to prevent infection and the potential of an adverse drug reaction occurring simultaneously with venom toxicity, antibiotics should be reserved for documented infection, a clinical appearance that cannot be easily distinguished from infection, or frank tissue necrosis.

A wide variety of ineffective and potentially harmful therapies for snake bite have been and, in some cases, continue to be popular (Table 113-1). Use of these methods in true envenomations may contribute to venom injury and could result in tragedy if they delay or supplant effective therapy.

Vitamin C

Pit Viper Envenomation

Prehospital

Appropriate care consists of immobilization of a bitten extremity, consideration of the need to slow systemic absorption by dependent positioning or lymphatic obstruction, and, most important, rapid transit to a hospital emergency department. Any treatment that increases or prolongs the local concentration of venom may result in greater local injury and should be used only when life-threatening systemic effects (e.g., profound hypotension, anaphylaxis, severe bleeding) are occurring. The application of a lymphatic constriction band (15 to 25 mm Hg) or a pressure immobilization bandage requires training and proper equipment and is rarely required. Popular prehospital treatments such as arterial or venous tourniquets, incision, suction, heat, cold, and electric shock are not helpful, can delay definitive treatment, and can cause additional trauma.

Hospital

The chance of a North American crotaline bite resulting in envenomation is around 80%. The onset of symptoms of pit viper envenomation is usually rapid and obvious but may be delayed for many hours. Potentially "dry" bites should be observed for at least 10 to 12 hours.

The ultimate severity of envenomation becomes apparent only over time, and "mild" envenomation may progress to "severe," depending on the venom load, venom components, and host factors. Definitive therapy for systemic symptoms of snake bite, including hypotension and coagulation abnormalities, is antivenom, which should be used for any significant or progressive envenomation. The starting dose is based on the severity of symptoms or signs and the rapidity of progression. Administration of blood product components is usually futile in the absence of adequate venom neutralization. With neutralization, the body replenishes platelets, fibrinogen, and clotting factors on its own. Blood products should be reserved for life-threatening bleeding and should be given in conjunction with additional antivenom.

The crotaline snake antivenom available in the United States, CroFab, consists of Fab antibodies to specific crotaline venoms that were raised in sheep. It is indicated and efficacious for all North American crotaline snakes. Because antivenom contains foreign proteins, type I (immediate) hypersensitivity reactions are possible, including anaphylaxis. With Fab antivenom, predominantly mild type I hypersensitivity reactions have been reported to date in less than 7% of patients. Cutaneous sensitivity testing before administration is not recommended and does not adequately predict the likelihood of a type I reaction in other settings. Type I hypersensitivity reactions are managed by stopping or slowing the rate of infusion and by administering H_1-blockers (e.g., diphenhydramine 50 mg IV), H_2-blockers (e.g., ranitidine 50 mg IV or cimetidine 300 mg IV), and epinephrine (0.3 mg SC as a 1:1000 dilution) as needed. It is usually possible to restart the infusion at a slower rate after treatment and to give the complete dose, although a risk-benefit reassessment should be made regarding the ongoing need for antivenom. Means of treating anaphylaxis should always be immediately available.

The initial dose of Fab antivenom is 4 to 6 vials, regardless of the patient's weight, because the objective is to neutralize a specific quantity of injected venom. Children may, in fact, require higher doses because of higher serum venom levels (a larger venom dose relative to weight) and particular

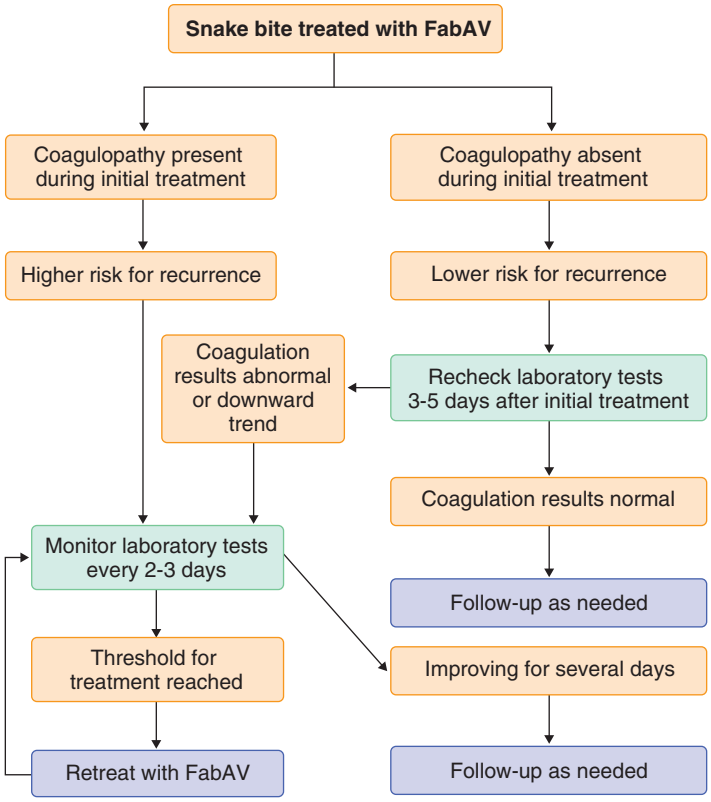

FIGURE 113-1. Monitoring for coagulopathy in patients treated with Crotalidae polyvalent immune Fab (ovine) (FabAV).

vulnerabilities, such as smaller airway size and the increased proportion of vascular volume lost into tissues. Additional antivenom doses may be administered as needed to obtain initial control of the signs and symptoms of envenomation. Initial control includes reversal of systemic symptoms, cessation of progression of proximal swelling or a reduction in circumferential swelling and tissue pressures, and cessation of worsening or evidence of improvement in coagulation components. Repeated dosing of Fab antivenom after initial control (2 vials every 6 hours for three doses) is recommended to prevent the recurrence of local effects (Fig. 113-1). Additional doses (2 vials) may be required for breakthrough local recurrences.

Management of elevated tissue or compartmental pressures (Chapter 115) is controversial. Dermotomy may be considered in areas without true compartments (e.g., fingers) if the degree of swelling compromises circulation; however, additional antivenom and elevation may reduce the swelling, making this procedure unnecessary. In practice, dermotomy is very rarely required. If there is concern about significantly elevated tissue or compartmental pressures, they should be measured directly. In general, additional antivenom and elevation are recommended for increased pressure (>30 mm Hg). Elevation is controversial because it decreases local tissue perfusion in the typical compartment syndrome. After snake bites, however, elevated compartmental pressures may be entirely secondary to subcutaneous edema and may respond to elevation with a proximal redistribution of tissue fluid and a reduction in tissue pressures. Conversely, in true compartment syndrome, owing to either direct intracompartmental injection of venom or lymphatic drainage of venom into the compartment, elevation may be harmful. Nevertheless, judicious elevation seems reasonable to see whether a reduction in pressures can avoid fasciotomy, which does not appear to be beneficial in compartment syndrome caused by venom injection.

Patients with early, severe coagulopathic abnormalities are at risk for recurrence of severe abnormalities of the same kind; about 70% of those with early coagulation defects return with late recurrences. Optimal management of severe recurrence is undetermined, but patients with severe abnormalities in multiple coagulation systems (e.g., platelets and fibrinogen) or with comorbid conditions (e.g., advanced age, hypertension, bleeding diathesis, risk-taking behavior) are at increased risk for significant bleeding and are candidates for repeat dosing of Fab antivenom (Table 113-2). Two vials should be given intravenously, and the patient should be monitored and possibly treated daily until a clear improving trend is observed (see Fig. 113-1).

Postacute Phase

In an effort to improve functional outcome, physical therapy should begin as soon as the acute phase of local injury has subsided, usually in 36 to 48 hours. Type III hypersensitivity reactions ("serum sickness," occurring 5 to 21 days after treatment) are usually mild with Fab antivenom but occur in up to 5% of cases. For management of mild type III hypersensitivity reactions, treatment is with nonsteroidal anti-inflammatory drugs (e.g., ibuprofen 200 to 800 mg orally four times a day as needed for arthralgia, myalgia, and fever) and antihistamines (e.g., diphenhydramine 25 to 50 mg orally four times a day as needed for urticaria). For more severe reactions, corticosteroids (e.g., prednisone 20 to 40 mg/day orally, with a taper over 2 weeks if treatment is needed for more than 5 days) are recommended. Type III reactions are self-limited and typically have a duration of 2 to 10 days, rarely lasting more than 3 to 4 weeks.

TABLE 113-2 RECOMMENDATIONS FOR RETREATMENT WITH ANTIVENOM FOR PERSISTENT OR RECURRENT HEMATOLOGIC ABNORMALITIES

Active, significant bleeding (in conjunction with blood products as needed)
Fibrinogen < 50 μg/mL
Platelet count < 25,000/mm^3
INR > 3.0 sec or aPTT > 50 sec
Multicomponent effects with lesser abnormalities
Worsening trend in a patient at risk for severe recurrence
High-risk behaviors for trauma in a patient with lesser abnormalities
Comorbid conditions that increase bleeding risk

aPTT = adjusted partial thromboplastin time; INR = international normalized ratio.

Coral Snake Envenomation

Prehospital

Appropriate care consists of immobilization of a bitten extremity and efforts to slow systemic absorption with the use of a pressure immobilization bandage. Proper application of this bandage requires training, and it is frequently misapplied by untrained providers; therefore, a lymphatic constriction band (blood pressure cuff inflated to 15 to 25 mm Hg) may be safer but possibly less effective. Most important is rapid transit to a hospital emergency department. Because local effects are minimal and neurologic toxicity may progress rapidly, there is little risk in the use of a properly applied pressure immobilization bandage or lymphatic constriction band. Popular prehospital treatments such as tourniquets, incision, suction, heat, cold, and electric shock are not helpful, can delay definitive treatment, and can cause additional trauma.

Hospital

The chance of a bite from an eastern coral snake resulting in envenomation is around 75%. The onset of neurologic symptoms may be quickly evident, but it may also be delayed for many hours. Because of minimal local effects and potentially delayed neurotoxicity, envenomation and the seriousness of such bites can easily be underestimated. The snake bite severity score is not valid for these snake bites. Potentially "dry" bites should be closely observed for at least 24 hours.

In the United States, the Food and Drug Administration–approved monovalent, equine IgG antivenom (manufactured by Wyeth) should be given at the first signs of envenomation by bites of the eastern coral snake (*Micrurus fulvius*) or the Texas coral snake (*Micrurus tener*). However, Wyeth ceased production in 2006, and supplies are limited and dwindling in endemic areas. It is estimated that replacement supplies will no longer be available in 2010 or 2011, after which remaining antivenom stocks, currently distributed primarily to hospitals in endemic areas, will gradually be consumed.

Skin testing is suggested by the manufacturer, although such testing is not adequately predictive of the risk for type I (immediate) hypersensitivity reactions, and an expert consensus panel has concluded that skin testing should not be performed. Regardless, testing should not delay administration in the event of life-threatening effects. When available, the initial dose is 3 to 6 vials, repeated as needed until progression of signs and symptoms ceases. Rarely are more than 10 vials required. Type III hypersensitivity reactions ("serum sickness") may occur; management is as described earlier.

If fresh Wyeth antivenom is not available, some advocate using expired Wyeth antivenom, despite medicolegal concerns. Neostigmine (infants, 0.025 to 0.1 mg/kg/dose; children, 0.025 to 0.08 mg/kg/dose; adults, 0.5 to 2.5 mg/dose, total dose not to exceed 5 mg) is efficacious against the neurotoxicity of other elapids, including several South American species of coral snake; doses can be repeated as needed to maintain reversal of blockade. Neostigmine may be considered a temporizing measure, adjunctive therapy, or monotherapy; however, there are no published reports on its use in U.S. coral snake envenomations. If neostigmine is used, atropine (0.4 mg per 1 mg of neostigmine) should be given several minutes before the neostigmine to counter unwanted cholinergic effects. Foreign antivenoms, which may have efficacy against U.S. coral snakes, can be located and obtained through the Antivenom Index, which can be accessed via the regional poison center (1-800-222-1222). If respiratory compromise results in intubation, days to weeks of respiratory support may be required.

Bites by Non-native Species

Management of bites by non-native species is challenging because of both their unfamiliarity and potential delays in obtaining appropriate antivenom, which is usually kept by zoos that have specimens of the biting species. Poison centers have access to information about zoo supplies of antivenom through an online listing, the Antivenom Index. Assistance in locating and obtaining species-specific antivenom and clinical case management can be obtained through the regional poison center (1-800-222-1222).

PROGNOSIS

In general, the prognosis is good if timely access to antivenom is possible. For coral snake bites, the mortality rate before the introduction of antivenom in 1967 was between 10 and 15%. Age and underlying disease can increase morbidity, particularly if hemorrhage and hypotension develop.

VENOMS AND POISONS FROM MARINE ORGANISMS

JAY W. FOX

The term *envenomation* implies penetration of a target by an organism for delivery of venom containing one or more toxins. In contrast, poisons are toxins acquired from the environment by mechanisms such as absorption, inhalation, and ingestion. In the marine environment, both forms of intoxication cause effects ranging from mild irritation and discomfort to death (Table 114-1). Severe outbreaks of poisoning can result from the ingestion of marine organisms that contain toxins, and such outbreaks have become more frequent as microorganisms in coastal waters increase, owing to a combination of global sea warming, eutrophication, aquaculture, and discharge of organisms from ship ballasts. Encroachment on the marine environment for recreation, living space, and food sources increases the frequency of adverse encounters with venomous and poisonous marine organisms.

VENOMOUS MARINE ORGANISMS

Venomous marine organisms deliver their venom by bites and stings. Envenomation involves penetration of the skin and may be complicated by secondary bacterial infections, especially after deep puncture wounds and bites.

Chordata

Sea Snakes

Sea snakes, which are members of the family *Hydrophiidae*, are generally found in tropical and subtropical waters, especially the coastal waters of Thailand, Indonesia, the Persian Gulf, Australia, and India. One species, the yellow-bellied sea snake (*Pelaramis platurus*), is found in the Pacific coastal waters of Central America. Sea snakes, which are very capable swimmers and are relatively immobile on land, inject their venom with two small maxillary fangs (2 to 4 mm long) that contain ducts connected to venom glands located posterior and ventral to the maxillary bone. The relatively short length of the fangs prevents effective envenomation through most protective clothing such as dive suits. If the subject reacts to envenomation by forceful retraction, the fangs are often dislodged from the maxillary bone of the snake and may remain in the site—a condition that imposes an additional risk for infection.

Because of the nature of the venom and the size of the fangs, the sea snake bite itself is not generally painful. One or two small prick marks are present at the envenomation site, occasionally with additional marks from the other teeth in the snake's mouth. The primary toxin in sea snake venom is a postsynaptic peptide neurotoxin that functions by blocking the acetylcholine receptor at neuromuscular junctions (Fig. 114-1). Ptosis, dysphagia, and nonrigid paralysis, which are the most common symptoms of sea snake envenomation, typically appear within 30 minutes to 2 hours after the bite. In severe cases, respiratory failure may develop, and respiratory support may be necessary. Antivenom is available.

Weeverfish, Lionfish, Scorpionfish, and Stonefish

Weeverfish belong to the *Trachinidae* family, whereas scorpionfish, stonefish, and lionfish all belong to the family *Scorpaenidae*. Members of the *Scorpaenidae* family are found mostly in tropical and subtropical waters, but weeverfish are in European and African waters. All of these fish sting by using dorsal spines. The anal spines of *Scorpaenidae* fish and the opercular spines of *Trachinidae* fish can also deliver venom. The spines are encased in an integumentary sheath that is torn when the spine punctures the victim's skin. Venom glands are located at the base of the spine.

Few details are known regarding the biochemistry and pharmacology of the toxins in weeverfish venom. The sting of the weeverfish is extremely painful and may produce systemic effects such as aphonia, fever, chills, dyspnea, cyanosis, nausea, syncope, hypotension, and arrhythmias. The wound is edematous, erythematous, and ecchymotic. Bacterial infection is typical, and gangrene has developed in severe cases of infection. The venom may be somewhat heat labile, and soaking in tolerably hot water may reduce pain and attenuate the effects of the venom. Death from an untreated weeverfish sting is rare.

Scorpaenidae envenomation symptoms are generally less severe for lionfish (*Pterois*), more severe for scorpionfish (*Scorpaena*), and most severe for stonefish (*Synanceia*). Lionfish (turkey fish, dragon fish, butterfly cod), which are found worldwide, have long thin spines. Scorpionfish have shorter, thicker spines and are primarily found in tropical and subtropical waters and the Mediterranean. The local consequences of edema and erythema from stings of these fish are very similar to those of the weeverfish. Immersion in hot water is generally effective to alleviate pain associated with envenomation.

The stonefish *(Synanceja)* group has short strong spines and is found throughout the Indo-Pacific area, China, Australia, and the Indian Ocean. Their toxins are high-molecular-weight, multimeric, heat-labile proteins. Symptoms of envenomation are similar to those from the stings of members of the other groups. A lethal toxin, stonustoxin, from the venom of *Synanceja horrida* causes muscle relaxation by producing nitric oxide and also causes hemolysis, platelet aggregation, and inhibition of neuromuscular function. Trachynilysin, a pore-forming neurotoxin from *Synanceja trachynis,* causes massive presynaptic release of acetylcholine. Soaking of the wound site in hot water (45° C) is recommended. In cases of severe blistering, the blisters should be excised to flush residual active venom from the blister fluid to ameliorate dermal necrosis. As with all fish stings, care should be taken to ensure that no broken portions of the spines remain in the wound; vigilance against bacterial infections is imperative. Antivenom should be used only if it is clear that envenomation has occurred.

Stingrays

Stingrays (family Dasyatidae) are found in most seas but are predominant in the Indo-Pacific area. Some members of the family are also found in fresh water. Venom containing serotonin is delivered by stings from spines (one or more) on the tail of the stingray. Stingray spines are retroserrated on the margins and are covered by an integumentary sheath. Venomous glandular tissue is located at the base of the spines. On puncture of the skin, the sheath is torn by the serrated spine, and venom flows along the two ventrolateral grooves of the spine into the surrounding tissue. The spines are often deeply embedded in the tissue and difficult to extract because of the retroserration. Care must be taken to remove all spine and sheath fragments. Depending on the location of the spine and the depth of penetration, specialized care may

TABLE 114-1 SIGNIFICANT VENOMOUS AND POISONOUS MARINE ORGANISMS

ORGANISM	MECHANISM OF INTOXICATION (EVENOMING/POISONING)	PRIMARY TOXINS	ANTIVENOM AVAILABLE (SOURCE)
Sea snakes (Hydrophiidae)	Bite	Postsynaptic neurotoxins	Yes (CSL, Ltd.)
Blue-ringed octopus (Octopodidae)	Bite	Tetrodotoxin (neurotoxin)	No
Cone shell (Conidae)	Sting	Presynaptic and postsynaptic neurotoxins	No
Box jellyfish (*Chironex fleckeri, Chiropsalmus quadrigatus*)	Sting	Hemolysins, proteinases, cardiotoxin, necrotoxins	Yes (CSL, Ltd.)
Portuguese man-of-war (*Physalia physalis*)	Sting	Hemolysins, proteinases, cardiotoxin, necrotoxins	No
Sea nettles (*Chrysaora quinquecirrha, Cyanea capillata*)	Sting	Hemolysins, proteinases, cardiotoxin, necrotoxins	No; generally no need
Sea anemone (*Anemonia sulcata*)	Sting	Neurotoxins	No; generally no need
Scorpionfish (Scorpaenidae)	Sting puncture	Hemolysins, necrotoxins?	Yes (CSL, Ltd.)
Lionfish (Scorpaenidae)	Sting puncture	Hemolysins, necrotoxins?	No
Stonefish (Scorpaenidae)	Sting puncture	Hemolysins, necrotoxins?	Yes (CSL, Ltd)
Weeverfish (Trachinidae)	Sting puncture	Hemolysins, necrotoxins?	No
Stingrays (Rajiformes)	Sting puncture	Uncertain	No
Dinoflagellates	Ingestion (found in seafood)	Ciguatera poisoning	No
Gambierdiscus toxicus	Ingestion (found in fish)	Ciguatoxins, maitotoxin (neurotoxins)	No
Ptychodiscus brevis	Ingestion (found in shellfish)	Neurotoxic shellfish poisoning, neurotoxins	No
Gonyaulax species	Ingestion (found in shellfish)	Paralytic shellfish poisoning	No
Pyrodinium species	Ingestion (found in shellfish)	Saxitoxin, neosaxitoxin, and gonyautoxin	No
Jania species	Ingestion (found in shellfish)	Okadaic acid (phosphatase inhibitors)	No
Pufferfish (Tetraodontiformes)	Ingestion	Tetrodotoxin (neurotoxin)	No
Porcupinefish (Tetraodontiformes)	Ingestion	Tetrodotoxin (neurotoxin)	No
Sunfish (*Mola* species)	Ingestion	Tetrodotoxin (neurotoxin)	No

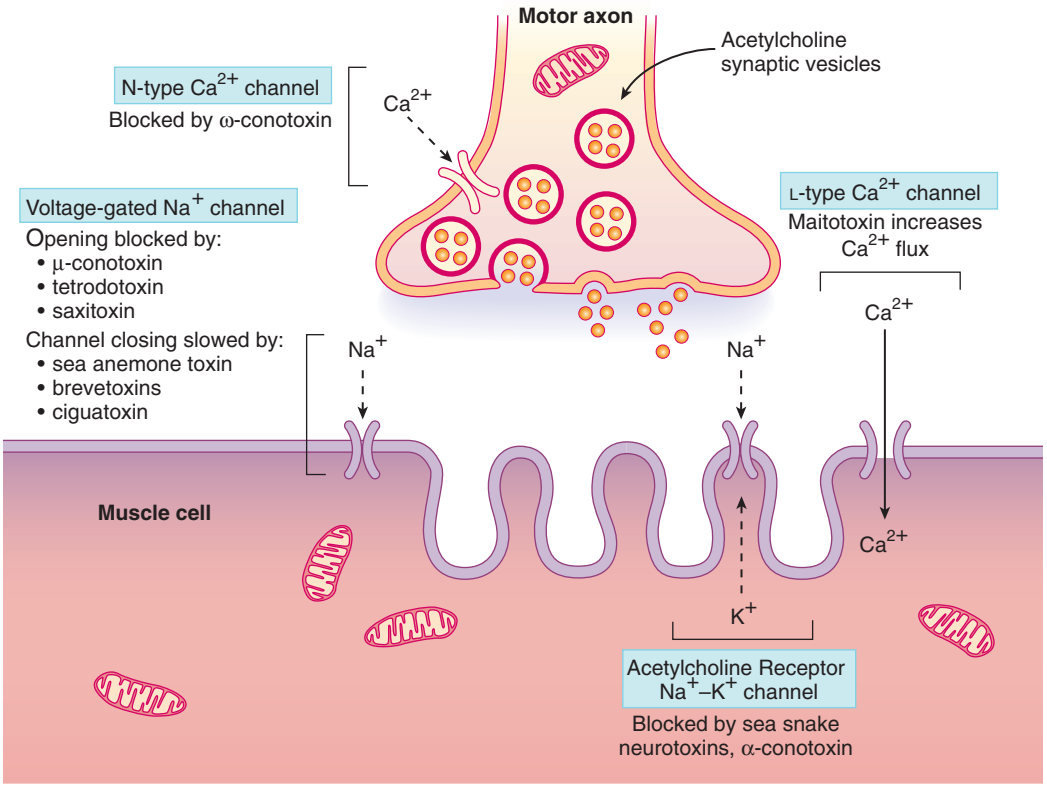

FIGURE 114-1. Schematic representation of a motor axon synapse and the sites of action of various marine neurotoxins.

be necessary to extract the spine and cleanse the wound. A sting produces severe pain and edema, which in extreme cases is accompanied by hemorrhage, syncope, vomiting, hypotension, and cardiac arrhythmias. In rare cases, death can occur, especially if the pericardial, peritoneal, or pleural cavities are penetrated. Soaking the wound in hot water inactivates some of the heat-labile toxins in the venom.

Mollusca

Cone Snails

Cone snail (Conidae) venom is injected into victims through a hollow, harpoon-like tooth. The venom, which is primarily neurotoxic, causes paresthesias, hypotension, and respiratory impairment or failure. Fourteen superfamilies of conopeptide toxins have been identified in cone snail venom:

A, I, M, O, P, S, T, I2, J, L, O2, O3, V, and Y. All of the conopeptides are short polypeptides that demonstrate a variety of neurotoxic actions by targeting specific subtypes of ion channels, neurotransmitter receptors, or transporters (see Fig. 114-1). The bite is very painful and may be followed by systemic symptoms such as dysphagia, aphonia, pruritus, blurred vision, syncope, muscular paralysis, and respiratory and cardiac failure. Treatment is supportive; in cases of severe envenomation, preparation for cardiovascular and respiratory support should be made. Rare cases of coagulopathy have been reported, and fatal envenomation has occurred.

Octopuses

The two species of blue-ringed octopuses (*Hapalochlaena maculosa* and *Hapalochlaena lunulata*), found in Australian waters, inject their venom by a relatively painless bite that produces two small puncture wounds. Hemorrhage at the site may occur. The major toxic component in the venom is tetrodotoxin, a neurotoxin that blocks action potentials of voltage-activated sodium channels and causes perioral and intraoral paresthesias, dysphagia, nausea, ataxia, aphonia, flaccid muscular paralysis, and respiratory distress or failure. Fatal envenomation has occurred, and urgent respiratory support may be required in severe cases.

Cnidaria

Jellyfish and Anemones

Jellyfish and anemones belong to the Cnidaria phylum, so named because of their venomous organelles called *cnidae*. The cnidae found in jellyfish and anemones (called *nematocysts* and *spirocysts*, respectively) are located on exposed tentacles. On tactile stimulation, the tentacles send forth a tethered projectile to deliver venom through the dermis. As the victim's surrounding musculature contracts, the venom is disseminated. Hemolysins, DNAase, and histamine releasers have been identified in some venoms. A number of peptide toxins of sea anemones mostly function by binding to sodium channel receptor site 3 to delay the inactivation phase of the channel. Other peptide toxins from anemones target the Kv3 potassium channel.

Stings by jellyfish and anemones typically produce immediate pain at the site of envenomation, followed by erythematous and urticarial lesions. Anaphylaxis is not common unless the patient has previously been sensitized. Depending on the severity of the sting, wheals and whiplike patterns may appear at the sites of envenomation within a few minutes or be delayed by several hours, followed in some cases by dermal necrosis. Eruptions sometimes recur days after the envenomation. Systemic reactions may include muscle spasms and cramps, vomiting, nausea, diarrhea, diaphoresis, and, in rare cases, cardiorespiratory failure.

Unfired nematocysts on tentacles adhering to the skin may be neutralized by vinegar or baking soda, depending on the species of jellyfish. Vinegar appears to be most useful for Australian blue bottle *(Physalia utriculus)* stings, whereas baking soda appears more efficacious for sea nettle *(Chrysaora quinquecirrha)* stings.

The box jellyfish *(Chironex fleckeri)* found in Australian waters is perhaps the most venomous jellyfish; it produces very severe stings that may cause death from hypotension, muscular and respiratory paralysis, and ultimately, cardiac arrest. Treatment of box jellyfish stings may require respiratory support and administration of antivenom.

The Portuguese man of war (*Physalia physalis*) is not a true jellyfish, and its venom differs from true jellyfish. It stings through nematocysts that cause intense pain and, occasionally, an allergic reaction. Flushing with salt water (sea water) followed by application of heat may ease the pain.

Sponges

Some sponges colonized by coelenterates produce toxins that can cause a pruritic, allergic dermatitis or an irritant dermatitis. These toxins are delivered by the sharp spicules, which penetrate the dermis. The toxins can cause the typical sponge diver's disease, which is characterized by local burning and itching and may be accompanied by soft tissue edema and purulent vesiculation. Serious illness is rare.

Corals

Fire coral *(Millepora alcicornis)* is found in shallow tropical waters. Stings are a common consequence of brushing or rubbing against the coral. Envenomation produces a burning or stinging sensation, followed by severe pruritus. Edematous wheals may develop but generally dissipate over the course of several days. The site of envenomation should be soaked in vinegar (5% acetic acid) or 70% isopropanol to relieve pain.

Annelida

Bristle worms

Bristle worms are segmented invertebrates found in tropical Pacific waters and the Gulf of Mexico. The bristles can penetrate the skin and produce severely painful envenomation, with pruritus and burning that may persist for several days. Local paresthesia is typical and may linger for weeks. Treatment is symptomatic, with consideration of possible tetanus infection (Chapter 304). Little is known regarding the chemistry of bristle worm venom.

Echinodermata

Sea Urchins

Of the echinoderms, sea urchins and sea stars are responsible for most stings in humans. The venom is delivered by the long spines and pedicellaria protruding from the sea urchin body. The spines are covered at the tips with a venom sac that is broken when it penetrates the skin. The pedicellaria, present on some species of sea urchins, are pincer-like appendages carrying venom glands. The toxins of sea urchin venom are not well characterized. Stings can produce pain, hemorrhage, aphonia, paresthesias, paralysis, hypotension, nausea, syncope, and respiratory distress. Immersion in hot water helps inactivate heat-labile toxins in the venom. Attached pedicellaria and embedded spines must be removed to prevent additional envenomation and infection.

POISONOUS MARINE ORGANISMS

Unlike envenomation, marine poisoning nearly always results from consumption of fish or shellfish that have accumulated various toxins from dinoflagellates. Most marine poisonings cause neurologic and gastrointestinal effects associated with the specific toxins found in the food source. Diagnosis is clinical, based on the type of fish ingested and the clinical symptoms presented. Neurotoxic marine poisoning is generally caused by one of six different toxins.

Neurotoxic Marine Toxins

Ciguatoxins

Ciguatoxins are occasionally found in reef fish of the Caribbean and Pacific. These toxins are cyclic polyethers that act as excitatory agents by binding to sodium channels. Maitotoxin, from the same dinoflagellate, is a water-soluble polyether that acts by enhancing calcium entry through L-type calcium channels. Symptoms of ciguatera poisoning generally appear within 2 to 12 hours after the ingestion of contaminated fish. Gastrointestinal symptoms, including diarrhea, abdominal pain, nausea, and vomiting, appear first, followed by neurologic and cardiovascular symptoms. Neurologic symptoms include aphonia, dental dysesthesias, fatigue, tremor, ataxia, pruritus, extremity and perioral dysesthesia, vertigo, headache, myalgia, arthralgia, temperature reversal, and hyporeflexia. Cardiovascular symptoms, such as bradycardia and hypotension, are less common. Treatment of ciguatera poisoning is supportive, with symptom-based therapy as indicated. Death from ciguatera poisoning is rare.

Tetrodotoxin

Pufferfish (i.e., blowfish, balloonfish, and toadfish), porcupinefish, and sunfish (*Mola* species) have a very potent toxin, tetrodotoxin, in their livers, gonads, intestines, and skin. The flesh of the fish (fugu) is a delicacy in Japan, where it is prepared by specially trained chefs to avoid serving significant amounts of toxins. Tetrodotoxin is a heterocyclic compound that binds at voltage-sensitive sodium channels to block sodium-channel conduction, thereby preventing nerve and muscle action potentials and resulting in paralysis. Symptoms occur rapidly (several minutes to several hours), beginning with circumoral paresthesias and progressing to descending widespread paresthesias. After the initial paresthesias, additional symptoms soon follow, including ataxia, weakness, aphonia, diaphoresis, excess salivation, dyspnea, dysphagia, weakness, and respiratory distress or failure. Gastrointestinal symptoms include nausea, vomiting, and diarrhea. Coagulopathies also may develop. Respiratory intervention is crucial because of the potential for complete flaccid paralysis. Without respiratory assistance, death is not unusual with severe intoxication.

Palytoxin

Palytoxin is an extremely potent toxin produced in sea anemones (*Palythoa* species) and accumulated in sharks, crabs, and marine turtles. The toxin functions by targeting sodium-potassium ion pumps, thereby disrupting ion

gradients. Symptoms include tachycardia, hemolysis, and angina-like chest pain. Treatment is generally symptomatic and supportive.

Saxitoxin and Gonyautoxin

Paralytic shellfish poisoning is typically associated with the ingestion of mussels, clams, and oysters. The two toxins associated with this poisoning, saxitoxin and gonyautoxin, are produced by marine microalgae dinoflagellates that are associated with harmful algal blooms, such as "red tides," and are then accumulated in bivalve shellfish to give rise to "paralytic" shellfish poisoning. The primary paralytic shellfish poisoning toxins are heterocyclic compounds that block nerve and muscle action potentials by binding to sodium channels at the same site as tetrodotoxin, thereby resulting in paralysis.

Paralytic shellfish poisoning, which is significantly more severe than neurotoxic shellfish poisoning, predominantly involves neurologic symptoms with less pronounced nausea, vomiting, or diarrhea. Symptoms appear soon after the consumption of contaminated shellfish (minutes to hours), beginning with circumoral and extremity paresthesias. Additional neurologic symptoms such as ataxia, arthralgia, dysphagia, dysmetria, diaphoresis, and tachycardia soon follow the initial paresthesias. Respiratory depression or failure can result in death, usually within 12 hours of the onset of symptoms. As with other shellfish poisoning, therapy is supportive, with close attention to potential respiratory distress or failure.

Brevetoxins

Neurotoxic shellfish poisoning is caused by eating shellfish that contain brevetoxins, which are produced by the annual blooms of the red tides that are associated with the dinoflagellate *Karenia brevis*. Brevetoxins are cyclic polyethers that function similarly to ciguatoxins. Gastrointestinal and neurologic symptoms of intoxication appear within 3 hours after toxic shellfish is eaten and are similar to those of ciguatera poisoning. Treatment is supportive. No deaths have been reported after neurotoxic shellfish poisoning.

Domoic Acid

Domoic acid is a neurotoxin produced by the algae *Nitzschia* during harmful algae blooms and causes amnesic shellfish poisoning following ingestion of contaminated shellfish. The toxin disrupts neuron function by altering calcium influx into cells. Symptoms include headaches, dizziness, loss of short-term memory, confusion, seizures, and coma. After about 24 hours, gastrointestinal symptoms may include diarrhea, vomiting, and abdominal cramping. Death is rare.

Non-neurotoxic Poisoning

Histamine

Scrombroid fishes, such as mackerel, bonito, and tuna, can contain an inordinate amount of histamines in their tissues as a result of bacterial destruction of fish proteins associated with spoilage. Ingestion of spoiled fish with high histamine concentrations can result in pseudoallergic symptoms such as diarrhea, flushing, headache, rash, and vomiting. A metallic taste in the mouth may be reported by some patients. Treatment usually is not necessary for scombrotoxic fish poisoning, and the symptoms usually resolve in several hours. For more severe cases, antihistamines or epinephrine have been reported to be effective.

RHABDOMYOLYSIS

FRANCIS G. O'CONNOR AND PATRICIA A. DEUSTER

DEFINITION

Rhabdomyolysis, an acute, potentially fatal clinical syndrome, reflects the dissolution and disintegration of striated muscle, with the release of muscle cell contents into the systemic circulation. Myoglobinemia and myoglobinuria are common. Skeletal muscle destruction can cause systemic effects mediated by substances released from affected muscle cells (e.g., myoglobin, calcium, potassium). Prerenal azotemia, complicated by the toxicity of free myoglobin on the renal tubules, may lead to acute renal failure, which exacerbates other metabolic abnormalities. At the extreme, arrhythmias, caused by the release of intracellular potassium and organic acids, coupled with hypocalcemia may be fatal.

EPIDEMIOLOGY

Approximately 26,000 hospitalized cases of rhabdomyolysis are reported each year in the United States. Rhabdomyolysis, which precipitates acute kidney injury in 13 to 67% of affected individuals, accounts for 5 to 10% of all cases of acute renal failure in the United States.

ETIOLOGY

Rhabdomyolysis is a complex and multifactorial clinical disorder, with multiple potential inherited and acquired causes (Table 115-1). In urban adults, alcohol (and other drug) abuse, muscle compression, and status epilepticus are common causes of rhabdomyolysis. In pediatric patients, the most common cause is trauma, followed by nonketotic hyperosmolar coma, viral myositis, dystonia, and malignant hyperthermia. However, exercise-induced rhabdomyolysis from repetitive exercise is also a concern in children. Importantly, children and adolescents with recurrent rhabdomyolysis are increasingly being recognized as possibly having inherited metabolic disorders.

Drugs and Intoxications

Among intoxications, which are a common cause of rhabdomyolysis, the most frequent illegal drug-associated causes are cocaine and heroin (Chapter 33), with nearly 20% of cocaine overdoses complicated by rhabdomyolysis. Other substances that can induce rhabdomyolysis include ethanol (Chapter 32), amphetamines, phenylalkylamine derivatives, caffeine, and statins. Statins (Chapter 213) may result in myalgias in up to 10% of patients receiving treatment, but reported rates of statin-induced rhabdomyolysis are only 0.1 to 0.2 cases per 1000 person years.

Exertional Rhabdomyolysis

Rhabdomyolysis can also be a consequence of excessive exertion, prolonged heat exposure (Chapter 109), coexisting sickle cell trait (Chapter 166), and the use of dietary supplements (e.g., ephedra). In one series, 35 of 225,000 emergency department visits to an urban tertiary care center were for exertional rhabdomyolysis. The average creatine kinase (CK) level was 40,000 U/L, but no patient developed acute renal failure. In another series, 57% of participants in an ultramarathon had evidence of myoglobinemia, but none progressed to acute renal failure. Rhabdomyolysis has also been diagnosed in other sports settings (e.g., baseball, football, track, wrestling), but none with a higher frequency than that seen with endurance events.

In the military, acute exertional rhabdomyolysis occurs in 2 to 40% of individuals undergoing basic training, usually within the first 6 days. Resolution of myoglobinuria typically occurs within 2 to 3 days, with clinical improvement within 1 week. Consistent risk factors are low levels of physical fitness and early introduction of repetitive exercises (e.g., squats, push-ups, sit-ups). Although most cases are self-limited, with no long-term evidence of renal or muscle injury, patients who demonstrate systemic signs, generalized clinical findings, or acute renal failure often have an underlying metabolic myopathy. Importantly, 25% of all cases of heatstroke in the military between 1980 and 2000 were associated with rhabdomyolysis; acute renal failure developed in 33%. A retrospective review of deaths in a military basic trainee

TABLE 115-1 INHERITED AND ACQUIRED CAUSES OF RHABDOMYOLYSIS

INHERITED	ACQUIRED
Glycolytic/glycogenolytic, e.g., McArdle's disease (myophosphorylase deficiency)	Exertion, e.g., exercise, status epilepticus, delirium, electrical shock, status asthmaticus, cardiopulmonary resuscitation (see also Table 115-2)
Fatty acid oxidation, e.g., carnitine palmitoyltransferase II deficiency	Crush, e.g., external weight, prolonged immobility, bariatric surgery
Krebs cycle, e.g., aconitase deficiency	Ischemia, e.g., arterial occlusion, compartment syndrome, sickle cell disease, disseminated intravascular coagulation
Pentose phosphate pathway, e.g., glucose-6-phosphate dehydrogenase deficiency	Extremes of body temperature, e.g., fever, exertional heatstroke, burns, malignant hyperthermia, hypothermia, lightning
Purine nucleotide cycle, e.g., myoadenylate deaminase deficiency	Metabolic, e.g., hypokalemia, hypernatremia or hyponatremia, hypophosphatemia, pancreatitis, diabetic ketoacidosis, renal tubular acidosis, hyperthyroidism or hypothyroidism, nonketotic hyperosmolar states
Mitochondrial respiratory chain, e.g., succinate dehydrogenase deficiency	Drugs or toxins, e.g., anticholinergics, amphetamines, antihistamines, arsenic, ethanol, opiates, statins, cocaine, succinylcholine, halothane, corticosteroids, cyclosporine, itraconazole, phenothiazines
Malignant hyperthermia susceptibility, e.g., familial malignant hyperthermia (*RyR1*) mutations, myotonic dystrophy, Duchenne's and Becker's dystrophies	Infections, e.g., Epstein-Barr virus, human immunodeficiency virus, herpes simplex, influenza A and B, *Borrelia burgdorferi*, tetanus
Other, e.g., familial recurrent myoglobinuria	Inflammatory and autoimmune disorders, e.g., polymyositis, dermatomyositis

population found an increased risk for nontraumatic exertional sudden death in African Americans with sickle cell trait.

The extreme exertion characteristics of military service carry over to the population of correctional inmates and civil servants. Reports indicate that unsupervised repetitive exercise in prison populations has led to exertional rhabdomyolysis. Among New York City firefighters, 32 of 16,506 candidates (0.2%) were hospitalized for rhabdomyolysis after a physical fitness test, with 4 requiring hemodialysis. In a group of 50 prospective police officers from Massachusetts, 13 trainees were hospitalized with rhabdomyolysis and CK levels greater than 32,000 U/L; 6 required dialysis, and 1 died 44 days later as a result of complications of heatstroke, rhabdomyolysis, and renal and hepatic failure.

PATHOBIOLOGY

Pathophysiology

The final common pathway for all cases of rhabdomyolysis is destruction of muscle cells as a result of direct or indirect injury, with displacement of their intracellular contents into extracellular fluid, the circulation, or both (Fig. 115-1). Cell function is critically dependent on the relationship between intracellular calcium (Ca^{2+}) and sodium (Na^{+}) concentrations. Sarcolemmal Na^{+}, K^{+}-ATPase regulates extracellular Ca^{2+} concentrations by exchanging Na^{+} for Ca^{2+} across the sarcolemma. A low intracellular Na^{+} concentration creates a gradient that actively results in efflux of Ca^{2+} as it is exchanged for Na^{+} ions. This process maintains intracellular Ca^{2+} levels at several orders of magnitude lower than extracellular Ca^{2+}.

When the cell is subjected to mechanical stress, stretch-activated channels in the sarcolemma can open and cause an influx of Na^+ and Ca^{2+}. With excessive intracellular Ca^{2+}, several pathologic processes begin. Excessive intracellular Ca^{2+} results in persistent contraction of myofibers, depletion of adenosine triphosphate (ATP), production of free radicals, activation of vasoactive molecules, release of proteases, and, ultimately, cell death. Cell death is followed by an invasion of neutrophils, which amplify the damage by further release of proteases and increased production of free radicals. Rather than simple necrosis, a self-sustaining, inflammatory myolytic reaction develops.

Rhabdomyolysis can be further complicated by reperfusion injury and compartment syndrome. In reperfusion injury, ischemia for a prolonged period is followed by restoration of vascular flow. The increase in blood flow results in the delivery of activated neutrophils in combination with an abundance of oxygen, which contributes to the development of highly reactive free radicals. Because most muscle groups are contained within rigid fascial compartments, rhabdomyolysis can quickly precipitate a secondary acute compartment syndrome. The swelling associated with traumatized tissue can also lead to increased intracompartmental pressure, which can provoke additional damage by compromising both venous and arterial blood flow. Thus, compartment syndrome can also lead to rhabdomyolysis.

Inherited and Acquired Rhabdomyolysis

Rhabdomyolysis can be classified into two major categories: inherited and acquired (see Table 115-1). Metabolic myopathies, though not the most common cause, should be carefully considered in patients who have recurrent episodes triggered by low levels of stress or exertion. A number of pathways that lead to the formation of ATP can be disrupted by genetic defects (e.g., inherited disorders of glycogenolysis, glycolysis, and lipid and purine metabolism). In one series of 77 patients who underwent biopsy for idiopathic myoglobinuria, 47% were found to have enzymatic defects. The most common disorders were deficiencies of carnitine palmitoyltransferase II and myophosphorylase.

Inherited Rhabdomyolysis

Malignant hyperthermia is a potentially fatal, heterogeneous, pharmacogenetic disorder triggered by volatile anesthetics in predisposed individuals (Chapter 440). The disorder is most commonly inherited in an autosomal dominant pattern. Evidence from molecular studies indicates that 25% of patients who are susceptible to malignant hyperthermia have mutations in the ryanodine receptor (*RyR1*) gene, which is responsible for coding proteins for one of the primary Ca^{2+} release channels involved in triggering muscle contraction. When a susceptible patient is exposed to a triggering agent, excessive release of Ca^{2+} into the myoplasm leads to a hypermetabolic state manifested by hypercapnia, tachycardia, and metabolic acidosis. Whether the genetic predisposition to malignant hyperthermia is related to exertional rhabdomyolysis and exercise-induced heat injury has not been proved.

Acquired Rhabdomyolysis

DRUGS AND TOXINS. Drugs and toxins, also common causes of rhabdomyolysis, operate through a number of mechanisms, including direct membrane toxicity (e.g., herbicides), indirect metabolic derangements (e.g., anticholinergics), ischemia (e.g., cocaine), and agitation (e.g., hemlock). The most commonly cited drugs precipitating rhabdomyolysis are alcohol, statins, cocaine, amphetamines, and phenothiazines. Alcohol can induce rhabdomyolysis through a combination of mechanisms, including immobilization, direct myotoxicity, and electrolyte abnormalities. Statins, which inhibit 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, can be directly myotoxic and appear to trigger sustained increases in intracellular Ca^{2+}. Although the precise mechanisms underlying statin-induced myopathy are currently incompletely understood, it can be aggravated by the concomitant administration of cytochrome P-450 3A4 inhibitors (e.g., itraconazole, erythromycin, cyclosporine, danazol) and fibrates, as well as by physical exercise, excessive alcohol intake, and preexisting comorbid medical conditions. Amphetamines and phenothiazines may lead to a clinical picture of rhabdomyolysis through the serotonin syndrome (Chapter 442) and the neuroleptic malignant syndrome (Chapter 427), respectively.

INFECTIONS. Both viral and bacterial infections can trigger rhabdomyolysis. Either cellular invasion or generation of various toxins may precipitate infection-induced rhabdomyolysis by the virus or bacterium. Influenza A and B (Chapter 372) are the most common viral causes, followed by human immunodeficiency virus (Chapter 394), coxsackievirus (Chapter 387), and Epstein-Barr virus (Chapter 385). The most common bacterial organisms that induce rhabdomyolysis are *Legionella* species (Chapter 322), followed by *Francisella tularensis* (Chapter 319) and *Streptococcus pneumoniae* (Chapter 297). Acute renal failure develops in approximately 57% (33 to 100%) of bacterial cases and 34% (0 to 100%) of viral cases of rhabdomyolysis.

TRAUMA. Trauma is traditionally thought of as the principal cause of rhabdomyolysis. Wars, natural disasters, and traffic and occupational accidents are frequent causes of trauma-induced "crush injury syndrome" (Chapter 112). Other less common causes of trauma- or compression-induced rhabdomyolysis include struggling against restraints, direct blows, child abuse, torture, prolonged immobilization (e.g., anesthesia, coma, drug- or alcohol-induced stupor), and bariatric and other forms of surgery. The primary mechanism of crush syndrome and compression-induced rhabdomyolysis is reperfusion of damaged tissue after a period of ischemia.

Exertional rhabdomyolysis can result from excessive exercise in fit and unfit individuals, particularly eccentrically based activities (lengthening contractions, such as lowering a weight), but it can also be triggered by exertion in combination with thermal stress, sickle cell trait, altitude, or the use of medications (e.g., anticholinergics) or ergogenic substances (e.g., caffeine, ephedra). Exertional rhabdomyolysis may also reveal or provide evidence of an underlying inherited disorder in certain individuals. The spectrum of exertional rhabdomyolysis is broad and can range from a subclinical event to catastrophic collapse and death. The underlying mechanisms may be either mechanical or metabolic in nature, but exertional rhabdomyolysis is associated with elevated myoplasmic Ca^{2+} concentrations.

A number of genetic mutations (Table 115-2) have been identified in association with metabolic myopathies, with exercise usually precipitating the rhabdomyolysis. Multiple mutations in the carnitine palmitoyltransferase II and myophosphorylase genes have been found, and although each mutation has been associated with exercise-induced myoglobinuria, the mutations alone may not explain the clinical episodes. Mutations in the *RyR1* gene, which are common in malignant hyperthermia (Chapter 440), have also been noted in persons with exertional rhabdomyolysis. Two single-point mutations in the gene coding for skeletal muscle myosin light chain kinase (*C37885A* and *C49T*) have been associated with an exaggerated CK response to an exercise challenge, but the role of these mutations in exertional rhabdomyolysis is not known. Yet to be identified are genes that can be used clinically to predict susceptibility to infection-, toxin-, exertion-, or drug-induced rhabdomyolysis.

CLINICAL MANIFESTATIONS

The classic manifestation of rhabdomyolysis includes acute myalgia and pigmenturia as a result of myoglobinuria in association with elevated serum muscle enzymes (CK in particular). Many clinical features are nonspecific, however, and the course and initial signs, symptoms, and laboratory abnormalities are clearly dependent on the underlying cause and severity of the event.

TABLE 115-2 GENETIC MUTATIONS ASSOCIATED WITH EXERTIONAL RHABDOMYOLYSIS

GENE	
Ryanodine receptor 1	*RyR1*
Myoadenylate deaminase	*AMPDA1*
Carnitine palmitoyltransferase II	*CPT2*
Myophosphorylase	*PYGM*
Phosphofructokinase	*PFKM*
Phosphorylase *b* kinase	*PHKA1*
Very long chain acyl coenzyme-A dehydrogenase	*ACAD9*
Phosphoglycerate mutase	*PGAMM*
Phosphoglycerate kinase	*PGK1*
Lactate dehydrogenase	*LDHA*
Cytochrome *c* oxidase	*COX I, II,* and *III*
Cytochrome *b* (complex III)	*CYTB*
Mitochondrial tRNA	*Mt-tRNA*
β-Sarcoglycan	*SGCB*

Rhabdomyolysis can be accompanied by both local and systemic features. Local features, generally noted in the area of the traumatized muscle groups, can occur within hours of the trauma and include muscle pain, tenderness, and swelling. Systemic features include tea-colored urine, chills, fever, and malaise. In extreme cases, patients complain of nausea and vomiting and demonstrate confusion, agitation, or delirium. Whenever systemic features such as chills, fever, malaise, or generalized muscular involvement are observed, an underlying metabolic myopathy should be considered.

Clinical findings may also include compartment syndrome, which can occur in muscle groups encased by fascia, especially the lower leg, forearm, and thigh muscle groups. Sensory abnormalities caused by nerve compression are an early manifestation of compartment syndrome; the loss of a pulse as a result of vascular compromise is a later finding. If compartment syndrome is not addressed within 6 to 8 hours, irreversible ischemic muscle and nerve damage may occur.

Laboratory findings are related to the degree of muscle involvement. Early findings include elevated blood levels of CK, myoglobin, potassium, urea, and phosphorus. CK levels typically peak 2 to 5 days after the initial insult; levels higher than 16,000 U/L are more likely to be associated with renal failure than are lower levels. Hypocalcemia, caused by the influx and deposition of Ca^{2+} in damaged muscle tissue, may accompany rhabdomyolysis. Moreover, an anion gap metabolic acidosis may develop because of the release of organic acids from damaged muscle. With resolution of rhabdomyolysis, sequestered Ca^{2+} may be released back into the circulation and cause hypercalcemia.

DIAGNOSIS

Creatine Kinase Levels

A diagnosis of rhabdomyolysis is made when there is clinical evidence of myonecrosis and release into the systemic circulation of muscle cell contents, including myoglobin, creatinine, CK, organic acids, potassium, aldolase, lactate dehydrogenase, and hydroxybutyrate dehydrogenase. The skeletal muscle subtype CK-MM is abundantly present in skeletal muscle and released as a result of muscle destruction. Serum levels exceeding 100,000 U/L are not uncommon with rhabdomyolysis. Because CK remains in the circulation longer than myoglobin does and can be detected clinically both easily and efficiently, it is the most frequently used marker to diagnose rhabdomyolysis. No universally accepted clinical or laboratory definition of rhabdomyolysis currently exists, but CK elevations ranging from more than 5 times to more than 50 times the upper limits of normal, as well as varying requirements for serum creatinine elevation, have been proposed. Importantly, gender, ethnicity, and baseline physical activity levels all affect individual baseline CK levels. African American males and young athletic men have the highest baseline CK levels, and non–African American women have the lowest. Thus, gender, ethnicity, and prior activity must be considered when using CK for the diagnosis of rhabdomyolysis. In general, CK levels in excess of 5 times normal, with the appropriate clinical presentation, are accepted as evidence of muscle breakdown, which may be consistent with a diagnosis of rhabdomyolysis.

Myoglobin Testing

Because myoglobinuria does not occur in the absence of rhabdomyolysis, myoglobin should be the best marker and the diagnostic cornerstone. However, testing for serum or urine myoglobin is problematic and is not always consistent. Myoglobin is normally bound to plasma globulins; therefore, only a small fraction reaches the glomeruli. In the presence of severe muscle damage, blood levels of myoglobin overwhelm the binding capacity of the circulating proteins, so free myoglobin reaches the glomeruli and eventually the renal tubules. Elevations in serum myoglobin occur before the rise in serum CK, but the elimination kinetics of serum myoglobin is more rapid than that of CK, which makes the often evanescent rise in serum myoglobin a less reliable marker of muscle injury. Furthermore, the liver can quickly metabolize myoglobin. Diagnostic tests for urine myoglobin are often not readily available; in addition, it may take more than 24 hours to obtain results, and urine myoglobin is not an accurate predictor of acute kidney injury. Nevertheless, urine screening for rhabdomyolysis may be performed by dipstick if the urine sediment is also examined. The orthotoluidine portion of the dipstick turns blue in the presence of hemoglobin or myoglobin, so if the urine sediment does not contain erythrocytes, one can assume, in the appropriate clinical setting, that a positive dipstick reading reflects the presence of myoglobin. Other associated laboratory findings in acute rhabdomyolysis can include hypocalcemia or hypercalcemia, hyperphosphatemia, metabolic (lactic) acidosis, thrombocytopenia, and disseminated intravascular coagulation.

Differential Diagnosis

The clinical findings of acutely swollen muscles or muscle weakness (or both) with reddish brown urine are not always the result of rhabdomyolysis, and the examining clinician must be careful to scrutinize all information. The differential diagnosis includes disorders that may indirectly affect myocytes, such as Guillain-Barré syndrome and periodic paralysis. Guillain-Barré syndrome (Chapter 428) is distinguished from rhabdomyolysis in that it is characterized as a fulminant polyneuropathy, usually after an antecedent viral infection. Periodic paralysis (Chapter 429) is frequently associated with transient electrolyte disturbances and is distinguished from rhabdomyolysis in that most cases follow periods of rest or sleep.

Myoglobinuria causes the urine to be reddish brown, but tea-colored (or cola-colored) urine does not necessarily indicate the presence of myoglobin. Other conditions associated with discoloration of urine include hemoglobinuria from hemolysis, intrinsic renal disease, porphyria, acute glomerulonephritis, "athletic pseudonephritis," or external factors such as ingestion of beets and various drugs (e.g., phenytoin, rifampin, vitamin B_{12}).

The diagnosis of rhabdomyolysis is complete when the clinician determines the cause. This step, though frequently established during the history and physical examination, may require further diagnostic assessment after initiating clinical treatment during the acute phase. Clinical issues that are both controversial and poorly defined include which patients warrant further testing and what tests to perform. Individuals with recurrent rhabdomyolysis, a positive family history of rhabdomyolysis or malignant hyperthermia, low exercise tolerance, no apparent cause, or a fulminant or explosive form of rhabdomyolysis appear to warrant further testing.

Testing may include a nonischemic forearm test, which involves isometric exercise at 70% of maximal voluntary contraction for 30 seconds under nonischemic conditions; electromyography; blood tests for muscle enzymes (e.g., mitochondrial myopathies [Chapter 429], fatty acid transport defects [Chapter 429], glycogen storage diseases [Chapter 214], diseases associated with myoglobinuria); muscle biopsy to investigate specific metabolic myopathies and other enzyme or genetic defects; or any combination of such testing. The forearm exercise test may help identify metabolic and genetic causes of rhabdomyolysis. Patients who have had an episode of malignant hyperthermia or exertional heat illness may be candidates for a caffeine halothane contracture test, which evaluates the force produced in small muscle biopsy samples after exposure to caffeine and separate exposure to halothane in the laboratory. Isolated, perfused muscle fibers must show an increase in tension of at least 0.2 g when exposed to 2 mM of caffeine or at least 0.7 g of tension after exposure to 3% halothane. Additionally, genetic investigation for mutations of the *RyR1* receptor gene may be warranted.

PREVENTION

Approaches for preventing rhabdomyolysis induced by infections, medications, toxins, heat stress, or exercise may emerge in the future, but no definitive guidelines can be presented at this time. To prevent further muscle injury, blood flow to ischemic areas must be promptly restored to minimize ischemia-reperfusion damage. Administration of free radical scavengers to prevent rhabdomyolysis may prove useful in the future.

TREATMENT Rx

Treatment of rhabdomyolysis begins with a careful history and physical examination to identify and manage any underlying illness; it then focuses on preserving renal function. All patients require aggressive early management because it is difficult to stratify risk initially (Table 115-3). Careful observation plus treatment of potential early and late complications is critical. Accordingly, vital signs, urine output, serial electrolyte levels, and CK levels should be obtained as soon as possible. Intensive care monitoring may be required, depending on the clinical situation.

Hydration

Hydration is the cornerstone of preserving renal function in patients with rhabdomyolysis. Providing fluids addresses the early threats to survival: hypovolemic shock and hyperkalemia. Currently, there is no way to accurately predict or stratify overall risk or risk of acute renal failure among patients with rhabdomyolysis, but CK levels greater than 15,000 U/L are thought to portend an increased risk. Patients with mild symptoms and serum CK levels less than 3000 U/L are considered to be at low risk and may be treated as outpatients with hydration, limited physical activity, and careful follow-up. Victims of collapse, trauma, or exertional heat injury, or patients who demonstrate moderate early symptoms with more than mild elevations in CK or abnormal

TABLE 115-3 STEPS IN THE PREVENTION AND TREATMENT OF RHABDOMYOLYSIS-INDUCED ACUTE KIDNEY INJURY

Check for extracellular volume status, central venous pressure, and urine output.*
Measure serum creatine kinase levels. Measurement of other muscle enzymes (myoglobin, aldolase, lactate dehydrogenase, alanine aminotransferase, aspartate aminotransferase) adds little information relevant to diagnosis or management.
Measure levels of plasma and urine creatinine, potassium, and sodium; blood urea nitrogen; total and ionized calcium, magnesium, and phosphorus; and uric acid and albumin. Evaluate acid-base status, blood cell count, and coagulation.
Perform a urine dipstick test, and examine the urine sediment.
Initiate volume repletion with normal saline promptly at a rate of approximately 400 mL/hr (200-1000 mL/hr, depending on the setting and severity), and monitor the clinical course or central venous pressure.
Target urine output of approximately 3 mL/kg body weight/hr (200 mL/hr).
Check serum potassium levels frequently.
Correct hypocalcemia only if symptomatic (e.g., tetany, seizures) or if severe hyperkalemia occurs.
Investigate the cause of rhabdomyolysis.
Check urine pH: if it is <6.5, alternate each liter of normal saline with 1 L 5% dextrose or 0.45% saline plus 100 mmol bicarbonate. Avoid potassium- and lactate-containing solutions.
Consider treatment with mannitol (up to 200 g/day; cumulative dose up to 800 g). Check for plasma osmolality and plasma osmolal gap. Discontinue if diuresis (>20 mL/hr) is not established.
Maintain volume repletion until myoglobinuria is cleared (as evidenced by clear urine or urine dipstick test that is negative for blood).
Consider renal replacement therapy if there is resistant hyperkalemia (>6.5 mmol/L) that is symptomatic (as assessed by electrocardiography), rapidly rising serum potassium levels, oliguria (<0.5 mL of urine/kg/hr for 12 hr), anuria, volume overload, or resistant metabolic acidosis (pH < 7.1).

*In the case of the crush syndrome (e.g., earthquake, building collapse), institute aggressive volume repletion promptly before evacuating the patient.
From Bosch X, Poch E, Grau JM. Rhabdomyolysis and acute kidney injury. *N Engl J Med.* 2009;361:62-72.

metabolic panels, should be treated with intravenous hydration in an inpatient setting. Hydration is accomplished by aggressive intravenous fluid therapy with isotonic fluids at a rate that results in a urine output of 200 mL/hour until CK levels begin to decrease. When fluid resuscitation fails to correct intractable hyperkalemia and acidosis, renal replacement therapy should be considered (Chapter 122).

Specific Therapeutic Measures

Several retrospective clinical studies and case reports, as well as animal models, promote the addition of bicarbonate and mannitol, but no prospective clinical trials have been conducted to support or refute their benefit in patients with rhabdomyolysis. Alkalinization of the urine decreases cast formation, minimizes the toxic effects of myoglobin on the renal tubules, inhibits lipid peroxidation, and decreases the risk for hyperkalemia. However, this approach can cause Ca^{2+} to precipitate and be deposited in the soft tissues, as well as contributing to a hyperosmolar state. Mannitol serves as an osmotic diuretic, volume expander, and free radical scavenger; it should be used very carefully in patients with marginal cardiac function, and only after adequate renal function is established.

Despite the absence of definitive evidence in humans, both mannitol and a forced alkaline diuresis are recommended for rhabdomyolysis caused by crush syndrome when CK levels are greater than 20,000 U/L. The treatment goals are to (1) achieve a urine output of 200 mL/hour, (2) maintain urine pH between 6 and 7, (3) keep serum pH below 7.50, and (4) achieve hemodynamic stability and prevent volume overload. Fluid resuscitation begins with a bolus of 1 L of 5% dextrose plus 0.22% NaCl and 100 mEq $NaHCO_3$ over a 30-minute period, followed by an infusion at 2 to 5 mL/kg/hour. A 20% mannitol infusion at a dose of 0.5 g/kg is given over a 15-minute period, followed by an infusion at 0.1 g/kg/hour. Adjustments are made to maintain urine output above 200 mL/hour. Urinary and serum pH levels should be monitored, with acetazolamide added if the serum pH exceeds 7.45 or urinary pH remains below 6.0. However, the use of mannitol and forced alkaline diuresis in patients with crush syndrome, as well as other clinical manifestations of rhabdomyolysis, has not been tested in randomized trials.

Management of Metabolic Abnormalities

Deposition of Ca^{2+}, which occurs early in rhabdomyolysis, is directly related to the degree of muscle destruction and administration of Ca^{2+}. Reversal of hypocalcemia may in fact worsen ectopic calcification and exacerbate hypercalcemia during the resolution phase. Accordingly, hypocalcemia should be treated only when clinical symptoms, signs of tetany, or severe hyperkalemia develops.

Management of Compartment Syndrome

Compartment syndrome (Chapter 112) is a well-described late complication as well as a potential cause of rhabdomyolysis. Compartment syndrome can occur as a direct consequence of muscle injury with increased vascular permeability, aggressive fluid resuscitation, or restoration of reperfusion. When a compartment syndrome is suspected, such as when the muscles are tense and swollen or there is evidence of neurovascular compromise, compartment pressures should be measured; in the proper clinical setting, pressures in excess of 30 mm Hg should prompt consideration of fasciotomy. However, late fasciotomy (>12 hours after the onset of symptoms) may be counterproductive by converting a closed injury to an open wound, with an increased risk of uncontrollable infection. Accordingly, late fasciotomy is relatively contraindicated.

Management of Crush Injury

Management of crush injury victims (Chapter 112) is unique, in that many individuals have the opportunity to receive treatment before extrication and reperfusion. Current recommendations for on-site management of trauma victims before extrication include aggressive hydration with intravenous normal saline. In the event of massive damage, amputation of the extremity may be required to protect the patient's overall health. A Mangled Extremity Severity Score (MESS) may be used to identify nonsalvageable extremities prospectively. The MESS is a grading system based on four groups of clinical criteria, including the degree of skeletal and soft tissue injury, rating of blood pressure (shock) and pulse (ischemia), and age. Scores from each group are added to obtain a total score that ranges from 0 to 14; higher scores indicate more severe involvement, and a score of 7 or greater has a positive predictive value of nearly 100% for amputation. It is hoped that ongoing clinical trials in this population will elucidate the roles of *N*-acetylcysteine, continuous renal replacement therapy, and deferoxamine in reducing the direct toxic effects of myoglobin on the kidneys.

Malignant Hyperthermia

One cause of rhabdomyolysis that requires rapid and aggressive management is malignant hyperthermia (Chapter 440). Episodes of malignant hyperthermia occur most commonly in the operating room and are recognized by the anesthesiologist. The typical clinical features represent an uncontrolled, exaggerated, hypermetabolic state; an increase in end-tidal carbon dioxide during ventilation is the most sensitive sign. With the clinical recognition of impending malignant hyperthermia, anesthetics should be discontinued, and the patient should be treated with dantrolene sodium. The usual initial dose is 2.5 to 4 mg/kg, followed by about 1 mg/kg every 4 hours for up to 48 hours to avoid recrudescence.

PROGNOSIS

The most serious consequence of rhabdomyolysis is acute renal failure, which occurs in up to 67% of all cases, regardless of cause. Although acute renal failure may be relatively benign, the mortality rate from myoglobinuric renal failure reportedly ranges from 3 to 80%. Various clinical factors are used to predict the risk for acute renal failure, including serum CK, creatinine, potassium, and Ca^{2+}, as well as the urine myoglobin level, but no single parameter has been established. However, mortality appears to be significantly higher in patients with CK values in excess of 75,000 U/L and in those with hyperkalemia or hypocalcemia. For compartment syndrome, a poor prognosis is associated with an ischemic period lasting longer than 6 hours.

The prognosis of patients with rhabdomyolysis improves markedly when treatment is started soon after the diagnosis is made. With mild episodes, the prognosis is customarily excellent, and the patient can typically resume usual activities within several weeks after CK levels have normalized. However, some patients do not return to normal and continue to experience extreme fatigue and muscle pain on exertion. These patients require additional testing (nonischemic forearm test, electromyography, muscle disease enzyme panel, muscle biopsy) to determine whether an underlying metabolic myopathy exists. The results of these tests will help determine future recommendations, but the patient's tolerance of and response to light and more strenuous exercise are important factors.

For patients with statin-induced myopathy, deciding when to discontinue statin therapy remains controversial. However, most authorities agree that suspension should occur with either intolerable muscle symptoms or evidence of rhabdomyolysis.

FUTURE DIRECTIONS

Although a number of genetic mutations have already been defined, the prevalence of such mutations is unknown. Moreover, a genetic linkage in individuals susceptible to exertional or drug-induced rhabdomyolysis

(or both) has not been thoroughly investigated. It is likely that the greatest progress will come from prospective trials that evaluate both diagnostic and treatment modalities for myoglobinuric renal failure.

APPROACH TO THE PATIENT WITH RENAL DISEASE

DONALD W. LANDRY AND HASAN BAZARI

DIAGNOSIS

The prominent functions of the kidney include the excretion of nitrogenous waste; the regulation of the excretion of sodium, potassium, and acid; and the synthesis of a variety of hormones, including 1,25-dihydroxyvitamin D, erythropoietin, and renin. A patient can have an isolated failure in a particular function, such as in acid excretion (Chapter 120), in which case the "approach to the patient" is distinct for the isolated defect. First and foremost, however, the kidney is a filtration organ, and acute kidney injury (Chapter 122) and chronic kidney disease (Chapter 132) refer specifically to defects in the filtration function of the kidney. In the context of impaired filtration, many of the individual functions may fail.

The approximately 2 million renal glomeruli normally filter about 180 L/day. The renal glomerulus is not simply a filter, but rather a size- and charge-dependent ultrafilter that excludes not only cells but also proteins larger than 60 kD from the ultrafiltrate. Smaller proteins are variably filtered at the glomerulus and endocytosed in the proximal tubule, so that the protein concentration of the urine is normally quite low. Kidney disease reflects a failure in the quantity or quality of the glomerular ultrafiltrate.

The normal glomerular filtration rate (GFR) may decline in hours or a few days in acute kidney injury or over months and years in chronic kidney disease. An acute decline in glomerular filtration is the necessary and sufficient condition for the diagnosis of acute kidney injury, but abnormal urinary findings can assist with elucidating of the etiology of the injury. Proteinuria, ranging from microscopic to the nephrotic range (Chapter 123), and urinary findings, from a few cells per microscopic high-power field to gross hematuria or pyuria, may be the only evidence of the earliest stages of chronic kidney disease. As chronic kidney disease advances, the decline in the GFR progresses until dialysis or transplantation (Chapter 133) is required to forestall or treat the syndrome of uremia.

Serum creatinine is, to a first approximation, neither secreted nor reabsorbed, so the amount appearing in the urine per unit time is a measure of the amount that was filtered at the glomerulus during that period. As a result, the rate of creatinine clearance is, at first approximation, equivalent to the GFR. A decrement in the GFR diminishes creatinine clearance but has no immediate effect on creatinine production by muscle; as a result, the serum creatinine concentration rises. The change in serum creatinine over time indicates the tempo of the renal disease and can distinguish acute injury from chronic kidney disease. Advanced chronic kidney disease (Chapter 132) is commonly associated with anemia, renal osteodystrophy, and a small kidney size on ultrasonography, although kidney size may be normal or increased with amyloidosis or diabetes mellitus. Hyperphosphatemia, which develops within 1 or 2 weeks after acute kidney injury, is less useful as a discriminator of acute versus chronic renal injury.

The serum creatinine level is elevated in both acute and chronic kidney disease, but an actively rising serum creatinine level confirms an acute or acute-on-chronic insult to kidney function. As a blood filtration organ, the kidney is susceptible to an acute compromise of renal arterial perfusion (Chapter 127), such as prerenal kidney injury, or blockage in urine outflow, such as urinary obstruction owing to benign prostatic hypertrophy (Chapter 131). The intrarenal causes of acute kidney injury (Chapter 122) include acute tubular necrosis, acute interstitial nephritis, acute glomerulonephritis, and acute vasculitis and vascular disease. Dysmorphic red blood cells in the urine or clumps of cells in the form of the renal tubules, so-called tubular casts, suggest the site of the lesion and narrow the range of potential etiologies.

Most of the diagnoses of renal disease can be made with a careful history and physical examination supplemented by review of basic laboratory tests, especially the urinary sediment. The specificity of the diagnosis can be improved by the use of serologic analysis, imaging, and, occasionally, invasive procedures such as angiography and renal biopsy.

History

The history reviews potential factors that contribute to the development of renal disease and identifies the systemic features of diseases that may affect the kidney. These factors include the following:

- Medication use
- Family history of renal disease
- The time of onset of symptoms of renal dysfunction
- Changes in bladder function, including nocturia, polyuria, and hesitancy
- Fatigue and weakness
- Dyspnea on exertion, a manifestation of fluid overload or acidosis
- Systemic features of vasculitis

A systemic vasculitis may present in a variety of ways, with skin manifestations including petechial rash, purpura, digital gangrene, and splinter hemorrhages. Otitis, sinusitis, epistaxis, hemoptysis, and nasal septal ulcers are common manifestations of Wegener's granulomatosis (Chapter 278). Pulmonary hemorrhage can be a catastrophic manifestation of Goodpasture's syndrome (Chapter 123) or anti–glomerular basement membrane (anti-GBM) disease. Abdominal distention may be seen in nephrotic syndrome with ascites, as well as in autosomal polycystic kidney disease (Chapter 129). Abdominal pain and tenderness and gastrointestinal hemorrhage may be observed in Henoch-Schönlein purpura and classic polyarteritis nodosa (Chapter 278). Lower extremity edema is common in cirrhosis (Chapter 156), heart failure (Chapter 58), and nephrotic syndrome (Chapter 123). Neurologic symptoms may be a manifestation of vasculitis, such as microscopic polyangiitis (Chapter 278) and cryoglobulinemia (Chapter 193).

Physical Examination

The vital signs are crucial. A patient with a "normal blood pressure" may be relatively hypotensive in the setting of renovascular disease. Orthostatic hypotension may explain the acute decompensation of kidney function in a patient with chronic kidney disease (Chapter 132). Pulsus paradoxus may reflect cardiac tamponade (Chapter 77).

The eyes may exhibit conjunctivitis, episcleritis, or uveitis. In the abdomen, ascites may be seen in cirrhosis, nephrosis, and heart failure. Hepatomegaly is seen in passive congestion and amyloidosis (Chapter 194). Splenomegaly may be seen in amyloidosis, endocarditis (Chapter 76), and lymphoma (Chapters 191 and 192). Kidney and liver enlargement may be seen in autosomal dominant polycystic kidney disease. Lower extremity edema can be seen in cirrhosis, nephrotic syndrome, and heart failure. Splinter hemorrhages, as well as Osler nodes and Janeway lesions, may represent bacterial endocarditis. Rashes can be seen in many of the vasculitides.

Cardiovascular Signs

Assessment of the jugular venous pressure (Chapter 50) can play a crucial role in the bedside evaluation of volume status. The presence of a pericardial friction rub can be observed in the serositis associated with systemic lupus erythematosus (SLE; Chapter 274) or the pericarditis associated with uremia (Chapter 132). Infiltrative diseases, such as amyloidosis and sarcoidosis (Chapter 95), can lead to restrictive cardiomyopathy with associated heart failure. The presence of a fourth heart sound (S_4) may be a sign of cardiac hypertrophy, and S_3 may be a sign of heart failure. Vascular bruits reflect generalized atherosclerosis, and the presence of an abdominal bruit may be an important clue to the presence of renovascular disease (Chapter 127).

Neurologic Signs

Peripheral neuropathy may be seen in vasculitis with involvement of the nerves as mononeuritis multiplex. Frank cerebrovascular accidents may be seen in SLE and in the antiphospholipid antibody syndrome (Chapter 179).

The signs and symptoms of chronic renal failure are shown in Figure 116-1.

Laboratory Findings

Measurement of Renal Function

Renal function is routinely assessed in clinical practice by the measurement of serum creatinine. Creatine is released as a waste product from myocytes and converted to creatinine in the liver. The normal range of serum creatinine is 0.6 to 1.5 mg/dL, and the value for a given patient is relatively fixed in the absence of a change in renal function. About 90% of the daily production of creatinine is excreted through glomerular filtration and the remainder by tubular secretion. Mild elevations of the plasma creatinine concentration can

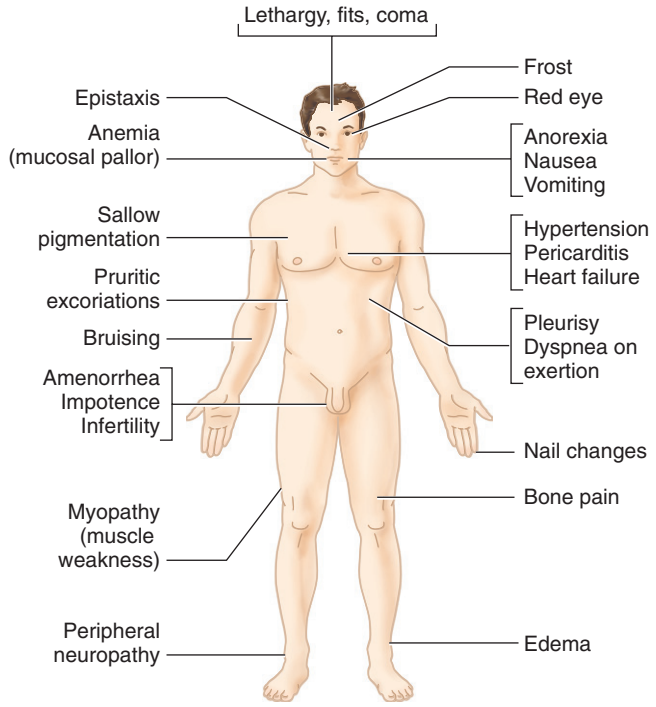

FIGURE 116-1. Common symptoms and signs of chronic renal failure. (Redrawn from Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

occur during treatment with cimetidine or trimethoprim, both of which interfere with the tubular secretion of creatinine, but neither is likely to cause significant elevations of the plasma creatinine level. Ketoacids (Chapter 236) can cause an artifactual increase in the plasma creatinine by interfering with the creatinine assay. The reciprocal relationship between the GFR and the serum creatinine level explains why the serum creatinine concentration will rise but still remain in the normal range despite a substantial loss of renal function. The concentration of blood urea nitrogen (BUN), which is a product of protein catabolism, is about ten-fold higher than the creatinine concentration; because the BUN-to-creatinine ratio commonly rises with arterial underfilling, the BUN typically is used as a marker of effective volume status. The BUN may be inappropriately high in other circumstances, however, such as with gastrointestinal bleeding or the use of steroids or tetracyclines. The BUN may be low in patients who have a poor dietary intake of protein or who have liver disease.

The creatinine clearance can be estimated from the serum creatinine concentration by the Cockcroft-Gault formula:

$$\text{GFR} = \frac{(140 - \text{age}) \times \text{weight [in kg]}}{72 \times \text{serum creatinine}} (\times 0.85 \text{ if female})$$

Creatinine clearance often is calculated using a 24-hour urine collection for measurement of the creatinine concentration. The patient must be instructed to discard the first-morning urine before initiating the collection and to conclude the collection by including the next morning void. The formula for calculating creatinine clearance is as follows:

$$\text{CCr} = (\text{urine Cr} \times \text{V}) / (\text{plasma Cr})$$

where *CCr* is creatinine clearance, *urine Cr* is urine creatinine concentration, *V* is urine flow rate, and *plasma Cr* is plasma creatinine. The creatinine clearance overestimates GFR by about 10% owing to tubular secretion of creatinine. This secretion can be modified by the use of cimetidine, which is a competitive inhibitor of tubular creatinine secretion.

Inulin, a 5200-D uncharged polymer of fructose, is an ideal marker for the measurement of GFR because it is not reabsorbed, secreted, synthesized, or metabolized. It is not available for routine clinical assessment, however. Iothalamate clearance is an accurate measurement of GFR and is available as a diagnostic tool in clinical studies. Other agents that are used for the measurement of GFR include technetium-99m diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA) and chromium 51-labeled ethylenediaminetetraacetic acid.

Urine Tests

The following aspects of the assessment of the urine are important in the approach to the patient with renal disease.

Twenty-Four-Hour Urine Collection for Protein Excretion

Proteinuria (as albuminuria) of greater than 3.5 g in 24 hours generally indicates glomerular disease (Chapter 123). Lesser quantities do not preclude glomerular disease, and electrophoresis gives valuable insight into the composition of the proteinuria (Chapter 193). Occasionally, overflow proteinuria of a low-molecular-weight protein, such as light chains in Bence Jones proteinuria, can be greater than 3.5 g/day without any of the manifestations or implications of the nephrotic syndrome; a urine protein electrophoresis study is important in making the distinction. Collection must be done by discarding the first morning void and collecting all urine output for the next 24 hours, including the first morning void the next day.

Protein-to-Creatinine Ratio

The 24-hour urine collection for protein excretion is cumbersome and subject to inaccuracies. Instead, a spot urine sample for protein and creatinine can be used to estimate the amount of protein excreted. A protein-to-creatinine ratio of 3 estimates that the 24-hour protein excretion is about 3 g. The ratio may be inaccurate in patients with orthostatic proteinuria.

Urine for Microalbumin

The excretion of abnormal quantities of albumin below the level detectable by the urine dipstick is called *microalbuminuria*. Normal albumin excretion, which is less than 30 mg/day, is best detected by radioimmunoassay or enzyme immunoassay. Microalbuminuria is the earliest clinically detectable stage of diabetic nephropathy (Chapter 126).

Fractional Excretion of Sodium

The excretion of sodium in the setting of oliguria and acute kidney injury (Chapter 122) often gives insight into the appropriateness of tubular function. The fractional excretion of sodium (Fe_{Na}) is calculated as follows:

$$Fe_{Na} = (\text{urine Na} / \text{plasma Na}) / (\text{urine Cr} / \text{plasma Cr}) \times 100$$

where *Na* is the sodium concentration (in millimoles per liter [mmol/L]), and *Cr* is the creatinine concentration (in mmol/L). In the setting of oliguria, an Fe_{Na} of less than 1% often denotes prerenal azotemia, whereas an Fe_{Na} of greater than 1% denotes intrinsic renal damage. Although this measurement is generally useful, an Fe_{Na} of less than 1% may be seen without evidence of a prerenal component, including contrast nephropathy, hepatorenal syndrome (Chapter 157), obstructive uropathy (Chapter 125), interstitial nephritis (Chapter 124), glomerulonephritis (Chapter 123), and rhabdomyolysis (Chapter 115). Conversely, a high Fe_{Na} can be seen in cases in which there is a prerenal component, including diuretic use, adrenal insufficiency, cerebral salt wasting, and salt-wasting nephropathy (Chapter 118). The Fe_{Na} must be evaluated in the context of the clinical situation because it can be low or high in a normal patient or in a patient with chronic kidney disease. Ultimately, volume assessment is done best by assessing the patient at the bedside and cannot be deduced from a measurement of electrolytes.

Fractional Excretion of Urea

Urea reabsorption varies with volume status, increasing in the setting of volume depletion. A fractional excretion of urea less than 30% indicates a state of decreased effective circulating volume. The formula for calculation of the fractional excretion of urea is as analogous to that of Fe_{Na}.

Twenty-Four-Hour Urine for Calcium, Uric Acid, Oxalate, and Citrate

These studies are performed in the evaluation of the patient with recurrent kidney stones (Chapter 128). Depending on the laboratory, the calcium measurement may be made on a different collection from the others. These measurements should be conducted with the patient on a normal diet and with normal activity, and they should not be done during a hospitalization. Often these tests need to be repeated before therapeutic decisions are made. The 24-hour urine creatinine excretion should be determined with each measurement to ensure an adequate collection.

Urine Potassium Excretion

Potassium is handled differently than sodium. Potassium is completely reabsorbed and then secreted in a flow-dependent manner. Secretion depends on

adequate distal sodium delivery and reabsorption to provide a sufficient electrochemical gradient for tubular potassium excretion (Chapter 119). The excretion of less than 15 mmol/day of potassium in the face of hyperkalemia suggests an inadequate renal response. The transtubular potassium gradient (TTKG) is an approximation of the gradient of potassium before the effect of antidiuretic hormone on the concentration of potassium in the urine. The formula for the measurement of the TTKG is as follows:

$$\text{TTKG} = (\text{urine K}/\text{plasma K})/(\text{urine Osm}/\text{plasma Osm})$$

where *K* is the potassium concentration and *Osm* is osmolality. A TTKG ratio of less than 4 in the setting of hyperkalemia implies either inadequate distal sodium delivery or inadequate distal potassium excretion system. A TTKG ratio of greater than 10 in the setting of hypokalemia supports the presence of renal potassium wasting, and further elucidation of the exact stimulus for potassium loss is warranted.

Urine Net Charge

Urine net charge measures the ability of the kidney to synthesize ammonia (NH_4^+) and to excrete acid in non–anion gap metabolic acidosis. The difference between the concentration of urine cations (Na^{++} and K^{++}) and that of urine anions (mainly Cl^-) represents the urine net charge:

$$\text{Urine net charge} = (\text{urine } Na^+ + \text{urine } K^+) - (\text{urine } Cl^-)$$

A negative urine net charge indicates NH_4^+ in the urine. This formula does not apply when an unmeasured anion is present in the urine in a patient with an anion gap metabolic acidosis (Chapter 120).

Urinalysis

The analysis of the urine sample involves simple observation and separate measurements using specific tools or commercially available dipsticks.

Appearance and Color

The normal color of the urine is derived from urochromes, which are pigments excreted in the urine. Abnormal color or appearance of the urine may be explained by many conditions (Table 116-1).

TABLE 116-1 MACROSCOPIC APPEARANCE OF URINE

APPEARANCE	CAUSE
Milky	Acid urine: urate crystals Alkaline urine: insoluble phosphates Infection: pus Spermatozoa Chyluria
Smoky pink	Hematuria (>0.54 mL blood/L urine)
Foamy	Proteinuria
Blue or green	*Pseudomonas* urinary tract infection Bilirubin Methylene blue
Pink or red	Aniline dyes in sweets Porphyrins (on standing) Blood, hemoglobin, myoglobin Drugs: phenindione, phenolphthalein Anthocyaninuria (beetroot, "beeturia")
Orange	Drugs: anthraquinones (laxatives), rifampicin Urobilinogenuria
Yellow	Mepacrine Conjugated bilirubin Phenacetin Riboflavin
Brown or black	Melanin (on standing) Myoglobin (on standing) Alkaptonuria
Green or black	Phenol Lysol
Brown	Drugs: phenazopyridine, furazolidone, L-dopa, niridazole Hemoglobin and myoglobin (on standing) Bilirubin

From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.

Specific Gravity

The specific gravity of the urine generally is related linearly with osmolality. However, it can be raised by the presence of molecules with relatively high molecular weight, such as glucose or contrast dye. A fixed specific gravity of 1.010, so called isosthenuria, is characteristic of chronic kidney disease (Chapter 132).

pH

Urine pH typically is 5 as a result of daily net acid excretion. An alkaline pH often is noted after meals, when an "alkaline tide" to balance gastric acid excretion increases urine pH. A high urine pH also is seen in patients who are on a vegetarian diet. An exceptionally high urine pH is indicative of an infection with a urea-splitting organism, such as *Proteus* species (Chapter 292). An inappropriately high urine pH in the setting of systemic non–anion gap metabolic acidosis may be seen in certain forms of renal tubular acidosis (RTA; Chapter 130). In a proximal RTA, the urine pH is high until the tubular reabsorption threshold for bicarbonate, which is abnormally low, is reached. At this point, the urine pH decreases to 5. In distal RTA, the inability to create a sufficient gradient for hydrogen ions results in a urine pH that is always higher than 5.5; the urine net charge gives complementary and confirmatory information. In type 4 RTA, the urine pH is often 5, and the urine net charge is often positive, thereby confirming the absence of significant amounts of ammonium in the urine; this defect is exacerbated by the accompanying hyperkalemia.

Glucose

Glucose in the urine is detected by an assay using dipsticks impregnated with the enzyme glucose oxidase. Glycosuria is seen in diabetes mellitus (Chapter 236), when pregnancy causes the tubular threshold for glucose reabsorption to change, and in tubular diseases that affect the proximal convoluted tubule and cause tubular glycosuria. Evidence for pan-proximal tubular dysfunction (e.g., glycosuria, aminoaciduria, phosphaturia) indicates that Fanconi's syndrome is present.

Protein

The dipstick for protein is a sensitive assay based on color change induced by the presence of proteins at a given pH. It is most sensitive to the presence of albumin and is much less sensitive to other proteins, such as the light chains of Bence Jones protein (Chapter 193). The presence of 1+ protein correlates with about 30 mg/dL of albuminuria, and 3+ protein correlates with greater than 500 mg/dL of proteinuria. Because the dipstick is not a quantitative measurement, small amounts of proteinuria in an oliguric patient may give the false appearance of high-grade proteinuria.

Heme

The dipstick for heme uses the peroxidase-like activity of hemoglobin and myoglobin molecules to detect the presence of heme pigment. The reaction occurs on exposure to hemoglobin, myoglobin, or intact red blood cells (RBCs). The presence of myoglobin, which is found in patients with rhabdomyolysis (Chapter 115), or free hemoglobin, which is seen in patients with intravascular hemolytic anemias (Chapter 163), is suspected if the heme reaction is intensely positive and there is a paucity of cellular elements in the sediment.

Leukocytes

The dipstick detection of leukocytes depends on the presence of leukocyte esterase. Leukocyte esterase is usually present in infections (Chapter 292) and in inflammatory conditions.

Urine Sediment

Cells

RBCs, white blood cells (WBCs), tubular cells, transitional cells, and squamous epithelial cells may be seen in the urine. Casts are formed in tubules and may contain cells or cellular debris, or may be acellular.

RBCs may originate from intrarenal vessels, glomeruli, tubules, or anywhere in the urogenital tract. Dysmorphic RBCs are cells that have been deformed by transit through the glomerulus and through the medullary interstitium, as opposed to RBCs from the remainder of the genitourinary tract (Figs. 116-2 and 116-3); these cells are often lysed and less refractile than nonglomerular RBCs. Dysmorphic RBCs often fragment with poikilocytosis and with blebs, forming so-called Mickey Mouse RBCs. Phase contrast microscopy aids in the identification of dysmorphic RBCs. The presence of

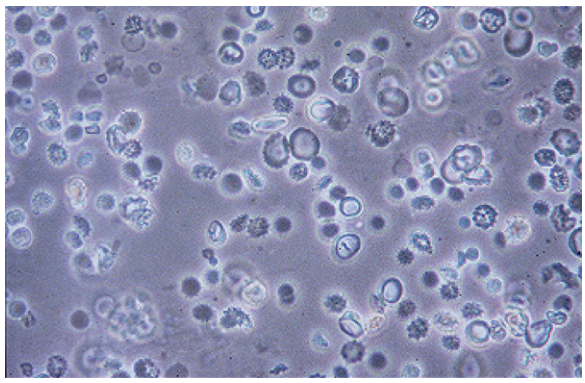

FIGURE 116-2. Dysmorphic erythrocytes. These dysmorphic erythrocytes vary in size, shape, and hemoglobin content and reflect glomerular bleeding. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

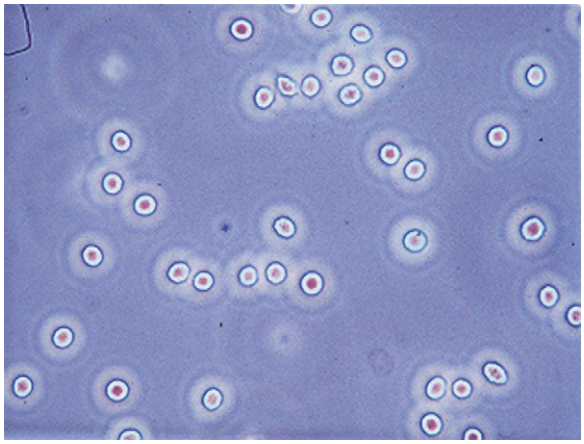

FIGURE 116-3. Isomorphic erythrocytes. These erythrocytes are similar in size, shape, and hemoglobin content. Isomorphic cells reflect nonglomerular bleeding from lesions such as calculi or papillomas or hemorrhage from cysts in polycystic renal disease. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

a majority of dysmorphic RBCs in a urine sediment points to a glomerular origin of the hematuria. The presence of RBC casts is often conclusive evidence for the presence of glomerulonephritis.

WBCs are seen most commonly in urinary tract infections, but they also can be seen in acute interstitial nephritis, with *Legionella* (Chapter 322) and *Leptospira* (Chapter 331) species infections, chronic infections such as tuberculosis (Chapter 332), allergic interstitial nephritis (Chapter 124), atheroembolic diseases (Chapter 127), and granulomatous diseases such as sarcoidosis (Chapter 95) and tubulointerstitial nephritis uveitis syndrome. Mononuclear cells often appear with transplant rejection. Tubular cells, which are seen in many conditions involving tubulointerstitial diseases, also are seen in ischemic and nephrotoxic injury, such as with myeloma kidney (Chapter 193) or cast nephropathy. Eosinophils require special stains, with the Giemsa stain being much less sensitive than the Hansel stain (Chapter 124). Urine eosinophils classically are seen in allergic interstitial nephritis (Chapter 124), but they also are seen in atheroembolic disease (Chapter 127), prostatitis (Chapter 131), and vasculitis.

Other Elements

Bacteria may be seen in the urine sediment. A spun urine sediment may show rods or cocci in chains, but bacteria are identified best by Gram staining of the urine sediment. Budding yeast forms, which are highly refractile, trichomonads, and spermatozoa also may be seen in the urinary sediment.

Casts

Casts, which are formed in tubules, are characterized by the arrangement of the cells in a clearly formed matrix composed of Tamm-Horsfall protein. Because casts are formed in the renal parenchyma, they may give a clue to the origin of accompanying cellular elements.

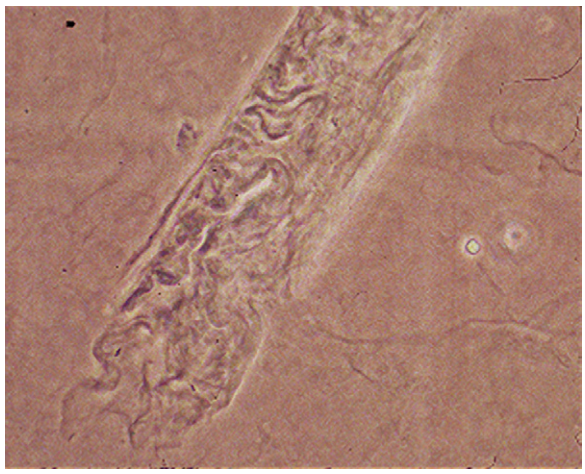

FIGURE 116-4. Hyaline cast of the type seen in small numbers in normal urine. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

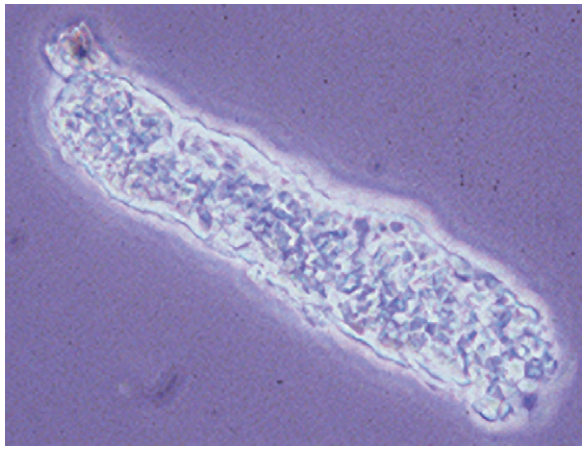

FIGURE 116-5. Number and type of granules and their density in the cast vary in different casts. The presence of erythrocytes in this cast may mean that the granules are derived partly from disrupted erythrocytes. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

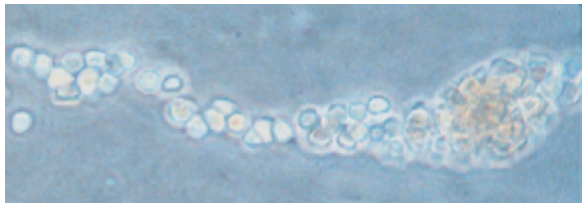

FIGURE 116-6. A cast composed entirely of erythrocytes reflects heavy hematuria and active glomerular disease. Crescentic nephritis is likely to be present if erythrocyte cast density is greater than 100/mL. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

Hyaline casts are composed of Tamm-Horsfall proteins that are formed normally and are seen in increased numbers after exercise (Fig. 116-4). *Granular casts* are degenerated tubular cell casts that are seen in the setting of tubular injury (Fig. 116-5). *Pigmented granular casts* are seen in rhabdomyolysis (Chapter 115) with myoglobinuria or, rarely, hemoglobinuria. *RBC casts* (Fig. 116-6) are rarely seen in allergic interstitial nephritis and diabetic nephropathy, but they are frequently seen in acute glomerulonephritis (Chapter 123). The presence of RBC casts in a patient with microscopic hematuria can narrow the focus of the evaluation to a glomerular lesion. *WBC casts* are seen commonly in pyelonephritis (Chapter 292) and in acute and chronic nonbacterial infections. They also are seen in other conditions in which WBCs are associated with parenchymal renal processes, such as allergic interstitial nephritis (Chapter 124), atheroembolic diseases (Chapter

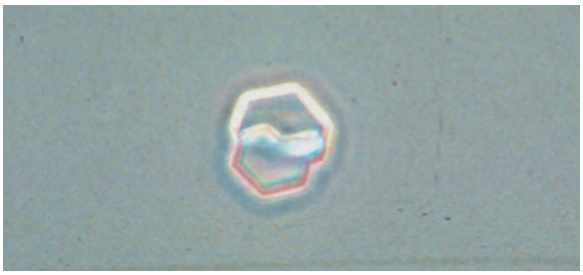

FIGURE 116-7. Typical hexagonal cystine crystal. A single crystal provides a definitive diagnosis of cystinuria. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

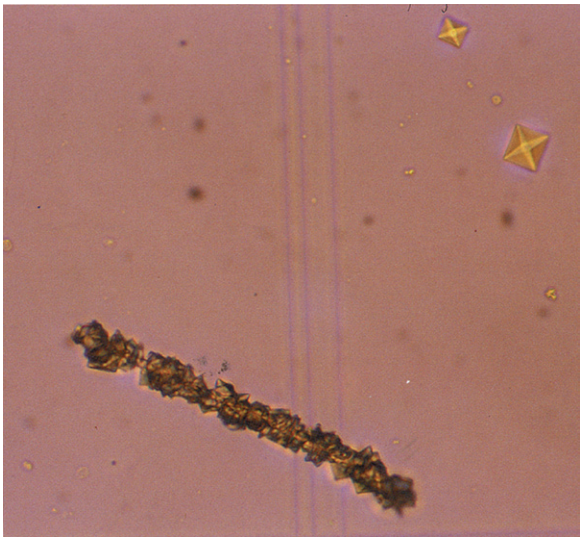

FIGURE 116-8. Oxalate crystals. A pseudocast of calcium oxalate crystals accompanied by crystals of calcium oxalate dehydrate. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

127), and granulomatous diseases such as sarcoidosis (Chapter 95). Rarely, WBC casts can be a dominant feature of many diseases that traditionally are thought of as glomerular diseases, such as SLE (Chapter 274) and Wegener's granulomatosis (Chapter 278). *Tubular cell casts* are seen with any acute tubular injury and are the dominant cellular casts in ischemic acute tubular necrosis (Chapter 122). They also can be seen with nephrotoxic injury, such as with aminoglycosides and cisplatin. Some casts may contain both leukocytes and tubular cells or be difficult to distinguish.

Crystals

Crystals can be a normal finding in the urine or serve as clues to pathophysiologic processes. Certain crystals, such as the hexagonal crystals seen with cystinuria (Chapter 130), are always abnormal (Fig. 116-7). Others, such as the octahedral calcium oxalate crystals (Fig. 116-8), may be a normal finding or may be evidence for ethylene glycol intoxication (Chapter 110). Triple phosphate crystals, which are composed of ammonium magnesium phosphate and are coffin shaped (Fig. 116-9), are seen in urinary tract infections with urea-splitting organisms (Chapter 292). Uric acid crystals, sodium urate crystals (Fig. 116-10), and calcium phosphate amorphous crystals are common and do not have pathologic significance.

Serologies for the Evaluation of Renal Disease

The evaluation of renal dysfunction has to follow a stepwise progression from noninvasive serologic evaluation to a definitive or confirmatory diagnostic evaluation, such as a renal biopsy. Sometimes an expeditious diagnosis is needed, and a biopsy may be done relatively early in the evaluation. Serologic diagnostic markers for certain diseases, such as Wegener's granulomatosis (Chapter 278), can sometimes avoid the need for a diagnostic renal biopsy in patients with renal insufficiency.

Antinuclear Antibody

An antinuclear antibody (ANA) can be useful to evaluate glomerular disease, especially the nephrotic syndrome. A high ANA titer (e.g., 1:320), especially if it is accompanied by a more specific finding such as anti-double-stranded DNA (anti-dsDNA) antibody or anti-Smith antibody, can be highly specific for the diagnosis of SLE renal disease (Chapter 274), which usually requires a renal biopsy. Lower titers (e.g., 1:80 or 1:40) are nonspecific.

Rheumatoid Factor

A rheumatoid factor titer will usually be elevated in patients with rheumatoid arthritis, but vasculitis is a relatively late and rare event. Rheumatoid factor can be detected in cryoglobulinemia (Chapter 193); immunoglobulin M (IgM), which is present in type II and type III cryoglobulinemia, has rheumatoid factor activity. Rheumatoid factor also can be seen as a nonspecific finding in bacterial endocarditis (Chapter 76) and systemic vasculitis (Chapter 278).

Complement

The levels of complement components C3 and C4 and the 50% hemolyzing dose of complement (CH_{50}) usually are measured in the evaluation of suspected rapidly progressive glomerulonephritis (Chapter 123). Complement levels are usually low in active SLE (Chapter 274), poststreptococcal glomerulonephritis (Chapter 123), endocarditis (Chapter 76), membranoproliferative glomerulonephritis, cryoglobulinemia (Chapter 193), shunt nephritis, and glomerulonephritis associated with visceral abscesses. A

particularly depressed C4 compared with C3 should raise the suspicion of cryoglobulinemia.

Serum and Urine Immunoelectrophoresis and Bence Jones Protein

Elevated polyclonal IgA levels are seen in about 50% of cases of IgA nephropathy (Chapter 123) and Henoch-Schönlein purpura (Chapter 123). Polyclonal elevation of IgG may occur in a variety of systemic diseases and is a nonspecific finding. The presence of a monoclonal protein in the serum should raise the suspicion for a monoclonal gammopathy–associated disease (Chapter 193). The differential diagnosis includes monoclonal gammopathy of uncertain significance, myeloma kidney, lymphomas (Chapter 191), amyloidosis (Chapter 194), light chain deposition disease, heavy chain deposition disease, immunotactoid glomerulonephritis, and cryoglobulinemia. The concentration of the monoclonal protein is higher when the diagnosis of multiple myeloma is made, but even small quantities of Bence Jones proteins in the serum can have clinical significance. Because a substantial fraction of multiple myelomas can have no heavy chain excretion and small quantities of light chains may be hard to detect by serum immunoelectrophoresis, a urine immunoelectrophoresis always should be obtained concomitantly to ensure a complete evaluation. A new, more sensitive assay for serum free light chains and an assessment of the ratio of kappa to lambda lights chains increase the sensitivity for detecting monoclonal gammopathies.

A urine test for Bence Jones protein complements the serum immunoelectrophoresis. Patients may have Bence Jones proteinuria even in the absence of an M component in the serum immunoelectrophoresis. Bence Jones proteinuria may be present in myeloma kidney, amyloidosis, light chain deposition disease, lymphoma, or, occasionally, monoclonal gammopathy of uncertain significance. However, many patients with systemic amyloidosis have a normal serum immunoelectrophoresis and no Bence Jones proteinuria (Chapter 193).

Antineutrophil Cytoplasmic Antibody

The antineutrophil cytoplasmic antibody (ANCA) assay has allowed for earlier and more definitive recognition of one of the most common causes of rapidly progressive glomerulonephritis. The ANCA test, when confirmed by enzyme-linked immunosorbent assay (ELISA), is highly sensitive and specific for a group of vasculitides (Chapter 278). The antibodies are present in the serum of the affected patient and cause two different patterns of staining: perinuclear staining (p-ANCA) and cytoplasmic staining (c-ANCA). Both antigens actually have a cytoplasmic distribution, and the former pattern is an artifact of the fixation method. The antigen for p-ANCA is myeloperoxidase, and the antigen for c-ANCA is proteinase-3. p-ANCA is associated with microscopic polyangiitis, idiopathic crescentic glomerulonephritis, or Churg-Strauss syndrome (Chapter 278). The c-ANCA serology result often correlates with the classic disease of Wegener's granulomatosis (Chapter 278). Immunofluorescence is highly sensitive but is not specific, unless used with ELISA and Western blotting. In the appropriate clinical setting, it can avoid the need for renal biopsy. Anti-GBM antibody staining also may occur in the presence of a positive ANCA, the significance of which is unclear. It is speculated that exposure of the Goodpasture antigen, as a result of the glomerular injury, leads to anti-GBM antibody formation as a secondary process.

Anti–Glomerular Basement Membrane Antibody

Anti-GBM antibodies are autoantibodies to the Goodpasture antigen, which resides in a domain of the α chain of type 4 collagen. An early and accurate diagnosis of Goodpasture's syndrome can be made by immunofluorescence and confirmed by Western blot analysis.

Cryoglobulins

Cryoglobulins (Chapter 193) are thermolabile immunoglobulins of single monoclonal type (type I cryoglobulinemia); in type II and type III cryoglobulinemia, the mixture of immunoglobulins includes one with rheumatoid factor activity against IgG. Type I and type II cryoglobulins are more likely to be associated with clinical disease, especially at higher titers. In type II cryoglobulinemia, the monoclonal component has rheumatoid factor activity and is often an IgM κ M component. Type III cryoglobulinemia is often of less clinical significance. Type I cryoglobulinemia is seen with Waldenström's macroglobulinemia and multiple myeloma (Chapter 193); type II, with hepatitis C infection (Chapters 150 and 151), Sjögren's syndrome (Chapter 276), lymphomas (Chapters 191 and 192), and SLE (Chapter 274); and type III, with hepatitis C (Chapters 150 and 151), chronic infections, and inflammatory conditions. When cryoglobulinemia is associated with hepatitis C, the hepatitis C virus (HCV) RNA is concentrated in the cryoprecipitate; the diagnosis can be made by an RNA assay of the cryoprecipitate at 37° C.

Other Serologies

Membranous nephropathy is associated with chronic hepatitis B infection with hepatitis B surface antigenemia (Chapter 151). Classic polyarteritis nodosa (Chapter 278) occasionally is seen with chronic hepatitis B infection, often with surface antigenemia and hepatitis B e-antigenemia.

Hepatitis C serology is associated with a variety of renal entities, including cryoglobulinemia, membranoproliferative glomerulonephritis, and membranous nephropathy. The evaluation may include the antibody test and an assay for HCV RNA. Occasionally, the HCV RNA analysis may have to be conducted on the cryoprecipitate at 37° C.

Human immunodeficiency virus (HIV)-associated nephropathy (Chapter 123) is associated with nephrotic syndrome and acute kidney injury. In the appropriate clinical setting, HIV serology and viral titers are appropriate tests for both clinical syndromes.

Streptococcal infection can be confirmed as the cause of postinfectious glomerulonephritis (Chapter 123) with an anti-DNase or antistreptolysin assay. Acute and convalescent serology assays are used to confirm recent infection.

Erythrocyte Sedimentation Rate

The erythrocyte sedimentation rate (ESR) is a relatively nonspecific test in the evaluation of renal disease. However, a high ESR often points to systemic vasculitis (Chapter 278), multiple myeloma (Chapter 193), or malignancy as the underlying cause. However, the ESR often is elevated in the nephrotic syndrome (Chapter 123), including diabetic nephropathy (Chapter 126).

Noninvasive Imaging

A variety of renal imaging techniques can assist in the evaluation of diseases of the kidney. Of note is that plain films and intravenous pyelography largely have been replaced by renal ultrasonography and computed tomography (CT) for the evaluation of renal size and the detection of stones and masses.

Renal Ultrasonography

Ultrasonography, which is the most commonly used renal imaging study (Fig. 116-11), provides reliable information regarding obstruction, renal size, the presence of masses, and renal echotexture. The study has only 90% sensitivity for the detection of hydronephrosis, however, and is not sufficient to exclude obstruction with certainty. Additionally, its inability to detect stones in the ureters and bladder limits its utility in the evaluation for kidney stones. Doppler imaging permits evaluation of the renal vessels and resistive index.

Computed Tomography

A stone protocol CT scan of the kidneys, ureter, and bladder has become the study of choice for the detection of kidney stones (Chapter 128) because of its ability to detect stones of all kinds, including uric acid stones and nonobstructing stones in the ureters (Fig. 116-12). Masses in the kidney can be evaluated using either contrast CT or a renal ultrasound. CT angiography with iodinated contrast material can assess possible renal artery stenosis

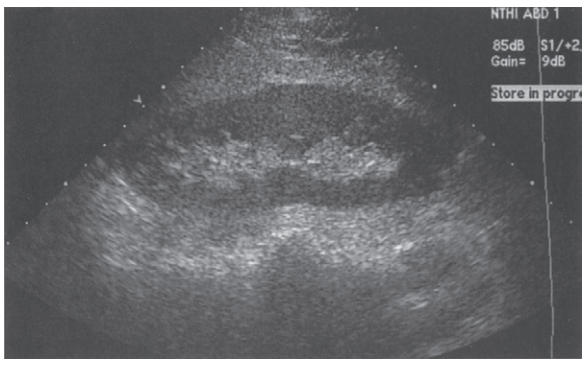

FIGURE 116-11. Normal sagittal renal ultrasound. The cortex is hypoechoic compared with the echogenic fat containing the renal sinus. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

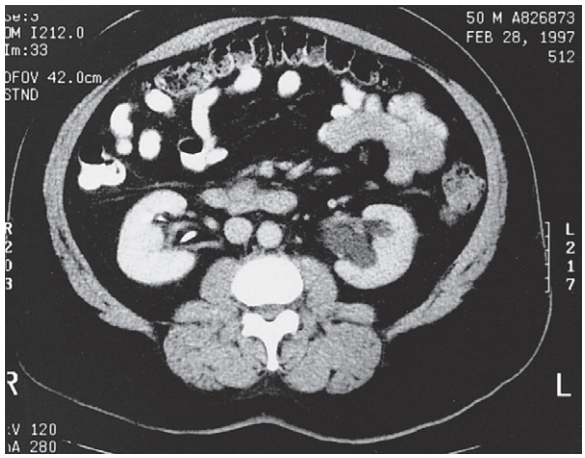

FIGURE 116-12. Delayed excretion in the left kidney secondary to a distal calculus. Contrast-enhanced computed tomography scan shows dilated left renal pelvis. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

(Chapter 127) with an accuracy comparable to magnetic resonance (MR) angiography.

Magnetic Resonance Imaging with Magnetic Resonance Angiography

Magnetic resonance imaging (MRI) with MR angiography (Fig. 116-13) is highly sensitive for detecting atherosclerotic renovascular disease (Chapter 127), but it tends to overestimate the degree of stenosis. Its accuracy in detecting fibromuscular dysplasia, however, is less well validated. MRI also can be used to evaluate renal masses. MRI does not require iodinated contrast material, but gadolinium-based contrast agents for vascular studies are associated with the syndrome of nephrogenic systemic fibrosis in patients with renal failure (Chapter 275).

Renography

The uptake by the kidneys of ^{99m}Tc-DTPA, as a marker of GFR, and mercaptoacetyl triglycine, as a marker of renal blood flow, can help evaluate patients with suspected renovascular disease. However, neither is commonly used now that CT angiography and MR angiography are widely available.

Invasive Evaluation

Renal Angiography

Renal arteriography, which is the gold standard in the evaluation of renal artery stenosis (Chapter 127), also is used for the evaluation of arteriovenous

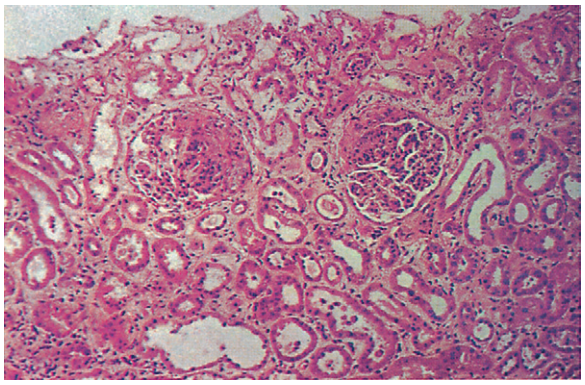

FIGURE 116-14. Systemic lupus erythematosus. This renal biopsy specimen shows proliferative change and crescent formation in both glomeruli (hematoxylin and eosin stain; magnification, 116×). (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

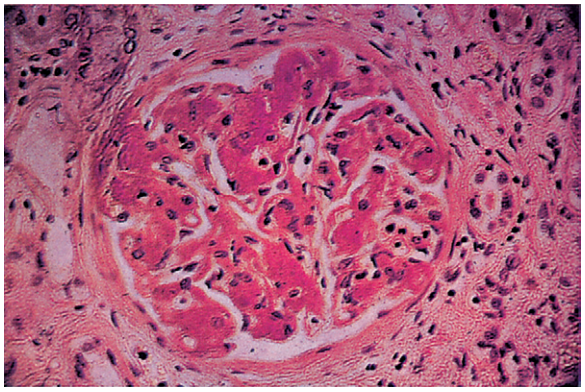

FIGURE 116-15. Renal amyloidosis. The glomerulus shows amyloid deposition, stained by Congo red, in the glomerular capillaries (magnification, 330×). (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

malformations, polyarteritis nodosa, and other vascular lesions of the kidneys. This invasive study uses iodinated contrast material and incurs a small risk for atheroembolic disease (Chapter 127). Therapeutic angioplasty and stenting can be done at the time of the angiogram.

Renal Biopsy

Renal biopsy usually is performed percutaneously with real-time ultrasound or CT guidance. The risk for bleeding that requires a transfusion is 1 to 2% in patients without coagulopathy. The transjugular approach can be used in patients in whom the risks for bleeding are high. Current indications for renal biopsy include the following:

1. Rapidly progressive glomerulonephritis. Biopsy is generally indicated for ANCA-related vasculitis unless the case is classic, such as red blood cell casts and renal dysfunction. For patients with cryoglobulinemia and SLE, biopsy is recommended to stratify patients before therapy.
2. SLE with renal involvement to categorize the degree of nephropathy, which cannot be assessed based on clinical criteria (Fig. 116-14). A repeat biopsy is indicated if a change in immunosuppressive therapy is planned and the clinical picture is at all ambiguous (e.g., serum creatinine, urine sediment, and proteinuria are in good control but anti-DNA antibody titers remain high).
3. Nephrotic syndrome without an obvious cause. In childhood nephrotic syndrome, empirical steroid therapy is used routinely because of the high prevalence of steroid-responsive minimal change disease. In adults, the approach generally is to use the biopsy to guide appropriate therapy (Fig. 116-15).
4. Unexplained renal failure of any cause, especially if immunosuppressive therapy is contemplated. Patients with hospital-acquired renal failure rarely require renal biopsy.
5. Unexplained proteinuria below the nephrotic range to exclude nephrosis in evolution. Biopsy is recommended if proteinuria exceeds 1 g per 24 hours or occurs in the setting of a reduced GFR.

6. Renal transplantation with acute and chronic renal failure, in which the biopsy information can be crucial in guiding diagnosis and treatment.

MAJOR RENAL SYNDROMES

Renal disease can be divided logically into major overlapping categories, which are used to characterize the most common renal syndromes.

Acute Kidney Injury

Acute kidney injury (Chapter 122) is a syndrome in which glomerular filtration declines over a period of hours to days. The patient with acute renal failure is approached best by evaluation for prerenal, renal, and postrenal causes. Most cases of acute renal failure in the hospital have hemodynamic or toxic etiologies. The careful and systematic evaluation of the patient should start with a thorough history and physical examination, which should be followed by selected laboratory tests and often an imaging test, such as renal ultrasonography.

Nephritic Syndrome

The acute nephritic syndrome is an uncommon but dramatic presentation of an acute glomerulonephritis (Chapter 123). The hallmark of the acute nephritic syndrome is the presence of dysmorphic RBCs and RBC casts, but their absence does not exclude the syndrome. The acute nephritic syndrome can be caused by any of the rapidly progressive glomerulonephropathies, all of which warrant urgent and usually inpatient evaluation.

Nephrotic Syndrome

The nephrotic syndrome (Chapter 123) is characterized by the presence of proteinuria of greater than 3.5 g/day/1.73 m^2, with accompanying edema, hypertension, and hyperlipidemia. Other consequences include a predisposition to infection and hypercoagulability. In general, the diseases associated with nephrotic syndrome do not cause acute kidney injury, although acute kidney injury may be seen with minimal change disease, HIV-associated nephropathy, and bilateral renal vein thrombosis (Chapter 127). The causes of primary idiopathic nephrotic syndrome, in decreasing order of prevalence, are focal and segmental glomerulosclerosis, membranous nephropathy, minimal change disease, and membranoproliferative glomerulonephritis. Secondary causes of the nephrotic syndrome include diabetic nephropathy (Chapter 126), amyloidosis (Chapter 194), and SLE (Chapter 274) with membranous nephropathy.

Tubulointerstitial Diseases

Tubulointerstitial diseases (Chapter 124) vary in presentation from acute kidney injury to chronic kidney dysfunction that manifests as asymptotic mild renal insufficiency (Table 116-2). The urine sediment often contains small-to-moderate amounts of proteinuria, usually less than 1 g/day, as well as WBCs, RBCs, tubular cells, and WBC casts. RBC casts are rare in acute interstitial nephritis and are more characteristic of glomerular disease.

Vascular Diseases of the Kidney

Vascular diseases of the kidney can be divided into large-vessel obstruction and medium- to small-vessel diseases (Chapter 127). Renovascular disease is a common cause of hypertension, heart failure, and renal insufficiency. About 90% of renal artery stenosis is atherosclerotic in origin, with most of the remaining caused by fibromuscular dysplasia, which is more common in women 20 to 50 years of age. Medium-sized arterial vessel diseases include polyarteritis nodosa, which is seen in patients with hepatitis B, HIV infection, or, rarely, hepatitis C. Symptoms include abdominal pain, hypertension, and mild renal insufficiency, often with a benign sediment; diagnostic findings include microaneurysms at the bifurcation of medium-sized arteries. Other diseases involving small vessels include atheroembolic disease (Chapter 127), which is seen either spontaneously or after arteriography or surgery; this syndrome typically affects the kidneys, gastrointestinal tract, and lower extremities, but it can also involve the central nervous system when the aortic arch is affected.

The thrombotic microangiopathies include hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (Chapter 174). Thrombocytopenic purpura is associated with an acquired inhibitor to, or the congenital inherited absence of, a protease that cleaves large-molecular-weight von Willebrand multimers. Hemolytic-uremic syndrome is caused by endothelial injury induced by Shiga toxin from *Escherichia coli* O157:H7 infection. The antiphospholipid antibody syndrome (Chapter 179) can cause large vessel thrombosis and stenosis as well as a thrombotic microangiopathy with proteinuria, hypertension, and renal insufficiency. Scleroderma renal crisis, which is a manifestation of systemic sclerosis (Chapter 275), often leads to an inexorable progression to end-stage renal insufficiency if it is untreated.

TABLE 116-2 MAJOR CAUSES OF TUBULOINTERSTITIAL DISEASE

Ischemic and toxic acute tubular necrosis
Allergic interstitial nephritis
Interstitial nephritis secondary to immune complex–related collagen vascular disease, such as Sjögren's disease or systemic lupus erythematosus
Granulomatous diseases: sarcoidosis, tubulointerstitial nephritis with uveitis
Pigment-related tubular injury: myoglobulinuria, hemoglobinuria
Hypercalcemia with nephrocalcinosis
Tubular obstruction: drugs such as indinavir, uric acid in tumor lysis syndrome
Myeloma kidney or cast nephropathy
Infection-related interstitial nephritis: *Legionella, Leptospira* species
Infiltrative diseases, such as lymphoma

Papillary Necrosis

Acute necrosis of the renal papilla is associated with sickle cell anemia (Chapter 166), analgesic nephropathy (Chapter 124), diabetic nephropathy (Chapter 126), and obstructive pyelonephritis (Chapter 125). In sickle cell disease (Chapter 166), the hypoxic and hypertonic milieu of the inner medulla promotes sickling, and chronic sickling at the vasa recta results in medullary ischemia. Massive and prolonged consumption of analgesics, particularly the combination of aspirin, caffeine, and acetaminophen, is associated with chronic interstitial nephritis and a predisposition to papillary necrosis (Chapter 124); medullary ischemia is thought to be caused by inhibition of synthesis of vasodilatory prostaglandins by aspirin, and direct toxicity is attributed to metabolites of phenacetin. Similarly, medullary perfusion is thought to be compromised in diabetic nephropathy (Chapter 126) and obstructive pyelonephritis (Chapter 125).

The clinical manifestations of papillary necrosis can include flank pain and hematuria. If the papilla is sloughed, obstruction may occur at the renal pelvis or ureter of the affected kidney, with referred pain migrating from the flank to the groin. A sloughed papilla may precipitate frank renal failure if the function of the contralateral kidney is impaired or if obstruction occurs at the level of the bladder or urethra (Chapter 125).

Classically, papillary necrosis is diagnosed on an excretory pyelogram as a calyceal defect after sloughing of a papilla, but CT with contrast is as good for advanced lesions. If the necrotic papilla is retained, however, the defect will be more subtle. Transitional cell carcinoma (Chapter 203) can occur in the setting of papillary necrosis or can mimic its appearance. Obstruction, if present, must be relieved, but treatment otherwise is limited to pain control and hydration.

Chronic Kidney Disease

Chronic kidney disease, which is defined as either kidney damage or a GFR of less than 60 mL/min/1.73 m^2 for longer than 3 months, includes five stages (Table 116-3). Kidney damage is defined as pathologic abnormalities or markers of kidney damage, including abnormalities in the composition of blood or urine or abnormalities on imaging tests. The excretion of 30 to 300 mg of albumin in a 24-hour period defines microalbuminuria. An estimated 12% of the adult U.S. population has abnormal albumin excretion in the urine, and the frequency increases with age. Kidney failure is defined as either a GFR of less than 15 mL/min/1.73 m^2 that is accompanied by signs and symptoms of uremia or a need for initiation of kidney replacement therapy for treatment of complications of decreased GFR. End-stage renal disease includes all cases requiring treatment by dialysis or transplantation regardless of the level of GFR.

Patients with chronic kidney disease warrant referral to a nephrologist. Care of these patients should focus on efforts to slow disease progression, optimize medical management, and make a seamless transition to renal replacement therapy (Chapter 132). The care should include optimal blood pressure control, use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers if indicated, dietary counseling, careful management of calcium and phosphorus levels, control of the parathyroid hormone level, and management of anemia with the use of erythropoietin and iron supplements. Early referral for placement of access for dialysis and initiation of

TABLE 116-3 STAGES OF CHRONIC KIDNEY DISEASE*

STAGE	DESCRIPTION	GFR (mL/min/1.73 m^2)
1	Kidney damage with normal or ↑GFR	≥90
2	Kidney damage with mild or ↓GFR	60-89
3	Moderate ↓GFR	30-59
4	Severe ↓GFR	15-29
5	Kidney failure	<15 (or dialysis)

*Chronic kidney disease is defined as either kidney damage or GFR <60 mL/min/1.73 m^2 for ≥3 months. Kidney damage is defined as pathologic abnormalities or presence of markers of damage, including abnormalities in blood or urine tests or image studies.
GFR = glomerular filtration rate.

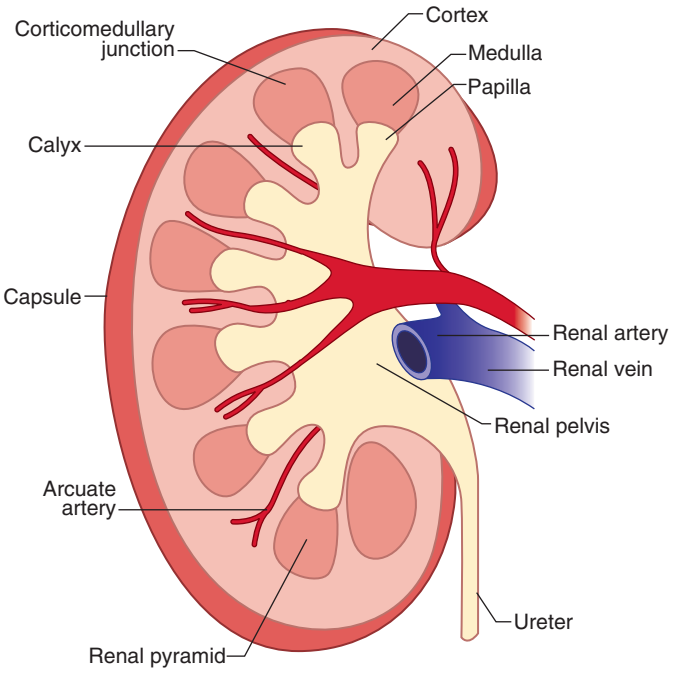

FIGURE 117-1. Sagittal section of the human kidney depicting gross anatomy and organization.

117 STRUCTURE AND FUNCTION OF THE KIDNEYS

QAIS AL-AWQATI AND JONATHAN BARASCH

The kidney regulates the ionic composition and volume of body fluids, the excretion of nitrogenous waste, the elimination of exogenous molecules (e.g., many drugs), the synthesis of a variety of hormones (e.g., erythropoietin), and the metabolism of low-molecular-weight proteins (e.g., insulin). Befitting such an array of responsibilities, the kidney receives 25% of the cardiac output. The gross anatomy of the kidney is notable for a weight of approximately 150 g and a characteristic bean shape with approximate dimensions of 11 × 6 × 2.5 cm. On bisection, a simple gross structure is evident with an outer cortex and a more central medulla that narrows to multiple papillae at the apices of so-called pyramids (Fig. 117-1).

Understanding the kidney, however, requires an appreciation of the intricate microstructure that underlies its complex functions. The kidney is a composite organ comprising approximately 1 million essentially identical functional units termed *nephrons*. All the functions of the kidney are performed by each individual nephron, and at a first approximation, all nephrons are independent of each other because they have their own innervation and blood supply. The nephron is made up of two functional subunits, the glomerulus and the following tubules and ducts (Fig. 117-2). The glomerulus begins with the branching of the afferent arteriole, an end artery of the corresponding renal artery, to a tuft of capillaries. The glomerular capillaries invaginate an epithelium with the visceral epithelial cells adjacent to the capillary and the parietal epithelial cells outside this tuft. The space between the epithelial layers is the urinary space. The fenestrated glomerular capillary endothelium, the intervening basement membrane, and the foot processes of the visceral epithelium, so-called podocytes, make up the glomerular filtration barrier. The balance of hydrostatic and oncotic pressures drives the extrusion of a protein-free filtrate through this barrier into the urinary space. The urinary space then leads to a series of tubules and ducts: the proximal tubule, the thin limb of the loop of Henle, the thick limb of the loop of Henle, the distal convoluted tubule, the cortical collecting duct, and the medullary collecting duct. The papillary collecting duct empties through the renal papilla into the renal pelvis and then to the ureter. The glomerular capillary bed coalesces to form the efferent arteriole, a vessel that is exquisitely sensitive to angiotensin II, and then to the peri (proximal) tubular capillaries. This system allows efferent arteriole constriction to regulate proximal tubule reabsorption, as described later.

The nephron regulates homeostasis by three actions. First, in the glomerulus, nephrons produce as much as 120 mL/minute of an ultrafiltrate of blood. Second, in different segments of the nephron, the composition of the filtrate is altered by the transfer of nearly 99% of its components (e.g., glucose, NaCl, water) from the lumen to the blood. Third, additional electrolytes (e.g., NH_4^+, K^+, HCO_3^-) are secreted from the blood into the lumen.

To perform these functions, each nephron segment, with the exception of the collecting ducts, is composed of a single epithelial cell type whose luminal or apical surface (facing the urine) and basolateral surface (facing the blood) differentially express various proteins and lipids. For example, the apical membrane often has microvilli or cilia, whereas the basolateral membrane does not. Apical polarized endocytosis and exocytosis are often important in the regulation of the number of transport proteins on the apical surface. In addition, epithelia are connected to one another by tight junctions, which confer a characteristic ionic permeability on the epithelial sheet. Transepithelial transport occurs largely through the cell, but transport through the tight junction (the *paracellular pathway*) can also be important in different segments of the tubule. For instance, Na transport begins with entry at the luminal surface down an electrochemical gradient, whereas its exit at the basolateral surface is uphill and requires adenosine triphosphate (ATP) hydrolysis. The Na^+, K^+-ATPase is located at the basolateral surface of all epithelia, and all "active" energy-consuming transport is coupled directly or indirectly to it with the exception of H^+ transport. Each segment has a distinct composition of channels, carriers, and ATPases, and each segment is regulated by different chemical and physical sensors, so the "final urine" contains the components that must be discarded to maintain constancy of body composition.

THE KIDNEY REGULATES EXTRACELLULAR FLUID VOLUME BY REGULATING ITS SODIUM CONTENT

Filtration of 180 L/day containing 24,000 mEq of Na^+ is followed by the reabsorption of more than 99% of the filtered Na^+. Na^+ reabsorption accounts for more than 90% of oxygen consumed by the kidney. Na^+ reabsorption is regulated by volume receptors, which are located in the carotid artery and

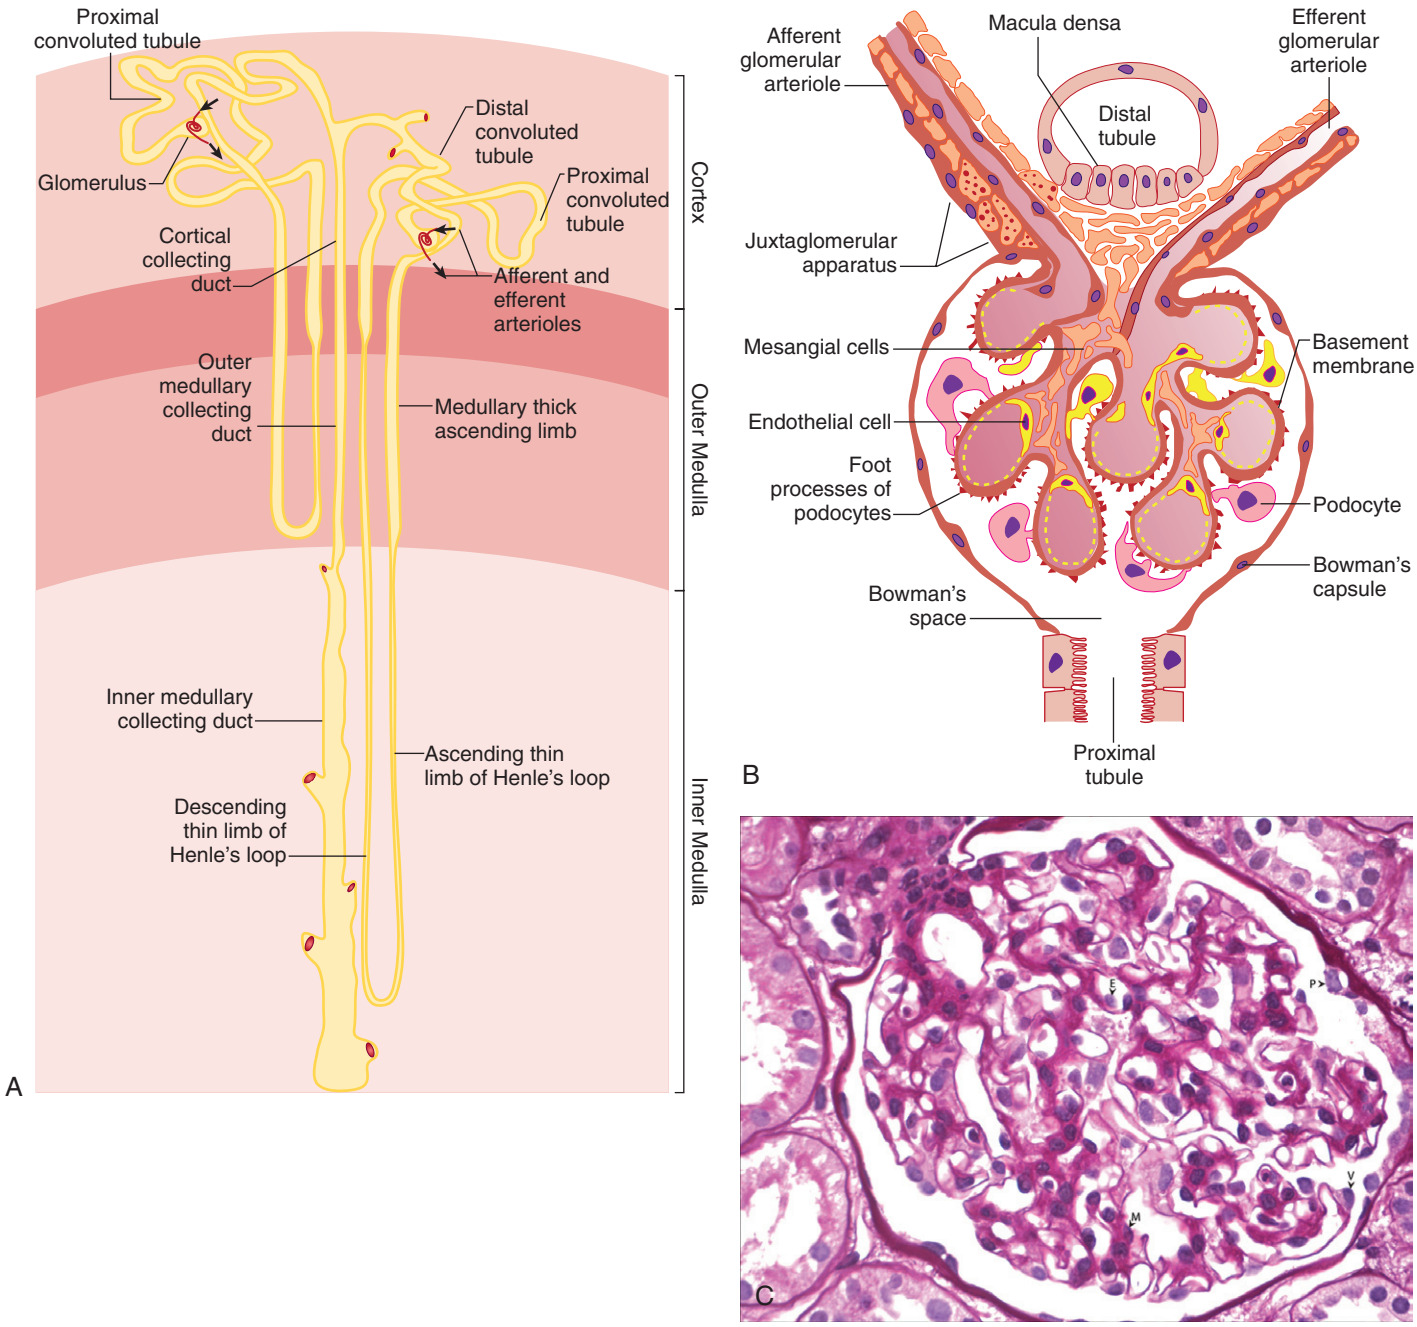

FIGURE 117-2. Structure of the nephron. A, Components of the cortical and juxtaglomerular nephrons. **B,** Anatomy of the glomerulus. **C,** Light micrograph of a human glomerulus. E = endothelial cell; M = mesangial cell; P = parietal epithelial cell; V = visceral epithelial cell. (**C,** Courtesy of Dr. Glen Markowitz.)

increase β-sympathetic output, which in turn release renin, an aspartate protease from the granular cells of the juxtaglomerular apparatus. The renin-releasing cells are close to the afferent arterioles, where renin cleaves angiotensinogen to angiotensin I, which is then converted locally to angiotensin II. Angiotensin II binds to angiotensin receptors and constricts the efferent arteriole, thereby affecting glomerular hemodynamics. The increased hydrostatic pressure within the glomerular capillaries drives the formation of an ultrafiltrate of plasma. As filtration progresses, a protein-rich, oncotically active solution in the capillary opposes the glomerular capillary hydrostatic pressure until a pressure equilibrium is achieved before the efferent arteriole is reached. Consequently, angiotensin II may not change glomerular filtration rate (GFR) markedly, but it can increase proximal reabsorption by reducing the hydrostatic pressure and increasing the oncotic pressure in the peritubular capillaries that surround the proximal tubule in a plexus, thereby favoring reabsorption of water and solutes such as urea.

The glomerular filtrate next enters the tubular portion of the nephron, where Na^+ traverses the cell by entering the apical membrane either through a cotransporter or countertransporter or through an Na^+ channel, depending on the specific mechanisms of different segments. In the apical membrane of the proximal tubule, an Na^+/H^+ (NHE_3) exchanger, an Na-coupled glucose carrier, and an Na^+-coupled amino acid and phosphate cotransporter are present. Subsequently, Na^+ is actively transported by the basolateral Na^+, K^+-ATPase into the paracellular space, thereby resulting in local hypertonicity, which causes osmosis through low-resistance tight junctions of the initial segments of the proximal tubule (Fig. 117-3).

In the thick ascending limb of Henle, Na^+ is absorbed by an NaK-2Cl cotransporter. The driving force for this neutral carrier allows Na^+ and Cl^- to enter the cell, but K^+ is then recycled across the apical membrane, thereby resulting in depolarization of the transepithelial membrane potential. In the distal convoluted tubule, Na^+ is absorbed by a thiazide-sensitive cotransporter, which conducts Na^+ and Cl^- in a strict 1:1 stoichiometry. Na^+ exits as usual by the Na^+, K^+-ATPase, but there is also a basolateral Na/Ca exchanger. In this short segment, the macula densa helps control the GFR by regulating renin release through secretion of adenosine and prostaglandins.

In the principal cells of the collecting duct, aldosterone, derived from the zona glomerulosa of the adrenal cortex, increases reabsorption of the final 50 to 100 mEq/day of Na^+ remaining in the lumen by increasing the number of open Na^+ channels (ENac), by activating expression of α-subunits, and by

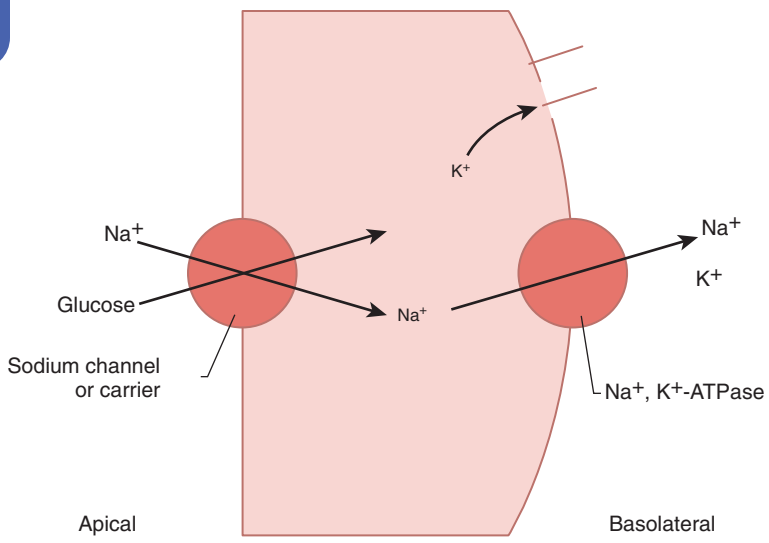

FIGURE 117-3. Sodium reabsorption in the proximal tubular cell.

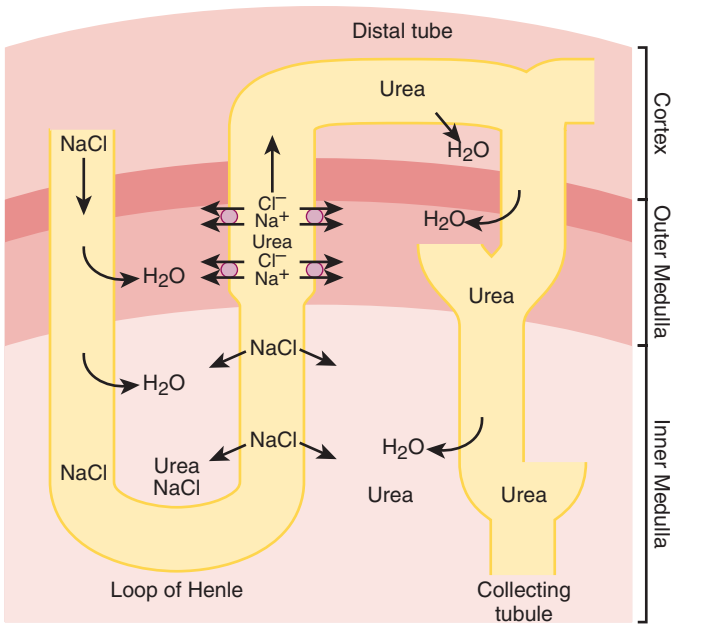

FIGURE 117-4. Regulation of water content.

increasing the activity of the basolateral Na^+, K^+-ATPase. Aldosterone is the final critical regulator of Na^+ balance.

A number of the steps that regulate Na^+ reabsorption can be counteracted by atrial natriuretic peptide (ANP), which is released from the atria in response to volume overload. ANP increases filtration in the glomerulus by dilating the afferent arteriole, thereby increasing glomerular capillary pressure and lowering the oncotic pressure. Additionally, ANP increases Na^+ excretion by inhibiting the release of renin, the production of aldosterone, and the tubular reabsorption of Na^+ in the terminal collecting duct.

THE KIDNEY REGULATES BODY FLUID OSMOLARITY BY REGULATING ITS WATER CONTENT

Water moves freely among all cells and compartments of the body, and its concentration, or osmolarity, is strictly regulated to prevent cells from swelling or contracting. The kidney regulates water content by varying the osmolarity of urine. It can dilute the urine by absorbing Na^+ without water in the thick ascending limb, the distal tubule, and the collecting duct. Conversely, the absorbed NaCl and urea provide a hyperosmotic region in the medulla, where the limited blood flow maintains an osmotic gradient. To concentrate the urine, water is removed from the filtrate by this osmotic gradient as it passes through the cortical and medullary collecting tubules.

Antidiuretic hormone (ADH), also called *vasopressin*, is a critical component of water reclamation. The neurohypophysis releases ADH as a result of activation of Trvp1 channels, which are responsive to cell shrinkage caused by changes in osmolarity of as little as 1%. In the kidney, ADH binds to the V2R receptor Trvp1 on collecting tubules and increases water permeability by reversibly inserting a water channel, called *aquaporin-2*, in the apical membrane by the fusion of vesicles. During states of water deprivation, the dilute urine generated by the thick ascending limb enters vasopressin-sensitive segments in the cortical collecting tubule, where the bulk of the water is absorbed into the cortex to increase the osmolarity of the urinary filtrate to 300 mOsm, which is the osmolarity of plasma. Subsequently, the urine becomes concentrated when it equilibrates with the osmolarity of the medulla as the urine courses down the medullary collecting duct (Fig. 117-4).

THE KIDNEY REGULATES PLASMA pH BY REGULATING HCO_3 CONTENT

The concentration of free H^+ in the intracellular and extracellular fluids is maintained at about 40 nM (pH 7.4) by the daily excretion of acid or base in amounts equal to what is generated by dietary intake and by cellular activity. The complete oxidation of carbohydrates and fats generates approximately 15 to 20 mol/day of the volatile acid CO_2, and nonvolatile acids generated by the metabolism of protein-rich diets account for 60 to 80 mEq/day. HCO_3^- is the most important buffer not only because it is consumed by metabolic acid, thereby producing CO_2 that can be exhaled, but also because it can be regenerated by the kidney. The overall relationship of this buffer system is described by the Henderson-Hasselbalch equation: $pH = pKa + \log [HCO_3^-]/\alpha P_{CO_2}$, where pKa is 6.1 and α represents the solubility coefficient of P_{CO_2} (which is 0.03). Because all the body buffers (e.g., bone, intracellular proteins) are in equilibrium, changes in the concentration of HCO_3^- regulate the pH of body fluids.

Although one task of the kidney is to replace the HCO_3^- that is lost as a consequence of the production of acid by oxidative metabolism, it must first reabsorb the 5000 mEq/day HCO_3^- that is filtered every day. The proximal tubule reabsorbs luminal HCO_3^- by secreting H^+ through an apical Na^+/H^+ exchanger, which is directly stimulated by angiotensin II to secrete H^+ in strict 1:1 exchange for Na^+, thereby mediating both sodium absorption and H^+ secretion. An H^+-ATPase is also present in the microvilli and apical endocytic vesicles that fuse with the apical membrane in response to elevated blood P_{CO_2}. H^+ secretion titrates filtered HCO_3 and, catalyzed by carbonic anhydrase, converts it to CO_2 and water, thereby allowing CO_2 reabsorption. H^+ secretion leads to an excess of OH^- in the cell, where it combines with this CO_2 to produce cellular HCO_3^-, which then exits across the basolateral membrane through an Na-HCO_3^- cotransporter (Fig. 117-5).

Given that the proximal tubule regulates bicarbonate reabsorption, the collecting duct must produce "new" HCO_3 to replace what is lost during titration by nonvolatile acids. The cortical and medullary collecting tubules contain intercalated cells that mediate H^+-HCO_3 transport; α- and β-cell types are present in the cortex, whereas only α cells are present in the medulla. H^+ secretion is mediated by the α-intercalated cell, where the H^+-ATPase is delivered to the apical membrane by fusion of apical vesicles as stimulated by ambient P_{CO_2} (Fig. 117-6).

In a reaction catalyzed by carbonic anhydrase II, the excess OH^- is carboxylated by CO_2 to form HCO_3^-. HCO_3^- is subsequently transported across the basolateral surface in exchange for Cl^- by an alternately spliced form of the red cell anion exchanger (band 3). In contrast, β cells secrete HCO_3^- by an apical Cl/HCO_3 exchanger (pendrin) and a basolateral H^+-ATPase. An H^+, K^+-ATPase in the collecting tubule also may play a role in K absorption and perhaps in H^+ secretion.

The collecting tubule is a "tight epithelium" that can maintain electrical and concentration gradients. Secretion of H^+ reduces the pH of the filtrate; the maximal gradient is 3 pH units or 180 mV, but both the size of the pH gradient and its transepithelial membrane potential can be modified to regulate H^+ secretion. For example, Na^+ absorption by the principal cell hyperpolarizes the membrane and can drive H^+ transport. Aldosterone can stimulate not only Na^+ absorption but also independently H^+ secretion—hence, it is the major hormone that stimulates acid secretion in the collecting tubule. Finally, chronic metabolic acidosis converts the β-intercalated cells into α-intercalated cells, thereby increasing the number of acid-secreting cells and reducing the amount of HCO_3^- secretion in this segment.

The secreted H^+ titrates urinary NH_3, and HPO_4^{2-}. NH_3, which is synthesized by the conversion of glutamine to α-ketoglutarate, is secreted into the

proximal lumen. In the loop of Henle and distal segments, the protonated ammonium ion is transferred into the interstitium, from where it reenters the nephron as ammonia gas. Once in the lumen, ammonia gas becomes reprotonated to ammonium, thus trapping a proton. The amount of NH_3 generated from glutamine increases up to four- to five-fold in the setting of metabolic acidosis. Net acid secretion is consequently urinary NH_4^+ plus titratable weak acids (such as HPO_4^{2-}) minus urinary HCO_3^-. Each of these components is regulated by the kidney.

THE KIDNEY REGULATES PLASMA POTASSIUM BY EXCRETION AND THE CONTROL OF EXTRACELLULAR PH

Because the membrane potential of most cells is governed by the ratio of intracellular to extracellular K, the plasma K concentration must be heavily regulated. Most dietary K^+ is pumped into the cell by the Na/K-ATPase, but about 90% of ingested K^+ eventually must be excreted into the urine. K^+ is filtered but is then reabsorbed by the proximal tubule and loop of Henle. K^+ is then secreted by the distal convoluted tubule and the principal cells through apical potassium inwardly rectifying (ROMK) and potassium large conductance calcium-activated (BK) channels. K^+ is secreted in response to a gradient, with cell K^+ greater than lumen K^+, which drives K^+ into the lumen. Secretion is enhanced by the increased entry of K^+ into the principal cell as a result of high extracellular concentration, by metabolic alkalosis, and by aldosterone. Aldosterone increases the synthesis of Na^+, K^+-ATPase and increases the probability that the ROMK channels will be open. Aldosterone also enhances Na^+ reabsorption by ENaC and thereby hyperpolarizing the transepithelial membrane potential, which increases the driving force for K secretion. High urinary flow rates deliver a large volume of fluid that is essentially K^+ free, thereby providing a concentration gradient. However, the flow rate also activates mechanosensory flagella that lead to an increase in cell calcium, which in turn activates BK channels. K^+ reabsorption is not regulated to the same extent as Na^+ retention, and profound K^+ depletion may be required for K^+ excretion by the kidneys to be eliminated completely.

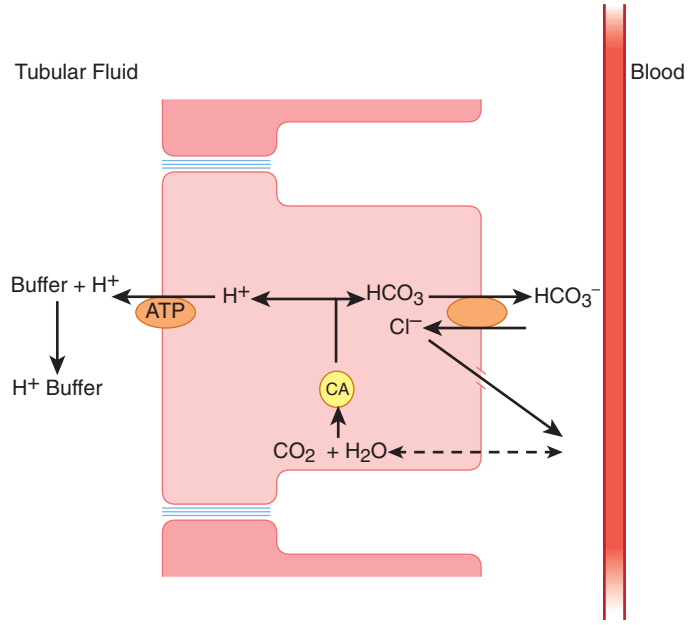

FIGURE 117-6. Mechanism of acid secretion in the collecting duct. ATP = adenosine triphosphate; CA = carbonic anhydrase.

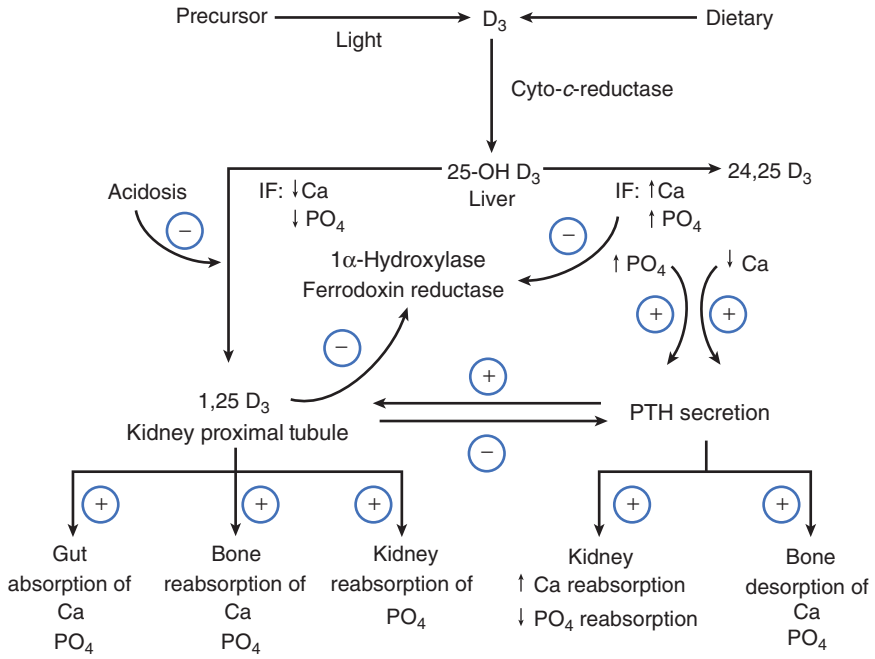

FIGURE 117-7. Calcium and phosphate metabolism. PTH = parathyroid hormone.

THE KIDNEY REGULATES PLASMA PO_4 AND CA^{2+} BY EXCRETION AND BY SYNTHESIZING VITAMIN D_3

The level of PO_4 also critically regulates serum Ca^{2+} because their plasma concentrations are close to their saturation, at which point crystallization occurs. Thus, any significant increase in PO_4 results in precipitation of $CaPO_4$.

The level of PO_4 is regulated by glomerular filtration. Initially, about 85% is reabsorbed by the proximal tubule NaPi-2a/c cotransporter. Parathyroid hormone and the heteromeric receptor FGFR/Klotho, which binds FGF23, inhibit the expression of NaPi and hence increase excretion of PO_4. Conversely, the proximal tubule generates vitamin D_3 [1,25-$(OH)_2$ cholecalciferol] by capturing 25-OH cholecalciferol, bound to its filtrable transport protein with brush boarder megalin (Fig. 117-7), after which 1α-hydroxylation is stimulated by low Ca^{2+} and PO_4. 1,25-vitamin D_3 inhibits parathyroid hormone and stimulates PO_4 reabsorption in gut and kidney, thereby counteracting parathyroid hormone and FGF23-Klotho. Nonetheless, Klotho signaling blocks 1,25-vitamin D_3 synthesis, thereby suggesting that it dominates the control of PO_4.

The level of serum calcium is also regulated by the kidney. Approximately 60% of serum Ca^{2+} is filtered, after which it follows Na^+ reabsorption in the proximal tubule and in the loops of Henle, where Ca^{2+} absorption is driven by the positive membrane potential generated by the Na-K-2Cl/K recycling transporter. In contrast, Ca^{2+} and Na^+ are regulated independently in the distal convoluted tubule by parathyroid hormone and Klotho, which increase reabsorption. Phosphate and calcium metabolism are regulated by Na^+ reclamation, parathyroid hormone, 1,25-$(OH)_2$ cholecalciferol, and Klotho in different segments of the nephron.

DISORDERS OF SODIUM AND WATER HOMEOSTASIS

KARL SKORECKI AND DENNIS AUSIELLO

SODIUM AND WATER HOMEOSTASIS

EPIDEMIOLOGY

Disturbances in sodium and water balance or distribution, with attendant perturbations in the volume or solute composition of body fluid compartments, are among the most frequently encountered abnormalities in clinical medicine. The principal clinical manifestations of these disturbances are *hypovolemia, hypervolemia, dysnatremia (hyponatremia* or *hypernatremia*), and *polyuria*. Disturbances in body tonicity, reflected by hyponatremia or hypernatremia, are estimated to affect up to 15 to 20% of hospitalized patients, with severe disturbances (>10% deviation from normal values) affecting 1 to 2% of patients. Prevalence rates for these abnormalities in ambulatory populations are lower, and elderly individuals and patients treated with multiple medications are the most susceptible.

PATHOBIOLOGY

Approximately 60% of body mass is composed of solute-containing fluid solutions that are divided into extracellular fluid (ECF) and intracellular fluid (ICF) compartments. Water flows freely across cell membranes through specific water channels (aquaporin family of transmembrane proteins) according to the dictates of osmotic forces, thereby maintaining near equality of the solute-to-water ratio (osmolality) in the ICF and ECF. However, the composition of the major solutes differs between the ECF and ICF (Fig. 118-1). Sodium and potassium are the major cations in the ECF and ICF, respectively. Chloride and bicarbonate are the major accompanying anions in the ECF, and negative charges on organic molecules maintain electroneutrality with potassium in the ICF. The difference in cationic solute composition between these two compartments is maintained by a pump-leak mechanism involving the activity of Na^+, K^+-adenosine triphosphate (ATPase) operating in concert with cell membrane sodium and potassium conductance pathways. The free movement of water ensures that the sodium concentration in ECF is nearly equivalent to the potassium concentration in ICF. *Osmolality* refers to the concentration of all solutes, whereas *tonicity* refers to the concentration of solutes that are "effective" in eliciting a water shift between body fluid compartments. Addition or removal of solutes causes a sustained shift of water to restore the near equality of concentrations, and they are thus considered effective solutes that contribute to body fluid tonicity. The restriction of sodium to the ECF compartment by virtue of the pump-leak mechanism, together with maintenance of osmotic equilibrium between the ECF and ICF, ensures that ECF volume is determined principally by the total body fluid sodium content and governs the partitioning of fluid between the ECF and ICF compartments. In contrast, solutes that permeate across most cell membranes, such as urea, do not elicit a sustained shift in water and therefore do not contribute to the steady-state partitioning of fluid volumes across body compartments. However, urea and glucose do contribute to the laboratory measurement of fluid osmolality. The addition or removal of water without solutes results in a proportionate reduction or increase, respectively, in both osmolality and tonicity of all body fluid compartments.

The mechanisms that govern body fluid homeostasis preserve near constancy of the volumes of the ECF and ICF compartments despite variations in dietary intake and extrarenal losses of sodium and water and adjust this

balance in response to variations in the capacity of these compartments. Thus, the overriding principle of body fluid and solute homeostasis is mass balance of total body intake and output of water as well as balance of osmotically active particles. Even the slightest perturbations in these parameters activate neural and hormonal mediators for restoration of balance. This restoration of balance is achieved through adjustments in the urinary excretion of sodium and water in response to perceived changes in ECF or ICF volume. Constancy of ECF volume, together with control of vascular capacitance, ensures a high degree of circulatory stability.

Sodium Balance

Sodium balance refers to the difference between intake and excretion. In the nonclinical setting, sodium intake is controlled by dietary habits. In the clinical setting, prescribed adjustments in sodium intake or the administration of sodium-containing medications or solutions cause variation to overall sodium intake. Although nonrenal loss is under some regulatory influence (e.g., aldosterone-mediated regulation of sodium concentration in stool and sweat), the fine adjustment of sodium balance in response to changes in intake is mediated by regulation of urinary sodium excretion. In the steady state, urinary excretion of sodium is closely matched to dietary salt intake. This balance depends on a series of afferent mechanisms that sense the volume of the ECF compartment relative to its capacitance and trigger effector mechanisms that modify the rate of renal sodium excretion to maintain ECF volume homeostasis. Normal functioning of these mechanisms in turn is impacted by the partitioning of the ECF into two subcompartments: intravascular and extravascular (interstitial) (see Fig. 118-1). The composition and concentration of small, noncolloid electrolyte solutes in these two ECF subcompartments are nearly equivalent, but there is a higher concentration of colloid osmotic particles, mostly molecules of albumin and globulin proteins, in the intravascular compartment. Opposing transcapillary hydraulic and colloid osmotic (oncotic) pressure gradients (Starling forces) favor the net transudation of fluid from the intravascular to the interstitial compartment. At the same time, lymphatic fluid movement from interstitial sites back to the circulation through the thoracic duct ensures that the intravascular subcompartment is replenished and maintains a nearly constant proportion of approximately 25% of the overall ECF, which corresponds to 3.5 L of plasma. The remaining approximately 75% of ECF volume (equivalent to 10.5 L in a normal 70-kg male) is contained in the interstitial spaces. Because intravascular volume is one of the key determinants of circulatory integrity, preservation of the constancy of ECF volume, and appropriate partitioning of the ECF volume between the intravascular and interstitial subcompartments are critical for hemodynamic stability.

Effective Arterial Blood Volume

The circulatory network is composed of central and peripheral venous compartments as well as renal and extrarenal arterial compartments. Each compartment reflects a unique characteristic of overall circulatory function (e.g., cardiac filling, tissue perfusion, renal perfusion, and transudation of fluid into the interstitial space) (Table 118-1).

The concept of effective arterial blood volume (EABV) is crucial to understanding the afferent mechanisms that govern the regulation of sodium homeostasis. Unlike ICF, ECF, and intravascular volume, EABV is not measurable as an anatomically defined space but rather is best understood in functional terms as an integration of hemodynamic parameters that emanate from specific sites in the arterial circuit that monitor tissue perfusion and trigger appropriate changes in urinary sodium excretion. These sites include the carotid baroreceptor and intrarenal mechanisms located at the glomerular afferent arterioles, the juxtaglomerular apparatus, and peritubular capillaries. EABV often, but not always, varies directly with actual ECF volume.

TABLE 118-1 MECHANISMS FOR SENSING REGIONAL CHANGES IN BODY FLUID VOLUME

Arterial volume sensors
Carotid and aortic arch baroreceptors
Renal volume sensors
Central nervous system sensors
Hepatic and gastrointestinal tract sensors

Low-pressure sensors (e.g., cardiac atrial transmural stretch and tension receptors) respond to the state of cardiac filling and tend to protect against overfilling of the ECF compartment, but they also have a role in renal sodium retention in states of perceived underfilling. Taken together, the integrated ECF volume-sensing signals elicit an appropriate renal response for modulating sodium excretion in an effort to maintain a constant ECF volume.

The filtered load of sodium vastly exceeds net intake, so tubular reabsorption usually serves as the principal modulator of urinary sodium excretion, the preservation of sodium balance, and the maintenance of a constant ECF volume. Specific luminal membrane sodium transporters or channels at each tubular segment mediate movement of sodium from the luminal fluid into the cell in a carefully regulated manner, followed by extrusion of sodium across the basolateral surface through Na^+, K^+-ATPase and other sodium transporters. Among many others, these regulated luminal transporters include the Na/H exchanger (proximal tubule), the Na-K-2Cl (NKCC2) cotransport pathway (loop of Henle), the NaCl cotransporter (NCCT) along the distal convoluted tubule, and the apical sodium channel (ENaC) along the connecting and cortical collecting tubule. At some nephron sites, sodium reabsorption is isotonic (e.g., proximal tubule), whereas at other sites, sodium reabsorption exceeds water resorption, so tubular fluid has a sodium concentration less than that of plasma (e.g., thick ascending limb of the loop of Henle). Sodium reabsorptive transport pathways are subject to a series of regulatory influences that sense EABV, including the renin-angiotensin-aldosterone pathway, natriuretic peptides, endothelium-derived endothelins and nitric oxide, the eicosanoid-prostaglandin system, guanylin peptides of gut origin, and urotensins. This redundancy of multiple hormonal mediators, which act together with the sympathetic nervous system, renal neural stimulation, and intrarenal physical factors (e.g., peritubular capillary Starling forces, tubule lumen sodium chloride delivery, and tubuloglomerular feedback), underscores the evolutionary importance of regulating urinary sodium excretion to maintain volume homeostasis.

Water Balance

Water balance refers to the difference between intake (oral, enteral, or parenteral) and excretion (insensible, gastrointestinal, perspiratory, and renal). Maintaining equivalency of intake and excretion of water ensures constancy of body fluid tonicity (osmoregulation). Osmoregulation ensures that the content of effective solutes in each body fluid compartment determines the volume of that compartment. Positive water balance or negative water balance and the corresponding changes in tonicity and cell volume are sensed by osmoreceptor and thirst center cells in the hypothalamus. The osmoreceptors are situated in the supraoptic and paraventricular nuclei of the hypothalamus; the thirst center is situated in the organum vasculosum of the anterior hypothalamus. Just a 2% change in effective osmolality or tonicity elicits a change in release of the hormone arginine vasopressin (AVP) from the posterior pituitary gland and the perception of thirst. Endothelin-1 also is released from the posterior pituitary in response to water deprivation and increases plasma AVP levels. Stimulation of thirst depends on centrally produced angiotensin II. A reduction of more than approximately 8% of ECF volume serves as an overriding afferent signal (carried by the ninth and tenth cranial nerves) for the nonosmotically driven release of AVP and also stimulates thirst by means of angiotensin II, even when body tonicity is not elevated (Fig. 118-2A).

The urinary excretion of water depends on the delivery of isotonic sodium-containing filtrate to the thick ascending limb of the loop of Henle, reabsorption of sodium and accompanying electrolytes in the thick ascending limb of the loop of Henle and the distal tubule, and the AVP-regulated reabsorption of the appropriate volumes of solute-free water through aquaporin-2 water channels in the cells of the collecting tubule. The hydro-osmotic movement of water from the collecting tubule lumen to the hyperosmotic milieu of the renal medulla minimizes urinary excretion of the hypotonic fluid generated in the thick ascending limb of the loop of Henle and the distal tubule, thereby promoting positive water balance. In the *absence* of AVP, this hypotonic fluid is excreted, and negative water balance ensues. Typical levels of urine osmolality that can be achieved in the human kidney by fluctuations in AVP action range between 50 and 1200 mOsm/kg, but this range narrows at the extremes of age or in the presence of intrinsic renal disease. Laboratory measurement of urine osmolality reflects overall renal concentrating ability, including the hydro-osmotic action of AVP. However, not all solutes that contribute to the laboratory measurement of urine osmolality correspond to effective solutes in terms of body fluid tonicity. Thus, excretion of urine with high concentrations of urea and low concentrations of sodium, potassium, and chloride

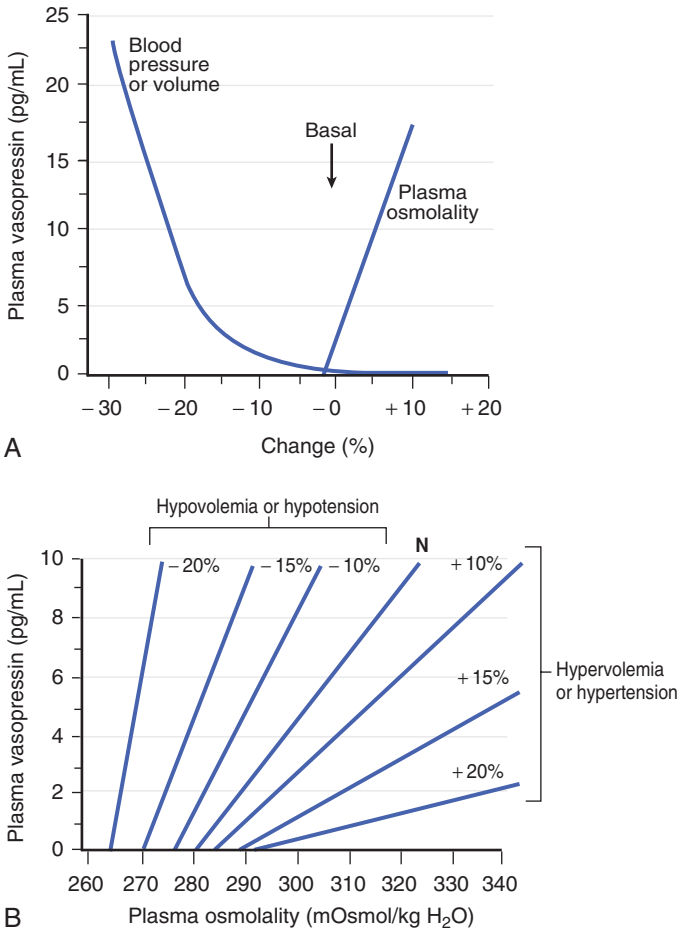

FIGURE 118-2. Relationship between arginine vasopressin (AVP) and osmolality. **A**, Comparative sensitivity of AVP secretion in response to increases in plasma osmolality versus decreases in blood volume or blood pressure in human subjects. The *arrow* indicates the low plasma AVP concentrations found at basal plasma osmolality. Note that AVP secretion is much more sensitive to small changes in blood osmolality than to changes in volume or pressure. **B**, The relationship between the osmolality of plasma and the concentration of AVP in plasma is modulated by blood volume and pressure. The line labeled N shows plasma AVP concentrations across a range of plasma osmolality in an adult with normal intravascular volume (euvolemic) and normal blood pressure (normotensive). The lines to the left of N show the relationship between plasma AVP concentration and plasma osmolality in adults whose low intravascular volume (hypovolemia) or blood pressure (hypotension) is 10%, 15%, and 20% below normal. Lines to the right of N are for volumes and blood pressure 10%, 15%, and 20% above normal. Note that hemodynamic influences do not disrupt the osmoregulation of AVP but rather raise or lower the set point and possibly also the sensitivity of AVP secretion in proportion to the magnitude of the change in blood volume or pressure.

indicates a strong renal concentrating capacity but contributes less to positive water balance than does excretion of urine with the same measured osmolality and higher concentrations of these electrolytes.

PATHOPHYSIOLOGY

Disturbances in sodium balance primarily affect ECF volume, and disturbances in water balance primarily affect body fluid tonicity. A cumulative negative balance of sodium (sodium deficit) in the absence of a change in tonicity results in ECF volume contraction (hypovolemia), whereas a cumulative positive balance of sodium (sodium surfeit) results in ECF volume expansion (hypervolemia). In contrast, a cumulative positive body water balance (water surfeit) results in volume expansion of all the body fluid compartments, whereas negative water balance (water deficit) results in volume contraction of all the body fluid compartments. However, because ICF volume is double that of ECF at baseline, the more prominent expansion or contraction in absolute volume terms involves the ICF compartment. Furthermore, maintenance of a surfeit or deficit of water relative to solutes results in a uniform decrease or increase in body fluid tonicity in all fluid compartments. Because the solute composition of the plasma component of the ECF compartment is sampled, a disturbance in tonicity is most commonly detected as an abnormality in plasma sodium concentration (hyponatremia for water surfeit and hypernatremia for water deficit). Frequently, disturbances in water and sodium balance occur together, and all combinations of surfeit or deficit can occur (Table 118-2). The clinical approach to a patient with a sodium or water balance disturbance (or both) can be facilitated by careful consideration of which states apply.

TABLE 118-2 PATHOGENIC PROCESSES LEADING TO DISORDERS OF BODY SODIUM AND FLUID HOMEOSTASIS

CLINICAL STATE	EXTRACELLULAR FLUID VOLUME	BODY FLUID TONICITY	PATHOGENIC PROCESS
Normal	↔	↔	
Hypervolemic normonatremia	↑	↔	Isotonic net gain of sodium and water
Hypervolemic hyponatremia	↑	↓	Hypotonic net gain of sodium and water
Hypervolemic hypernatremia	↑	↑	Hypertonic net gain of sodium and water
Normovolemic hyponatremia	↔	↓	Net water gain ± sodium loss
Normovolemic hypernatremia	↔	↑	Net water loss ± sodium gain
Hypovolemic hypernatremia	↓	↑	Net loss of water in excess of sodium
Hypovolemic normonatremia	↓	↔	Isotonic net loss of sodium and water
Hypovolemic hyponatremia	↓	↓	Net loss of sodium in excess of water

↔ = Unchanged.

SODIUM BALANCE DISORDERS

Hypovolemia

DEFINITION

Hypovolemia is a reduction in the volume of the ECF compartment in relation to its capacitance. In states of absolute hypovolemia, a deficit in sodium reflects past or ongoing negative sodium balance. The volume of the ECF intravascular and extravascular (interstitial) subcompartments may vary in the same or opposite directions. ICF volume is reflected by the measurement of plasma osmolality and sodium concentration and may be concomitantly disturbed (see Table 118-2).

EPIDEMIOLOGY

Causes of absolute and relative hypovolemia (Table 118-3) can be categorized into extrarenal and renal causes. Bleeding is the most frequent and direct cause of a reduction in the absolute volume of the intravascular subcompartment of the ECF (Chapters 106 and 137). Other causes of absolute hypovolemia include fluid loss from the kidney or from the gastrointestinal, integumentary, or respiratory systems. Infectious diarrhea remains a leading cause of death from hypovolemia in many areas of the world. Burns allow the loss of large volumes of plasma and interstitial fluid and can rapidly lead to profound hypovolemia similar to what is seen with bleeding (Chapter 112). Enhanced evaporative water loss from the respiratory tract can occur with exercise, in response to heat stress (Chapter 109), in febrile states, and in patients undergoing mechanical ventilation with inadequate humidification.

ECF also can be sequestered into compartments within the body without an evident history of loss. Such pathologic conditions are often referred to as third space loss and include gastrointestinal obstruction, sequestration of fluids in subcutaneous tissue after trauma or burns (Chapter 112), and sequestration in the retroperitoneal or peritoneal space in patients with pancreatitis (Chapter 146) or peritonitis (Chapter 144), respectively. The accumulation of ascites may also compromise intravascular volume.

In any form of kidney disease in which tubular reabsorption of the filtered sodium load does not match the sum of this filtered load plus dietary intake, a renal sodium-wasting state may ensue. Most of the widely used diuretic medications inhibit specific pathways for sodium reabsorption at various sites along the nephron and should more properly be referred to as natriuretic medications. Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) are the most potent diuretics, and their potential to induce renal

sodium loss is augmented when they are combined with other classes of diuretic agents (thiazides, carbonic anhydrase inhibitors, aldosterone antagonists, and distal epithelial sodium-channel blockers).

Natriuretic medications often are used to treat hypervolemic states, but their overuse or inappropriate use can result in hypovolemia. Tubular sodium reabsorption also may be disrupted by inherited or acquired renal tubulopathies, such as various forms of proximal tubulopathy and different forms of Bartter's and Gitelman's syndromes (Chapter 130).

Impairment of renal tubule sodium reabsorption may also occur with nonoliguric acute kidney injury and the recovery phase after oliguric acute kidney injury or after release of urinary obstruction (Chapters 122 and 125). Interstitial renal disease (Chapter 124) may result in fluid and electrolyte abnormalities, which can include renal sodium wasting. Nonelectrolyte urinary solutes such as glucose (in severe hyperglycemia) and mannitol cause polyuria and hypovolemia. Mineralocorticoid deficiency and resistance, including adrenal insufficiency (Chapter 234), should always be considered in a patient with evidence of urinary sodium loss in the face of hypovolemia. In cerebral salt wasting (also referred to as renal salt wasting), tubular sodium reabsorption is impaired in the setting of acute head injury (Chapter 406) or intracranial hemorrhage.

In *relative hypovolemia*, ECF volume is not reduced in absolute terms, but the capacitance of the ECF or intravascular compartment is expanded, thereby leading to clinical manifestations that mimic those of absolute hypovolemia. Relative hypovolemic states can be classified into two categories: states of vasodilation and states of generalized edema. Vasodilation occurs in response to endogenous endothelial substances (e.g., nitric oxide) and to exogenous agents that induce vasodilation (e.g., vasodilator drugs). Peripheral vasodilation occurs in sepsis (Chapter 108) and in normal pregnancy. Relative hypovolemia also occurs in patients with a positive sodium and water balance and generalized edema but a reduced intravascular volume. Examples include heart failure (Chapters 58 and 59), decompensated cirrhosis with ascites (Chapter 156), and the nephrotic syndrome (Chapter 123).

PATHOBIOLOGY

Extrarenal Causes of Absolute Hypovolemia

The immediate effect of bleeding is a proportionate net loss in plasma and erythrocytes and hence an isotonic reduction in ECF volume. Compensatory hemodynamic responses include tachycardia and vasoconstriction, followed by a shift of fluid from the interstitial to the intravascular compartment because of altered transcapillary Starling hydraulic forces. Additional neural and hormonal responses result in renal sodium and water retention, with the aim of restoring intravascular volume and stabilizing the circulation.

Besides dietary intake, approximately 7 L of isotonic fluid enters the gastrointestinal tract on a daily basis, the bulk of which is reabsorbed to minimize fecal fluid loss. Because these fluids contain varying concentrations of sodium and accompanying anions, enhanced secretion or impaired reabsorption causes absolute ECF volume depletion. The composition of the fluid and electrolyte loss differs according to the cause and source of gastrointestinal fluid loss (Chapters 134 and 142).

Given its large surface area, it is not surprising that fluid losses from the integumentary system can be an important cause of hypovolemia. In the absence of medical intervention, hemoconcentration and hypoalbuminemia ensue; however, because of the isotonic composition of the lost fluid, no changes in plasma osmolality or sodium concentration are expected. Exertion in hot environments increases thermoregulatory fluid losses from the skin in the form of sweat. Fluid loss through perspiration can reach 1 L/hour or more, depending on exertion and environment. The sodium concentration in sweat varies among individuals (range of approximately 20 to 50 mmol/L). Thus, although the fluid loss is hypotonic, a significant sodium deficit and ECF volume contraction can ensue. The extent of hypovolemia and the resulting body fluid composition (plasma osmolality and sodium concentration) will depend on fluid replacement, which is determined primarily by thirst and availability.

All extrarenal causes of hypovolemia are expected to invoke a renal response, whose hallmark is sodium and fluid conservation. Obviously, this expected response is absent when the kidney itself is responsible for sodium loss, whether owing to the effect of pharmacologic or hormonal influences or to intrinsic renal disease.

Renal Causes of Hypovolemia

When the glomerular filtration rate (GFR) and plasma sodium concentration are normal, approximately 24,000 mmol of sodium are filtered per day. Even when the GFR is markedly impaired, the quantities of sodium filtered far exceed normal dietary intake. Thus, the small quantities of sodium excreted in urine relative to the filtered load depend on the integrity of tubular sodium reabsorptive mechanisms to match urinary sodium excretion to dietary intake through volume sensing and effector mechanisms. Impairment in the integrity of one or more of these sodium reabsorptive mechanisms can result in a profound sodium deficit and absolute volume depletion.

An underappreciated but frequent clinical setting for renal sodium loss occurs after the iatrogenic administration of high volumes of volume-expanding, salt-containing solutions to hospitalized patients. Such patients are usually in the postoperative or post-trauma setting and are frequently administered many liters of saline or other sodium-containing maintenance intravenous fluids for several consecutive days, during which tubule reabsorption of sodium is downregulated. There may be a lag in the restoration of full tubule reabsorptive capacity, when intravenous fluids are discontinued, and high volumes of urine rich in sodium continue to be excreted. During this lag phase, the patient may become mildly, but transiently, hypovolemic. This scenario can be avoided by a graduated reduction in administered sodium-containing fluids, at a pace that allows sodium reabsorptive tubular pathways to be upregulated and restored to their normal reabsorptive levels.

Diabetes insipidus represents a spectrum of conditions resulting from deficiency or tubular resistance to the action of AVP. However, because it is the tubular reabsorption of water and not solutes that is impaired, the impact on ECF volume is generally a minor consideration in comparison to the impact on ICF and body fluid tonicity.

CLINICAL MANIFESTATIONS

The clinical manifestations of hypovolemia depend on the magnitude and rate of volume loss, the solute composition of the net fluid loss (taking into account ingested or administered fluids), and vascular and renal responses. A detailed history is often helpful in assessing bleeding, vomiting, diarrhea, polyuria, medications, and diaphoresis.

However, the absence of symptoms does not exclude mild to moderate hypovolemia, especially if the volume loss has occurred gradually. Intravascular volume contraction of less than 5% does not usually elicit symptoms and readily escapes detection by physical examination. With greater degrees of absolute hypovolemia (corresponding to intravascular volume contraction in the 5 to 15% range), symptoms and signs begin to appear. Patients may exhibit nonspecific symptoms related to end-organ hypoperfusion, including weakness, muscle cramps, and postural lightheadedness. Thirst may be an early manifestation but more likely reflects a concomitant hypertonic state.

A number of clinical scenarios illustrate the relationship of clinical manifestations to causes of hypovolemia. For example, a patient with an acute *gastrointestinal hemorrhage* (Chapter 137) of 0.5 L of whole blood can experience tachycardia, postural hypotension, peripheral vasoconstriction with cool extremities, lightheadedness, and oliguria, with high urine osmolality

and low urine sodium concentration. Hemoglobin and albumin will probably remain constant initially, and then a drop in hemoglobin will ensue after movement of ECF from the interstitial to the intravascular compartment. The plasma solute composition (sodium and potassium concentration, acid-base parameters) is not likely to change initially. The plasma concentration of urea may rise somewhat as a result of increased proximal tubular reabsorption of urea, increased proximal reabsorption of salt and water, and the increased nitrogen load from the destruction of erythrocytes in the gastrointestinal tract. Jugular venous pressure is expected to fall, and central venous pressure (CVP) will generally be less than 5 cm H_2O in the absence of confounding factors. Urine output is expected be low, with a high specific gravity and osmolality and a low urine sodium concentration.

In another scenario, a patient inappropriately receiving potent *loop diuretics* over a period of many days for localized peripheral edema may suffer a cumulative net ECF loss of 3 L, or about 20%; approximately one third of this lost volume will have originated from the intravascular compartment, with the remainder coming from the interstitial compartment. This degree of intravascular loss usually induces weakness, tachycardia, low jugular venous pressure, and hypotension. However, because the deficit may have accumulated over time, a degree of adaptation would attenuate the severity of these clinical manifestations and lead the clinician to underestimate the extent of hypovolemia. The plasma sodium concentration may remain unaltered because disruption of the urine-concentrating mechanism by loop diuretics attenuates the tendency to water retention, and an intact thirst mechanism prevents hypertonicity. Because loop diuretics enhance urinary potassium and ammonium excretion, hypokalemic metabolic alkalosis is expected. The ongoing effect of the loop diuretic would mitigate oliguria and lead to inappropriately high concentrations of solutes including sodium and potassium in urine. After cessation of the loop diuretic, the appropriate renal response of oliguria, high urine osmolality, and sodium concentration would be expected.

A third scenario is a patient with relative hypovolemia owing to the vasodilation that typically accompanies *bacteremic sepsis* (Chapter 108). No source of fluid loss would be identified in the history, but the patient would usually manifest symptoms of weakness and even prostration, accompanied tachycardia and hypotension. The extremities may be warm, but reduced tissue perfusion may reduce the level of consciousness and cause oliguria, elevated plasma urea and creatinine levels, and lactic acidosis.

DIAGNOSIS

The most readily appreciated physical findings related to contraction of the intravascular compartment include tachycardia, orthostatic hypotension, and reduced jugular venous pressure. Although low CVP often reliably reflects intravascular volume contraction, an elevated CVP does not necessarily exclude hypovolemia because of the possible confounding influence of cardiac or lung disease. Severe degrees of hypovolemia (corresponding to intravascular volume contraction exceeding 10 to 20%) cause hypotension (even in the supine position), peripheral cyanosis, cold extremities, and reduced levels of consciousness (extending even to coma) as a result of end-organ and cerebral hypoperfusion. Hemodynamic collapse (hypovolemic shock; Chapter 106) also can occur with more rapid volume loss, comorbid conditions, and greater degrees of hypovolemia. When the source of volume loss is purely extrarenal, oliguria is expected. Physical findings such as reduced skin or eyeball turgor and dry mucous membranes are not reliable indicators of hypovolemia.

Laboratory Findings

Laboratory measurements are an adjunct to clinical assessment but do not replace symptoms and physical examination findings as a primary diagnostic tool. Decreases in *hemoglobin* indicate past or ongoing bleeding, but a normal or stable hemoglobin does not exclude acute bleeding. Hemoconcentration is often observed when hypovolemia is not the consequence of bleeding, but comorbid disease processes that produce anemia may mitigate this rise.

The *albumin* concentration may rise with gastrointestinal, urinary, or skin losses of albumin-free fluids. Conversely, fluid losses that are accompanied by albumin loss (e.g., proteinuria, protein-losing enteropathy) may mitigate this rise or even result in hypoalbuminemia. Similarly, burns and hepatic disease are often accompanied by hypoalbuminemia as a result of the loss or third spacing of protein-rich fluid.

Serum levels of *sodium* and *other electrolytes* also can vary widely. Even subtle and subclinical degrees of hypovolemia trigger urinary water retention and result in a hypotonic hyponatremic plasma composition if the patient is exposed to solutions that are more hypotonic than that of the fluid lost. In contrast, loss of hypotonic fluids with inadequate water ingestion or replacement results in a hypertonic plasma composition and hypernatremia.

Acid-base (Chapter 120) and *potassium* (Chapter 119) changes point to specific causes. For example, hypokalemia with metabolic alkalosis frequently accompanies vomiting and some causes of diarrhea (e.g., a villous adenoma). More often, diarrheal fluid loss is associated with a non–anion gap metabolic acidosis. Loop and thiazide diuretic-induced hypovolemia is often associated with hypokalemic metabolic alkalosis, as are the inherited tubulopathies (Bartter's and Gitelman's syndromes) (Chapter 130), which disrupt sodium reabsorptive mechanisms at the loop of Henle and distal convoluted tubule, respectively. Severe hypovolemia with circulatory compromise and tissue hypoperfusion is often accompanied by lactic acidosis.

Increases in *plasma urea* and *creatinine* concentrations are frequently observed in hypovolemic states and reflect reduced renal plasma flow. If acute tubule injury does not supervene, the rise in plasma urea concentration is often disproportionate to the rise in plasma creatinine concentration (see Prerenal Azotemia in Chapter 122). The rise in plasma urea and creatinine concentrations is particularly common when hypovolemia is a consequence of urinary fluid losses. In such conditions, the patient is not oliguric, even though renal plasma flow and GFR are compromised. Other forms of urinary sodium loss, such as occur with adrenal insufficiency or aldosterone unresponsiveness, are accompanied by a tendency toward hyperkalemia and mild metabolic acidosis.

Urinary biochemical parameters may also help in the clinical assessment of hypovolemic states. When fluid loss is extrarenal, the expected renal response of water and sodium conservation results in oliguria with an elevated urine specific gravity (>1.020) and osmolality (>400 mOsm/kg) and a sodium concentration less than 20 mmol/L because of enhanced renal tubule reabsorptive activity. More complex indices of the appropriate renal response to hypovolemia include fractional excretion of sodium less than 1% and fractional excretion of urea less than 30 to 35%. Intrinsic renal injury confounds the diagnostic value of these urinary indices.

Differential Diagnosis

Relative hypovolemia secondary to arterial vasodilation mimics some of the clinical manifestations of absolute hypovolemia. With vasodilation, as seen for example in sepsis (Chapter 108), tachycardia and hypotension are common, but the extremities may be warm. However, tissues are actually underperfused, as reflected by reduced renal and cerebral function and lactic acidosis.

TREATMENT Rx

Absolute Hypovolemia

The major goal in treatment of hypovolemia is to restore hemodynamic integrity and tissue perfusion. The treatment approach includes treatment of the underlying disease state when possible, replacement of the volume deficit, and fluid administration to maintain ECF volume in the event of continuing losses. Beyond the specific treatments, the mainstay of therapy involves fluid administration. The important issues are the volume, rate of administration, and composition of the replacement and maintenance fluids. These decisions may vary during different stages of treatment and should be adjusted according to the patient's response as determined by closely monitored clinical parameters.

The choice of oral or intravenous replacement fluids (or both) for hypovolemic states is dictated principally by the disturbances in other electrolyte and acid-base parameters. The rate of replacement is a function of the urgency of the threat to circulatory integrity and consideration of complications related to overzealous or too rapid correction.

Fluid therapy for hypovolemic states sometimes begins with a diagnostic fluid challenge. In situations in which clinical parameters do not permit a firm diagnosis of hypovolemia, the response to a fluid challenge can be informative and serve as the initial treatment step. For example, a patient with known long-standing compensated heart failure who is being maintained on a therapeutic regimen that includes diuretics may have tachycardia, a reduction in blood pressure from baseline values, poor cognition, and renal dysfunction. Such a clinical scenario could have a number of different explanations, including superimposed volume depletion with inadequate left ventricular filling volume. CVP, whether measured directly or assessed by jugular venous pressure, may be misleading in the face of right ventricular dysfunction, but direct measurement of pulmonary capillary wedge pressure does not significantly improve clinical outcomes. In such a case, a carefully monitored diagnostic fluid challenge can minimize the risk for fluid overload. Such monitoring should include clinical assessment of parameters indicating pulmonary venous hypertension (pulmonary congestion or edema by physical examination or

chest radiograph). Reversal of the disturbed clinical parameters would support the diagnosis of volume depletion.

Another example is a patient with hyponatremia in the setting of suspected volume depletion. Often the degree of volume depletion is too subtle to be detected by clinical examination, and a therapeutic challenge with fluid of the appropriate composition can be informative.

The initial volume and rate of therapeutic replacement fluid should be determined by ongoing monitoring of clinical parameters rather than a priori estimates of volume deficit. In some settings, the clinical state will dictate rapid fluid replacement, as in a patient with unambiguous hypovolemic shock and life-threatening circulatory collapse. In such cases, fluids can be administered at the most rapid rate possible, limited only by intravenous access, until blood pressure and tissue perfusion are restored. However, in most cases, much slower rates are indicated, especially in elderly patients, patients whose medical background is unclear, or those with known comorbid conditions. It is important to note that replacement fluids of different compositions have quite disparate volumes of distribution in the body fluid compartments and therefore differ in their efficiency of restoring ECF volume. *Crystalloid solutions* with sodium as the principal cation are the mainstay in fluid replacement therapy for hypovolemic states and are indicated primarily for hypovolemic states that are caused by renal, gastrointestinal, or sweat-based sodium losses. These solutions also are useful initial agents and adjuncts to therapy for the hypovolemia of hemorrhage and burns. *Isotonic saline* is confined to the ECF compartment (except in cases of severe dysnatremia). Thus, retention of 1 L of infused isotonic saline increases plasma volume by about 300 mL, with the remaining portion distributed in the interstitial subcompartment of the ECF. In contrast, a solution of *5% dextrose in water (D_5W)* is equivalent to administering solute-free water and distributes uniformly throughout all body fluid compartments (one third of the retained volume of infusate remains in the ECF compartment and only approximately 10 to 15% in the intravascular compartment). Infusing a given volume of *half isotonic saline (0.45% sodium chloride plus 5% glucose)* can be considered equivalent to infusing half that volume as solute-free water (distributed throughout body fluid compartments) and the other half as isotonic saline (confined to the ECF compartment). The retained solute-free volume reduces body tonicity and the plasma sodium concentration, potential benefit in the follow-up treatment of patients whose hypovolemia is accompanied by hypertonicity and hypernatremia, but a detriment for patients with normotonic or hypotonic hypovolemia.

When hypovolemia is accompanied by hypobicarbonatemia (metabolic acidosis), it may be appropriate to design a solution in which a portion of the sodium is accompanied by bicarbonate (Chapter 120). For example, it is possible to add a given quantity of hypertonic sodium bicarbonate to a solution of half isotonic saline (in which chloride is the anion accompanying sodium) to obtain an isotonic replacement fluid appropriate for the given acid-base status of the patient. Similarly, in patients with concomitant potassium depletion (Chapter 119), especially when accompanied by metabolic alkalosis, addition of potassium chloride to the replacement solution may be indicated. A number of crystalloid solutions with predetermined concentrations of potassium, lactate (converted to bicarbonate by the liver), and other electrolytes are commercially available, but it is more appropriate to begin with a sodium chloride–containing solution at a concentration appropriate to body tonicity, then to add other solutes as indicated or at a separate intravenous administration site. This approach provides maximal flexibility in tailoring individualized fluid replacement therapy to patient needs.

Colloid-containing solutions include albumin or high-molecular-weight carbohydrate molecules (e.g., hydroxyethyl starch or dextran) at concentrations that exert a colloid osmotic pressure equal to or greater than that of plasma. Banked human plasma is also considered a colloid solution. Because large molecules such as albumin and high-molecular-weight carbohydrates do not readily cross the transcapillary barrier, they are thought to expand the intravascular compartment more rapidly and efficiently than crystalloid solutions. However, a randomized trial showed no benefit of colloids compared with crystalloids for fluid resuscitation.■ Nevertheless, albumin-containing solutions may be useful in hypovolemia associated with burns (Chapter 112), when cutaneous protein losses are appreciable. Furthermore, because of the capacity for rapid intravascular volume expansion with just a small volume of replacement fluid, colloid-containing solutions are frequently used when rapid intravascular expansion is desired, such as at trauma sites outside of the hospital setting. Some large-molecular-weight carbohydrates are nephrotoxic and should be used with caution in patients with renal impairment. In patients with multiorgan system failure and capillary leakage, albumin is both rapidly catabolized and redistributed into the interstitial compartment, so it can aggravate interstitial edema without providing an intravascular volume repletion benefit. It is for these reasons that crystalloid-containing solutions remain the mainstay of volume replacement therapy.

Blood products can be used for volume replacement in hypovolemic states, and a unit of packed red blood cells remains entirely in the vascular compartment. However, erythrocytes are actually considered part of the intracellular compartment and do not contribute to organ plasma flow. The role of packed red cells in the treatment of hemorrhage is to restore the principal function of the erythrocyte in oxygen carriage and delivery, not as a means of ECF volume replacement.

In addition to replacement fluids, maintenance fluids must be provided to counteract ongoing losses. Such ongoing losses may be a continuation of the underlying disease state (e.g., continued vomiting, diarrhea, polyuric states, or severe burns). The volume, rate of administration, and composition of these replacement fluids are best determined by actual measurements of the corresponding ongoing fluid losses, with appropriate adjustments for the patient's clinical assessment parameters.

Relative Hypovolemia

The treatment approach to relative hypovolemia is more complex than for absolute hypovolemia. When relative hypovolemia is the result of peripheral vasodilation, therapy should be directed toward reversal of the underlying cause and restoration of normal vascular reactivity. Bridging to maintain circulatory integrity until the underlying cause is successfully reversed can be achieved by infusion of an *isotonic crystalloid solution* such as normal saline. In such situations, selection of volumes and rates must be done with extreme caution because there is no absolute deficit and the administered volume will have to be excreted or removed once systemic vascular resistance and vascular capacitance are restored to normal. Furthermore, it is more difficult to estimate an increase in vascular capacitance than it is to estimate an absolute volume deficit. Occasionally, it is appropriate to consider the use of vasoconstrictor agents. When relative hypovolemia occurs in the setting of an edema state, therapy must take into account the fact that the patient actually has a total body sodium surfeit with excess ECF volume, but a maldistribution of that volume away from the EABV. When crystalloid solutions are provided to such patients, a variable, but usually substantial, proportion of administered fluid is distributed into the interstitial compartment and consequently does not contribute to restoration of EABV. This vicious cycle emphasizes the importance of treatment directed at the underlying disease state.

Hypervolemia

DEFINITION

Hypervolemia refers to expansion of ECF volume, which varies, even in normal individuals, with dietary sodium intake. Thus, an individual in steady state with low daily dietary sodium intake (e.g., 20 mmol/day, corresponding to approximately 1.2 g of table salt per day) will have correspondingly low urinary sodium excretion, equivalent to dietary intake minus extrarenal losses. A shift to much higher sodium intake (e.g., 200 mmol/day, corresponding to approximately 12 g of table salt per day) will bring the individual to a new steady state characterized by a correspondingly higher urinary sodium excretion rate. This shift is accompanied by an increase in ECF volume, which triggers the sensor and effector mechanisms for increased urinary sodium excretion (described earlier). In most individuals, this increase in ECF volume is not clinically detectable and does not have pathologic consequences. In some individuals, however, this upward shift in ECF volume increases systemic arterial blood pressure. When the sodium surfeit expands the ECF volume beyond the range necessary for the adjustment needed to restore sodium balance, a state of pathologic hypervolemia ensues.

EPIDEMIOLOGY

Primary and secondary renal sodium retention (Table 118-4) can lead to hypervolemia. Patients with oliguric renal failure of any cause (Chapters 122 and 132) have a limited ability to excrete both sodium and water. Urinary sodium retention can be one of the cardinal manifestations of primary glomerular diseases (Chapter 123), even when the GFR is well preserved. States of *mineralocorticoid excess* (Chapter 234) or enhanced activity are associated with a phase of sodium retention; however, because of the phenomenon of "mineralocorticoid escape," the clinical manifestation is generally that of hypertension rather than hypervolemia. Both heart failure (Chapter 58) and cirrhosis (Chapter 156) are associated with renal sodium retention.

PATHOBIOLOGY

Two pathophysiologic mechanisms can lead to sodium retention with ECF volume expansion. The first involves renal sodium retention that is primary and unrelated to the activation of afferent sensor mechanisms. This category includes primary renal diseases and endocrine disorders characterized by excess mineralocorticoid action. In the second category, EABV is reduced, and afferent sensory mechanisms activate effector responses that drive renal sodium retention. In these conditions, ECF volume is expanded; intravascular volume may be expanded, normal, or contracted; but the volume homeostatic mechanisms of the body mimic those of hypovolemia because of the perception of reduced EABV. The degree of solute-free water retention that

TABLE 118-4 PRIMARY AND SECONDARY RENAL SODIUM-RETAINING STATES

Oliguric renal failure
Chronic kidney disease
Glomerular disease, including nephrotic syndrome
Severe bilateral renovascular obstruction
Mineralocorticoid excess
Inherited sodium-retaining tubulopathies
Cardiac failure
Cirrhosis
Idiopathic edema

accompanies the sodium surfeit has a relatively small influence on the extent of hypervolemia but influences the accompanying tonicity state and determines whether the hypervolemia is hypotonic or isotonic.

When the ECF volume is expanded, the relative distribution between the intravascular and extravascular (interstitial) compartments depends on a number of factors. When cardiac and hepatic functions are normal and peripheral transcapillary Starling forces are intact, the excess ECF volume is evenly distributed between the intravascular and interstitial fluid compartments. In such cases, edema does not occur until there is a substantial surfeit of sodium, and hypertension is expected. In contrast, concomitant disruption of transcapillary Starling forces in a given microcirculatory bed would favor the accumulation of retained fluid at one or more such interstitial locations (e.g., dependent edema progressing to anasarca, ascites, pleural effusion, pulmonary congestion).

Primary Renal Sodium Retention

Patients who retain ingested or administered sodium and water loads expand their ECF volume. In patients with chronic kidney disease, the filtered load of sodium remains well above dietary intake until very late stages of severely reduced GFR: even when the GFR is decreased by as much as 90%, the daily filtered load of approximately 2400 mmol still greatly exceeds dietary intake. Nevertheless, the relationship between tubular reabsorption and filtered load may be disrupted in kidney disease.

Monogenic disorders that cause or mimic enhanced mineralocorticoid activity or are associated with enhanced activity of the distal nephron sodium reabsorptive pathways include Liddle's syndrome and pseudohypoaldosteronism type II (Chapters 67, 119, and 130). In these conditions and in other causes of mineralocorticoid excess, the only clue to mild hypervolemia may be hypertension, which can be severe. Mineralocorticoid excess, glucocorticoid remediable hypertension, apparent mineralocorticoid excess, and Liddle's syndrome are associated with hypokalemia, whereas pseudohypoaldosteronism type II or Gordon's syndrome are often accompanied by hyperkalemia.

Secondary Renal Sodium Retention

With both low-output and high-output heart failure, and both systolic and diastolic dysfunction, sodium retention is typical (Chapter 58). Low cardiac output, diversion of cardiac output away from arterial intravascular volume-sensing sites, or a high cardiac output that still is not sufficient to meet tissue demands appears to be a necessary and sufficient condition for initiating renal sodium retention. In the case of cirrhosis with ascites (Chapter 156), hepatic intrasinusoidal hypertension is a sufficient and necessary condition for initiating renal sodium retention. These pathophysiologic disturbances in cardiac or hepatic function disrupt afferent signals that govern normal sodium homeostasis and trigger effector mechanisms that lead to enhanced tubular reabsorption of sodium at multiple nephron sites. At the very earliest stages of disease, sodium retention occurs independently of any measurable or detectable reduction in the volume of the intravascular compartments or any of its measurable subcompartments. At more advanced stages of disease, reduced intravascular volume serves as the overriding stimulus for renal sodium retention and thereby leads to a decompensated state of intractable ECF volume accumulation. The more advanced stages, which often are accompanied by a disproportionate degree of positive water balance and consequent hyponatremia, herald imminent compromise of the GFR. Among the many neuronal and humoral abnormalities that characterize the sodium retention associated with heart failure and cirrhosis are endothelial dysfunction, enhanced sympathetic nerve activity, activation of the renin-angiotensin-aldosterone axis, and resistance to natriuretic peptides. In cirrhosis with ascites (Chapter 156), portosystemic shunting together with translocation of intravascular volume to the splanchnic and venous circulation further compromise EABV. In addition, synthetic dysfunction with resulting hypoalbuminemia favors transudation of fluid into the interstitial compartment. At the level of intrahepatic hemodynamics, intrasinusoidal hypertension results in enhanced hepatic lymph formation. When the rate of enhanced hepatic lymph formation exceeds the capacity for return to the intravascular compartment through the thoracic duct, hepatic lymph accumulates in the form of ascites, and the intravascular compartment is further compromised.

CLINICAL MANIFESTATIONS

In addition to the clinical manifestations of the underlying disease, the clinical manifestations of *hypervolemia* depend on the amount and relative distribution of accumulated fluid in the various ECF subcompartments, including the venous and arterial components of the intravascular compartment (jugular venous distention and hypertension), the interstitial spaces of the extremities, subcutaneous tissues of the lower back and the periorbital region (peripheral pitting edema, whose predominant location depends on the patient's position), the peritoneal and pleural spaces (ascites and pleural effusion, respectively), and the alveolar space (pulmonary edema). When cardiac and hepatic function is normal and the transcapillary Starling forces are not disrupted, the excess volume is distributed proportionately throughout the ECF compartment. *Hypertension* may be an early manifestation depending on cardiac function and the state of systemic vascular resistance. Jugular venous distention (see Fig. 50-3 in Chapter 50) and peripheral edema (see Fig. 50-7 in Chapter 50) may be present. Clinically detectable pitting peripheral edema usually signifies the accumulation of at least 3 L of excess interstitial volume. Because intravascular plasma volume is itself only 3 L, any state of generalized peripheral edema must signify ECF volume expansion and therefore past or ongoing renal sodium retention, or both.

When cardiac function is impaired because of myocardial disease, valvular disease, or pericardial disease, pulmonary and systemic venous hypertension predominates, and systemic arterial pressure may be low as a result of disproportionate accumulation of intravascular volume in the venous as opposed to the arterial circulation (Chapter 58). The presence of transudative ascites (see Fig. 148-5 in Chapter 148) signifies the substantial accumulation of excess ECF volume in the peritoneal cavity, most commonly secondary to disruption of intrahepatic hemodynamics in the setting of liver disease. Pleural effusions can also be a manifestation of hypervolemia, particularly in the setting of heart failure or advanced cirrhosis with ascites.

DIAGNOSIS

Hypervolemia usually is easily detected by findings of generalized edema, ascites, elevated jugular venous pressure, inspiratory pulmonary crackles, or evidence of the presence of pleural effusion. The prevailing systemic arterial blood pressure often provides a clue about whether the hypervolemic state is secondary to reduced EABV or instead due to primary renal sodium retention. The history and physical examination are often sufficient to yield the diagnosis of an underlying secondary cause of sodium retention, such as heart failure or cirrhosis. Adjunctive laboratory tests providing evidence of cardiac dysfunction or liver disease may be helpful. The presence of glomerular-range proteinuria with hypoalbuminemia indicates a glomerular cause of the sodium retention and hypervolemia. Elevated creatinine points to renal failure, which can be intrinsic or may occur in association with advanced stages of some of the aforementioned conditions, such as heart failure or hepatic cirrhosis (hepatorenal failure). Hypoalbuminemia is characteristic of both cirrhosis and nephrotic syndrome.

A low urine sodium concentration and low fractional excretion of sodium confirm renal sodium retention secondary to a perceived decrease in EABV in the edema states, even in the face of overall hypervolemia. More recently, elevated concentrations of brain natriuretic peptide have been used to support the diagnosis of hypervolemia, particularly in the setting of cardiac failure and renal disease.

TREATMENT Rx

Recognition and treatment of the underlying disease is the most important step in ameliorating renal sodium retention. Optimization of hemodynamic parameters in heart failure (Chapter 59), improvement of liver function (Chapter 157), or remission of nephrotic syndrome (Chapter 123) improves or reverses sodium retention. Therapeutic intervention to reduce ECF volume

without addressing the underlying disease is often met by complications, especially when ECF volume expansion is associated with decreased intravascular volume or EABV. Nevertheless, three treatment modalities are available to reduce ECF volume directly by inducing negative sodium balance: dietary sodium restriction, diuretics, and extracorporeal fluid removal by ultrafiltration. The modality and the desired rate of sodium removal vary with the clinical setting and depend on the relative distribution of the sodium surfeit and excess volume in the body fluid compartments. Therefore, before initiating any treatment, the clinician should identify the specific disturbances that are harmful to the patient in clinical parameters and monitor the improvement in these parameters during the course of treatment. Harmful manifestations of hypervolemia include hypertension, pulmonary congestion and edema or pleural effusions with compromised respiratory function, hepatic congestion and ascites, and degrees of peripheral edema that compromise skin integrity and predispose the patient to cellulitis. Once ECF volume reduction has removed these threats to the patient's well-being, rates of sodium removal should be slowed significantly. Thus, a patient with mild peripheral edema, small pleural effusions, minimal ascites, jugular venous distention, and normal blood pressure might be managed with sodium restriction and limited use of natriuretic medications to induce a gradual negative sodium balance over a period of many days to weeks. In contrast, a patient with limb- or life-threatening anasarca, pulmonary congestion, or hypervolemia-induced hypertension might require the continuous intravenous infusion of natriuretics or in some cases extracorporeal ultrafiltration therapy.

Sodium Restriction

Other modalities are futile if not accompanied by restriction of sodium intake because renal sodium avidity results in the reaccumulation of ECF fluid as soon as the influence of diuretics has ceased. Dietary sodium restriction in the range of 20 to 40 mmol/day is often recommended and requires abstention from added salt as well as from foods rich in sodium. Sodium substitutes can be useful, although caution needs to be exercised in patients with a tendency to hyperkalemia because some salt substitutes contain potassium. Caloric intake and nutritional parameters should be monitored to ensure that an overly draconian diet does not induce protein-energy malnutrition. In hospitalized patients, it is particularly important to ensure that the sodium content of administered intravenous fluids and sodium-containing medications is monitored and reduced to the minimum possible. The practice of infusing sodium-containing solutions on the one hand and simultaneously treating with diuretics has no sound physiologic or therapeutic basis. Furthermore, water restriction is not appropriate in hypervolemic edema states unless severe (plasma sodium concentration <135 mmol/L) or symptomatic hyponatremia supervenes.

Diuretics

Diuretics and other natriuretic medications (Table 118-5) enhance the urinary excretion of sodium-containing fluid by inhibiting tubule reabsorption at specific nephron sites (Fig. 118-3).

Proximal Tubule Natriuretics

The cardinal example of a proximal tubule natriuretic is acetazolamide, a carbonic anhydrase inhibitor that blocks proximal reabsorption of sodium bicarbonate. Consequently, prolonged use of acetazolamide may lead to hyperchloremic acidosis, in contrast to all other natriuretics, which act at loci before the late distal nephron. Metolazone, a congener of the thiazide class of natriuretics, blocks sodium chloride absorption in the proximal tubule as well as the early distal tubule. Because the major locus for phosphate absorption is in the proximal nephron, the phosphaturia accompanying metolazone administration considerably exceeds that observed with other thiazide-class diuretics. Proximal tubule natriuretics rarely are used as primary therapy but are used as supplements to loop natriuretics when loop natriuretics alone are ineffective.

Loop Natriuretics

Loop natriuretics, such as furosemide, bumetanide, torsemide, and ethacrynic acid, induce natriuresis by inhibiting the coupled entry of Na^+, Cl^-, and K^+ across apical plasma membranes in the thick ascending limb of the loop of Henle, which is responsible for the reabsorption of approximately 25% of filtered sodium. Loop diuretics, which are the most potent diuretics, continue to be effective even in patients with relatively compromised kidney function.

Distal Tubule Natriuretics

Distal tubule natriuretics, such as hydrochlorothiazide, chlorthalidone, and metolazone, interfere primarily with sodium chloride absorption in the earliest segments of the distal convoluted tubule, where they block the sodium chloride cotransport mechanism across apical plasma membranes. Distal tubule natriuretics generally are used in the same conditions as loop natriuretics, but not in chronic kidney disease and in disorders of calcium metabolism. Whereas loop natriuretics are calciuretic and are valuable for managing acute hypercalcemia (Chapter 253), thiazide natriuretics promote hypocalciuria and calcium retention and are useful in managing hypercalciuric states. With the exception of acetazolamide, which impairs bicarbonate absorption, tubule natriuretics can cause hypokalemia and metabolic alkalosis.

Collecting Duct Natriuretics

Spironolactone and eplerenone compete with aldosterone and inhibit sodium absorption in the collecting duct, while concomitantly suppressing potassium and proton secretion. Triamterene and amiloride directly block sodium uptake by collecting duct cells and concomitantly suppress potassium and proton secretion. These agents are used in combination with thiazide and loop natriuretics to offset hypokalemia. However, hyperkalemia and hyperchloremic metabolic acidosis may complicate the injudicious use of any of these agents. Spironolactone and eplerenone are useful in managing disorders characterized by secondary hyperaldosteronism, such as cirrhosis with ascites, in promoting natriuresis in hypokalemic patients, and in competitively blocking nonepithelial mineralocorticoid receptors in patients with left ventricular dysfunction (Chapter 59).

Nesiritide is the recombinant version of a naturally occurring brain natriuretic peptide with unique vasodilator and natriuretic actions. Nesiritide may compromise renal function, especially when high levels are achieved after an initial bolus, so its usefulness appears to be quite limited and to require frequent monitoring of urine output, plasma urea, and creatinine concentrations.

Patients with severe degrees of renal sodium avidity can be resistant to conventionally recommended doses of individual classes of diuretic agents. In such patients, combinations of diuretic agents acting at different sites along the nephron may overcome this resistance and induce a natriuretic response.

TABLE 118-5 DIURETICS AND OTHER NATRIURETIC MEDICATIONS

DIURETICS IN COMMON USE	DAILY DOSE RANGE	ADVERSE REACTIONS	COMMENTS
Thiazides (oral)		Rash, neutropenia, thrombocytopenia, hyperglycemia, hyperuricemia	Usually not effective below GFR of 30-40 mL/mm (metolazone 20-30 mL/mm)
Hydrochlorothiazide	25-100 mg		
Metolazone	2.5-5 mg		
Chlorthalidone	20-50 mg		
Loop diuretics (oral or intravenous)			Rapid onset, short duration: split doses in normal renal function, give intravenously in acute situations or if reduced GI absorption; can use up to 500 mg furosemide (or equivalent) in severe renal insufficiency
Furosemide	20-320 mg	Ototoxicity at high doses	
Bumetanide	1-8 mg		
Torsemide	20-200 mg		
Potassium sparing		Hyperkalemia	Not very potent
Spironolactone	25-400 mg		
Triamterene	25-100 mg		
Amiloride	5-20 mg		
Eplerenone	25-50 mg		

GI = gastrointestinal; GFR = glomerular filtration rate.

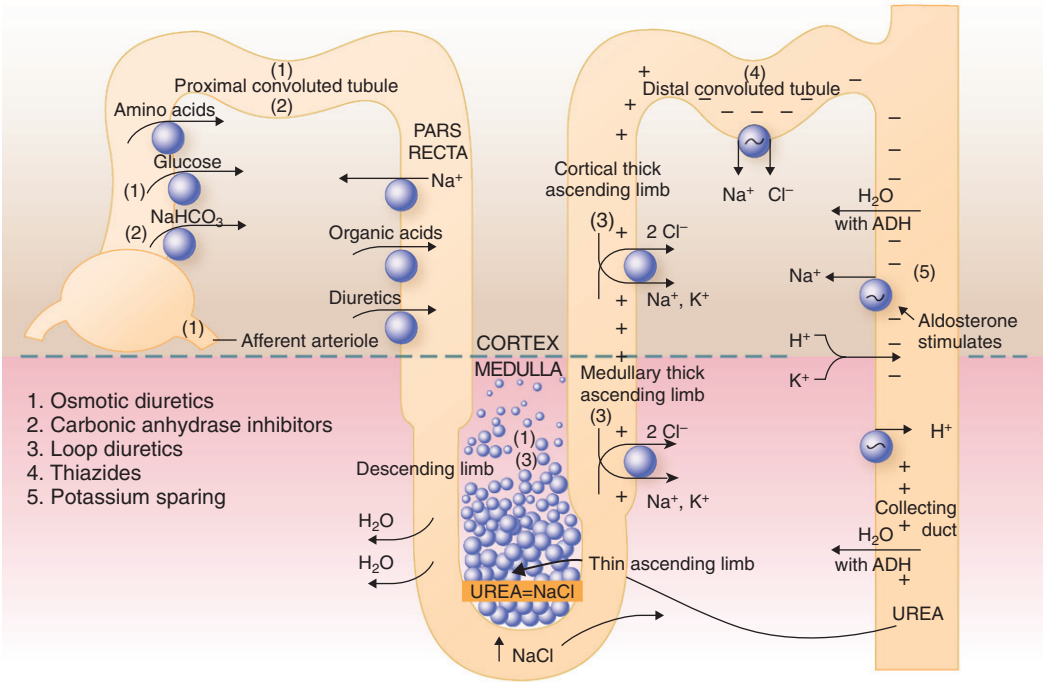

FIGURE 118-3. Major transport processes along the nephron segment and primary sites of action of diuretics. The numbers next to the diuretics in the insert refer to the site of action along the nephron. ADH = antidiuretic hormone. (From Kokko JP. Diuretics. In: Alexander RW, Schlant RC, Fuster V, eds. *The Heart*, 9th ed. New York: McGraw-Hill; 1998.)

The continuous intravenous infusion of furosemide, sometimes in conjunction with intermittent bolus infusions of albumin, also can overcome natriuretic resistance in some hospitalized patients. Monitoring of plasma sodium, potassium, magnesium, calcium, and phosphate concentrations is mandatory in patients treated with high or frequent doses or continuous infusions of natriuretic agents. Besides body tonicity and electrolyte disturbances, other potential adverse consequences include a reduction in GFR. Drug-specific idiosyncratic adverse responses such as allergic cutaneous reactions, interstitial nephritis, pancreatitis, and blood dyscrasias are much less common.

Extracorporeal Ultrafiltration

In a small subset of patients, either superimposed renal impairment or extreme resistance to natriuretic action requires the direct removal of excess ECF volume by hemofiltration or peritoneal dialysis (Chapter 133). Chronic ambulatory peritoneal dialysis has been used for the symptomatic relief of pulmonary congestion and anasarca in some patients with chronic heart failure who are unresponsive to other therapeutic modalities and are not candidates for cardiac transplantation.

WATER BALANCE DISORDERS

Water balance disorders generally come to medical attention because of one or more of three clinical manifestations: hyponatremia, hypernatremia, or polyuria.

Hyponatremia

DEFINITION

Hyponatremia, which is defined as a plasma sodium concentration less than 136 mmol/L, is the most frequently encountered electrolyte abnormality in hospitalized patients.

EPIDEMIOLOGY AND PATHOBIOLOGY

Hyponatremia does not necessarily signify a hypotonic state. *Hypertonic hyponatremia* occurs when there is an accumulation in the ECF compartment of non-sodium-containing effective solutes such as very high concentrations of glucose in diabetic patients or exogenously administered mannitol or glycerol. These hypertonic hyponatremic states are characterized by a shift of water from the ICF to the ECF compartments, with ICF shrinkage rather than swelling. The accumulation of a solute such as urea, which contributes to the measured plasma osmolality but is not an osmotically effective solute in terms of transcellular water shift, should not be included in the category of hypertonic hyponatremic states. *Isotonic hyponatremia* signifies the laboratory finding of hyponatremia in patients with no disturbances in body fluid tonicity and almost always reflects the interference of marked hyperlipidemia or marked hyperglobulinemia with certain laboratory techniques for the measurement of the plasma sodium concentration; these situations are termed *pseudohyponatremia* and should not prompt diagnostic or therapeutic measures to alter water balance or body tonicity.

True *hypotonic hyponatremia* always reflects an important underlying disorder that leads to abnormal body water balance, and the hypotonic state indicates either past or ongoing expansion of ICF volume. Even in chronic hypotonic hyponatremic states, in which cell volume has been restored to normal by osmotic adaptive mechanisms, the compensation occurs at the price of loss of intracellular solutes and compromised cell function.

Heart failure (Chapter 59) and cirrhosis with ascites (Chapter 156) are examples of hypervolemic hyponatremia. In these conditions, reduced EABV stimulates the release of AVP and also may limit the delivery of glomerular ultrafiltrate to the diluting segments of the nephron.

Most fluid lost from the body is hypotonic compared with plasma, so sweat, most gastrointestinal losses, and even many cases of urinary fluid loss do not cause hyponatremia. However, if the replacement fluid that is ingested or administered is more hypotonic than the lost fluid (e.g., ingestion of water or intravenous administration of D_5W), the net result is to decrease body tonicity. Another important consideration is the potassium concentration in the lost fluid. For example, diarrheal fluid and natriuretic-medication-induced polyuric urine are often rich in potassium as well as sodium; even if the concentration of sodium alone is less than that in the ECF, combined loss of sodium plus potassium can cause hypotonicity.

CLINICAL MANIFESTATIONS

The finding of hyponatremia is often incidental on routine laboratory testing, on laboratory testing of patients with nonspecific complaints, or as part of the investigation of other clinical syndromes. The symptoms of hypotonic hyponatremia depend on its duration. In the first hours to days, the major clinical manifestations are neurologic and are due to acute brain swelling or cerebral edema. Symptoms include headache, lethargy, seizures, and a progressively decreased level of consciousness that can progress to coma and death. The severity of these neurologic manifestations depends more on the rate of the hypotonic decline in plasma sodium concentration than on the absolute concentration. In addition, women between menarche and menopause are particularly susceptible to the life-threatening neurologic manifestations of acute hyponatremia, even of relatively mild degree. If a patient survives the acute hyponatremia, osmotic adaptation tends to mitigate the symptoms of cerebral edema.

DIAGNOSIS

After immediate assessment of the clinical urgency of the situation, the first step in the diagnostic approach to a patient with the laboratory finding of hyponatremia is to confirm the presence of true hypotonic hyponatremia. A repeat set of plasma determinations, including electrolytes, osmolality, urea, and glucose, allows comparison of the measured with the calculated plasma osmolality according to the following equation:

$$\text{Plasma osmolality (mOsm/kg)} = 2\text{Na}^+\text{(mmol/L)} + \text{(blood urea nitrogen [mg/dL]/2.8)} + \text{(glucose [mg/dL]/18)}$$

A careful history, including a search of the medical record for previous measured concentrations of plasma sodium, is critical. The history, together with the physical examination, usually provides important clues to underlying disorders, disease states, or medication exposures that can inform the diagnosis. A history of weight gain or loss also can be helpful in the assessment of recent fluid mass balance. The physical examination should focus on attempts to establish the state of ECF volume. The presence of generalized edema with jugular venous distention and ascites, especially in the setting of heart or liver disease, points quite clearly to hypervolemic hyponatremia. Orthostatic hypotension and tachycardia, particularly in the setting of a history of natriuretic medication use or gastrointestinal fluid losses, suggests hypovolemia, but the absence of these findings does not exclude hypovolemia.

Laboratory tests should include a repeat set of plasma electrolyte concentrations, including potassium and chloride levels, which together with determination of acid-base parameters (pH, P_{CO_2}, and bicarbonate) can point to processes not always elicited in the history, such as vomiting, diarrhea, or natriuretic medication exposure. Other laboratory tests should include liver function tests and measurement of plasma urea, creatinine, uric acid, thyroid-stimulating hormone, cortisol concentrations, and, if indicated, an adrenocorticotropic hormone stimulation test. High levels of both urea and creatinine point to intrinsic renal disease, whereas a disproportionate elevation of urea over creatinine might support hypovolemia with a tendency to prerenal azotemia (Chapter 122). In contrast, very low levels of urea and uric acid are typical of both the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and the cerebral salt-wasting syndrome.

Marked elevation in the plasma glucose concentration increases both measured and calculated plasma osmolality and indicates a state of hypertonic hyponatremia that should be approached as a state of body fluid hypertonicity with cell shrinkage (see later) rather than hypotonicity. The plasma sodium concentration declines by approximately 1.6 mmol/L for each 100-mg/dL (5.5-mmol/L) increase in plasma glucose concentration. However, the value of approximately 1.6 is quite variable and is greater in states of progressively severe hyperglycemia. In contrast to hyperglycemia, an elevated urea concentration should not be considered as contributing to plasma or ECF tonicity, even though urea does contribute to the laboratory measurement of plasma osmolality. Thus, a hyponatremic patient with a normal or elevated laboratory measurement of plasma osmolality, which can be fully attributed to an increased urea concentration, should be considered as having hypotonic hyponatremia. A discrepancy in which measured plasma osmolality exceeds calculated plasma osmolality and cannot be attributed to either glucose or urea indicates the presence of an unidentified small solute (osmolar gap), including alcohols (e.g., ethanol, methanol, ethylene glycol, and isopropyl alcohol), and the organic anions of weak acids, which raise the plasma anion gap. Because these small solutes are not effective solutes in terms of water movement, the water balance and tonicity status of the patient is determined by the plasma sodium concentration. Just as for urea, a patient with hyponatremia and normal or elevated measured plasma osmolality as a result of one of these small solutes should be approached as having a true hypotonic hyponatremia, notwithstanding the normal or elevated plasma osmolality measurement. However, the finding of such an osmolar gap should prompt a thorough investigation for poisoning, intoxication, or an organic acidosis (Chapter 120).

Once a state of true hypotonic hyponatremia has been established, determination of the cause and further diagnostic approach follows a classification into one of three categories based on assessment of the volume status of the patient (Fig. 118-4). Abnormal liver function test results can provide adjunctive support for hepatic disease and a hypervolemic hyponatremic state. The diagnosis of heart failure should be made clinically, but it can be assisted by a brain natriuretic peptide level, chest radiograph, or echocardiograph (Chapter 58). A radiograph or chest computed tomography (CT) scan may help identify intrathoracic lesions that are associated with SIADH.

Approximately 85% of hyponatremic inpatients have true hypotonic hyponatremia; among these patients, about 25% are hypovolemic, about 25% have an edema state, about one third are normovolemic, and most of the remainder have renal failure.

In the absence of a clinically obvious edema state, a low urine sodium concentration (<20 mmol/L) or a low fractional excretion of sodium (<1%) supports the diagnosis of hypovolemic hyponatremia secondary to extrarenal losses or past renal losses that have since abated. If hypovolemia is due to ongoing renal losses, the urine sodium concentration may remain high in the face of hypovolemia, but a low fractional excretion of urea (<35%) may still be evident. High urinary concentrations of potassium point to persistent vomiting or the ongoing effect of potassium-depleting natriuretic drugs. In

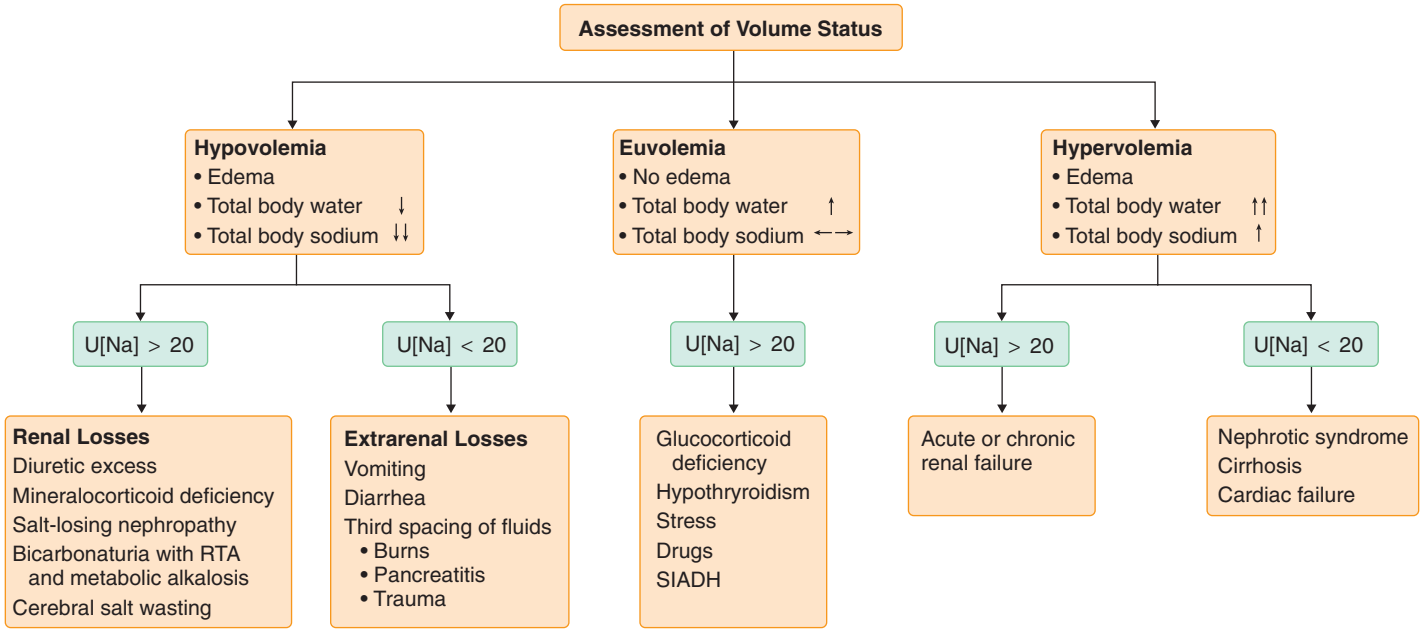

FIGURE 118-4. Diagnostic approach to hyponatremia. RTA = renal tubular acidosis; SIADH = syndrome of inappropriate antidiuretic hormone secretion. (Modified from Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady H, Wilcox C, eds. *Therapy in Nephrology and Hypertension*. Philadelphia: Saunders; 1999:256.)

SIADH, the urine sodium concentration often reflects sodium intake, as well as mild volume expansion, and is therefore most often greater than 40 mmol/L and frequently higher than 100 mmol/L. The combination of hypotonic hyponatremia in a patient without evidence of either hypovolemia or hypervolemia, together with low plasma urea and uric acid concentrations without hypothyroidism or adrenal insufficiency, strongly suggests SIADH. If there is any doubt about the presence of hypovolemia, a carefully monitored volume challenge can be of diagnostic as well as therapeutic benefit (see later). Lack of sustained improvement after an adequate salt-containing volume challenge lends further support to the diagnosis of SIADH. Once the diagnosis of SIADH has been established in this manner, the cause should be sought, including a thorough review of medication exposure, review of the history for symptoms and signs of malignancy, and magnetic resonance imaging (MRI) or CT of the brain and chest (see Table 118-5).

Hypervolemic Hyponatremia

A patient with hypervolemic hyponatremia suffers from a surfeit of both sodium and water, but the surfeit of water is disproportionate to that of sodium. As for any hypervolemia, the clinical approach is to establish that the patient is hypervolemic and to determine the cause of the sodium surfeit. The most frequently diagnosed causes are heart failure, decompensated cirrhosis with ascites, and renal failure. The occurrence of hyponatremia in any of these conditions often signifies either advanced disease or overzealous sodium deprivation and natriuretic medications. Patients who have heart failure or cirrhosis with ascites experience avid renal sodium retention with urine sodium concentrations less than 20 mmol/L and fractional sodium excretion less than 1% in the face of clear-cut clinical evidence of ECF volume expansion, usually with generalized edema. However, these urine parameters can be masked by the ongoing influence of medications. The edema state of the nephrotic syndrome is less commonly associated with hyponatremia, unless the patient has been exposed to severe salt restriction and natriuretic therapy. Water retention with hyponatremia is a feature of renal failure only in its more advanced stages (stages IV and V chronic kidney disease; Chapter 132).

Normovolemic and Hypovolemic Hyponatremia

It is often difficult to distinguish normovolemic from hypovolemic hyponatremia because mild hypovolemia can easily escape clinical detection. The initial history and physical examination should try to establish or exclude a cause of hypovolemia. In extrarenal hypovolemia, a low urine sodium concentration and low fractional excretion of sodium are characteristic. When the hypovolemia is due to urinary loss, the urine sodium concentration is usually elevated rather than decreased.

Hypovolemic hyponatremia always signifies past or ongoing sodium loss (often with potassium), accompanied by a degree of net water loss that does not match the electrolyte loss and hence leaves the patient hypotonic. The high levels of AVP that are associated with hypovolemic hyponatremia are usually an appropriate response to the physiologic stimulus of hypovolemia. The most common extrarenal causes of hypovolemia leading to hyponatremia are gastrointestinal fluid losses and excessive sweating. In gastrointestinal fluid losses, any concomitant nausea and vomiting may be independent triggers for the central release of AVP. Clues to vomiting include the characteristic plasma and urine biochemical parameters of metabolic alkalosis (Chapter 120), often with higher than expected urinary concentrations of sodium and bicarbonate. Hyponatremia is a more common complication of diarrhea when the diarrheal fluid is secretory and rich in electrolytes. Sweating-induced hyponatremia occurs when individuals ingest high volumes of hypotonic fluid, often pure water, while losing sodium in sweat.

The renal causes of hyponatremic hypovolemia (see Fig. 118-4) include thiazide-induced hyponatremia, which occurs when patients with impaired urinary diluting capacity excrete concentrated urine because thiazides do not affect the ability of the renal medulla to concentrate urine. Thiazide-treated patients are particularly susceptible to hyponatremia when they ingest or receive hypotonic solutions that exceed their maximal capacity to excrete electrolyte-free water in their urine. In cerebral salt wasting (also known as renal salt wasting), patients who have suffered a head injury or intracranial hemorrhage experience a state of negative sodium balance because urinary fluid loss stimulates the release of AVP, coupled with the ingestion or administration of hypotonic fluids. In these patients, urine sodium concentrations can be impressively high, and the syndrome can be difficult to distinguish from hyponatremia caused by the syndrome of inappropriate secretion of AVP (see later). Persistent uricosuria, even after correction of the hyponatremia, remains an unexplained distinguishing feature of this syndrome.

TABLE 118-6 CAUSES OF THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Cyclophosphamide
Morphine
Amitriptyline
Selective serotonin reuptake inhibitors

In normovolemic hypotonic hyponatremia, there is neither an osmolar nor a volume stimulus to the release of AVP. Thus, concentrated urine, usually containing high concentrations of sodium (often >40 mmol/L as a result of dietary intake plus the effects of mild ECF volume expansion), indicates either inappropriate secretion or an augmented renal response to AVP. Conditions that can result in inappropriate AVP secretion or responsiveness include tumors, central nervous system lesions or disorders, intrathoracic or chest wall disease, and numerous drugs and medications (Table 118-6). All syndromes in which AVP levels or the kidney's responsiveness are inappropriately high and not attributable to osmolar or volume stimuli are known collectively as SIADH (Chapter 232). Patterns of abnormal AVP secretion (Fig. 118-5) include erratic release of AVP from the neurohypophysis without any apparent coordination with incoming volume or osmotic stimuli (type A pattern), a constant low-level leak of AVP from the neurohypophysis (type B pattern), a reduced threshold for osmotic release of AVP at a lower than normal plasma osmolality (type C pattern), or an abnormal renal response to circulating AVP in patients whose neurohypophysial regulation is intact (type D pattern). However, no consistent correlation between these various patterns and an underlying cause has emerged. A specific monogenic disorder involves a mutation in which the V_2 AVP receptor is constitutively active in the absence of ligand. Hypothyroidism (Chapter 233) and adrenal glucocorticoid insufficiency (Chapter 234) can be associated with hypotonic hyponatremia without clinically evident hypovolemia and with a clinical and biochemical profile that mimics SIADH; abnormal regulation of the aquaporin-2 water channel may be involved. Pregnancy, which also is associated with a reduction in both the osmotic threshold for AVP release and thirst, results in mild hyponatremia (Chapter 247). Another unusual setting for normovolemic hyponatremia is the "beer potomania" syndrome. Because the minimal urine osmolarity, even in the absence of AVP, is 30 to 50 mOsm/L, the upper limit of solute-free water excretion depends on total obligate solute excretion. A paucity of available urinary solutes sets an upper limit on the total water intake that can be tolerated without inducing hyponatremia. For example, when patients consume large volumes of beer (rich in carbohydrates and water, but poor in sodium and electrolytes), the absence of protein intake limits urea production and excretion, thereby limiting nonelectrolyte urinary solutes and hence urinary water excretion. Together with the large volumes of beer ingested, the result is the unusual combination of a normovolemic hypotonic hyponatremic state with low urine osmolality.

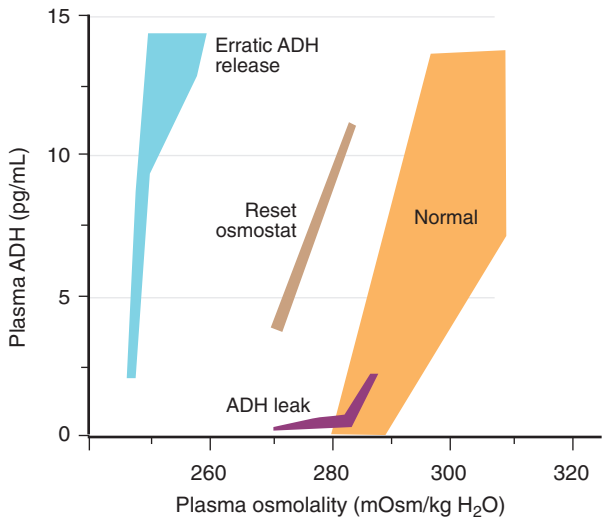

FIGURE 118-5. Patterns of serum antidiuretic hormone (ADH) abnormalities in the syndrome of inappropriate ADH secretion (SIADH). The *shaded areas* indicate the normal relationship between increases in effective extracellular osmolality and ADH levels; the normal osmotic threshold is lower than the normal serum osmolality. The *three shaded areas* indicate ADH patterns in SIADH. (Adapted from Zerbe R, Strope L, Robertson G. Vasopressin function in the syndrome of inappropriate diuresis. *Annu Rev Med.* 1980;31:315-327.)

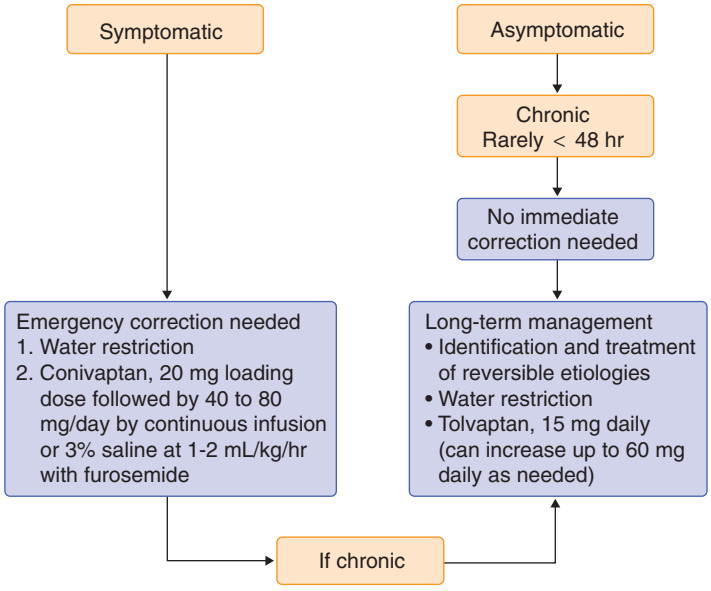

FIGURE 118-6. Treatment of severe normovolemic hyponatremia. (From Thurman J, Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady H, Wilcox C, eds. *Therapy in Nephrology and Hypertension*, 2nd ed. Philadelphia: Saunders; 2003.)

TREATMENT

Rx

Treatment of hyponatremia varies depending on the category and underlying diagnosis (Fig. 118-6). The overall treatment approach can be divided into the immediate approach to newly appreciated hypotonic hyponatremia and the long-term management of chronic persistent hyponatremia.

The first principle is the importance of identifying and treating any underlying disorder. Thus, in a patient with hypervolemic hyponatremia associated with heart failure, measures to optimize cardiac function are the most appropriate and effective means of restoring normal sodium concentration. Indeed, restoration of normal sodium concentration provides one of the most reassuring indices for successful management of this underlying disorder.

Another principle common to all causes of hypotonic hyponatremia, irrespective of the underlying cause, is that the sodium concentration and the rate of correction should be guided by the patient's age, gender, neurologic status, and any information about recent past plasma sodium concentrations or osmolality values. Delayed correction of hyponatremia can perpetuate cerebral edema and result in irreversible neurologic damage and death, especially in women of reproductive age and in patients whose hyponatremia developed at a rapid pace that outstripped the rate of osmotic adaptation by brain cells. In contrast, too rapid correction or correction to a sodium concentration that is above the level needed to safeguard the patient from the neurologic sequelae of cerebral edema can result in the *osmotic demyelination syndrome.* This devastating and often irreversible syndrome is characterized by fluctuating levels of consciousness, pseudobulbar palsy, ataxia, dysarthria, difficulty swallowing, and characteristic MRI abnormalities in the region of the brain stem. Osmotic demyelination syndrome can be fatal, and recovery in nonfatal cases is either slow or incomplete, often with irreversible residual neurologic sequelae.

Hypotonic Hyponatremia

Current guidelines suggest that if the hyponatremia is known to be acute (<24 to 48 hours) and is accompanied by severe neurologic symptoms such as seizures or decreased level of consciousness, correction should be rapid and should reach a target sodium concentration based on amelioration of neurologic symptoms. However, even under these circumstances, the desired rise in sodium concentration should not exceed 2 mmol/L/hour, and the total increase in sodium concentration during the first 12 to 24 hours of treatment should not exceed 12 mmol/L. The only exceptions to these guidelines would be an unusual patient who has suffered documented severe acute water intoxication, such as occurs during the inadvertent instillation of a glycine-containing irrigation solution during prostate surgery or the administration of hypotonic solutions to a patient who is anuric.

Chronic Hyponatremia

If the rate of decline in plasma sodium concentration has been slow, brain cells have the opportunity to undergo osmotic adaptation by extruding or eliminating intracellular solutes. It is this subgroup of patients who are most susceptible to osmotic demyelination after too rapid or overzealous correction of hyponatremia. Patients in whom there is no previous record of sodium concentration or osmolality should be considered in the same category and treated accordingly. In such cases, the targeted rate of increase in sodium concentration should not exceed 0.5 mmol/L/hour, and the total rise in sodium concentration should not exceed 8 mmol/L in the first 24 hours, even (and especially) if the initial sodium concentration is extremely low (<110 mmol/L), provided that the hyponatremia is not accompanied by severe neurologic symptoms. Patients with severe degrees of chronic hyponatremia in the setting of malnutrition, alcoholism, or chronic illness are particularly susceptible to osmotic demyelination. Frequent monitoring of the plasma sodium concentration and osmolality is crucial, and osmotic demyelination can be prevented by slowing the rate of correction, or even returning to a lower plasma sodium concentration by the judicious readministration of hypotonic solutions or administration of vasopressin analogues (see later).

Having established a target goal and rate of correction, the specific approach varies with the underlying diagnosis. Mild degrees of hyponatremia can be tolerated over long periods, and only symptomatic hyponatremia or sodium concentrations below 125 to 130 mmol/L require specific additional treatment. In hypervolemic hyponatremia, there is a surfeit of both sodium and water, but in tonicity terms, the excess water is disproportionate to the excess sodium. Thus, the goal of treatment is to remove both sodium and water, but to replace proportionately less water than sodium. Water restriction is helpful but is often inadequate or impractical because patients are thirsty, and their adequate nutrition requires caloric intake that is accompanied by obligate water ingestion and metabolic water production. The AVP V_2-receptor antagonist tolvaptan (starting at 15 mg once daily, with a maximal dose of 60 mg once daily) ameliorates hyponatremia and improves symptoms and outcomes in patients with hypervolemic hyponatremic syndromes, including decompensated heart failure and hepatic cirrhosis. It is useful in normovolemic hyponatremic states, such as SIADH (see later), but should be assiduously avoided in hypovolemic hyponatremic states. Two related oral drugs, lixivaptan and conivaptan, have not been proved to be as effective in reducing symptoms of heart failure.

Hypovolemic Hypotonic Hyponatremia

A frequent diagnostic dilemma is the distinction between hypovolemic and normovolemic hypotonic hyponatremia. When hypovolemia is clearly evident (appropriate clinical history, orthostatic hypotension, low urine sodium concentration in the setting of extrarenal fluid losses, elevated plasma urea and uric acid concentrations), administration of volume repletion in the form of isotonic saline is the treatment of choice. The salutary effect of saline derives mostly from the effect of volume repletion to remove the hypovolemic stimulus to release of AVP, thereby inducing a water diuresis, with a minor contribution of the osmolar effect of the infused solute. However, great caution should be exercised in the administration of isotonic saline to these patients because sometimes the administration of small volumes of isotonic saline can induce a brisk and rapid decrease in urine osmolality and an accompanying water diuresis, with an overly rapid correction of hyponatremia. Accordingly, whenever isotonic saline or other forms of volume repletion therapy are

administered to patients with known or suspected hypovolemic hyponatremia, careful hour-by-hour monitoring of urine output, urine osmolality, the plasma concentration of sodium, and plasma osmolality are required. A rapid drop in urine osmolality accompanied by water diuresis should prompt cessation of volume repletion and, in some cases, administration of hypotonic solutions or even analogues of AVP itself (see later) to halt or reverse the rapid rise in sodium concentration to within the recommended guidelines so as to prevent osmotic demyelination. When hypovolemia is not clearly evident but cannot be excluded, a brisk drop in urine osmolality in response to a saline challenge confirms the suspicion of hypovolemia and simultaneously initiates therapy. In contrast, failure to induce such a response lends support to the diagnosis of normovolemic hyponatremia.

Normovolemic Hyponatremia

In patients with normovolemic hyponatremia, the appropriate therapeutic approach is to address the underlying disease. Hypothyroidism (Chapter 233) and adrenal insufficiency (Chapter 234) should be corrected with appropriate hormonal replacement therapy. Medication-induced SIADH mandates identification and cessation of the offending medication when possible. If the underlying disease cannot be identified or reversed, treatment is aimed at removing the water surfeit. The therapeutic outcome depends on the minimal urine osmolality that can be achieved, which in turn depends on the severity of SIADH. In many cases, when urine osmolality cannot be suppressed below certain high levels, the severity of water restriction required would not be consistent with the need for caloric intake nor compatible with reasonable expectations for patient adherence. Therefore, maneuvers to generate a gradual net negative water balance are required. In such cases, titrated dose oral tolvaptan (beginning at 15 mg once daily and increasing to a maximum of 60 mg once daily) and reliance on an intact thirst mechanism are crucial to avoid polyuria or hypernatremia. In rare cases with an urgent need to correct the hyponatremia because of a neurologic emergency or definitive documentation that the sodium concentration has decreased acutely over a 24- to 72-hour period, intravenous conivaptan (20 mg loading dose followed by 40 to 80 mg/day by continuous infusion) can be used cautiously to avoid overly rapid correction of hyponatremia. When in doubt about volume status, however, these agents are better avoided until the possibility of hypovolemic hyponatremia has been addressed. Hemodialysis, which can rapidly raise the plasma sodium concentration, should be reserved for the most extreme cases of acute-life threatening hyponatremia for which no other solution is available (Chapter 133).

Hypernatremia

DEFINITION

Hypernatremia, defined as a plasma sodium concentration greater than 144 mmol/L, always reflects a state of hypertonicity, with an increase in the ratio of the concentration of osmotically active solutes to water throughout all body fluid compartments because sodium is an osmotically effective ECF solute.

EPIDEMIOLOGY AND PATHOBIOLOGY

Hypernatremic patients have undergone a process whereby water has moved from the ICF to the ECF compartment, accompanied by a reduction in ICF volume and cell shrinkage. Cell shrinkage in the brain is associated with intracerebral hemorrhage, which often punctates but sometimes disrupts blood vessels, particularly at the brain surface and arachnoid interface. In an effort to restore their cell volume, brain cells undergo osmotic adaptation by accumulating sodium and other electrolytes and then subsequently producing nonelectrolyte small solutes (osmolytes) such as inositol, taurine, glutamine, and glutamate, among others. This process partially reverses cell shrinkage, but at the price of an altered intercellular solute composition with consequent perturbations in neuronal function.

Hypernatremia is the most frequent but not the only hypertonicity state in clinical medicine. Glucose, mannitol, and glycerol can produce hypertonicity states that may not be accompanied by hypernatremia and, in fact, are frequently accompanied by hyponatremia (see earlier). In hypertonicity states, the measured plasma osmolality is always high, but the converse is not necessarily true because a number of solutes that contribute to the measured plasma osmolality are not osmotically effective in terms of movement of water from the ICF to the ECF compartment. Thus, patients with high concentrations of urea or small alcohols (e.g., methanol, ethylene glycol, ethanol) often have elevated plasma osmolality but should not be considered to have a hypertonicity state.

TABLE 118-7 CAUSES OF HYPERNATREMIA CLASSIFIED BY TOTAL BODY SODIUM CONTENT

Hypervolemia	Hypertonic saline excess Hypertonic sodium bicarbonate solutions
Hypertonicity with near normovolemia	Diabetes insipidus Febrile fluid loss
Hypovolemia	Gastrointestinal loss (diarrhea, vomiting) Skin fluid loss (burn, sweat) Loop diuretics Osmotic diuresis Impaired thirst perception

Although hypernatremia can be diagnosed as an incidental laboratory abnormality, it most commonly occurs in the setting of a severe underlying disease with other accompanying disturbances in body fluid homeostasis (Table 118-7).

In *hypervolemic hypernatremia*, a disproportionate excess of sodium as opposed to water expands ECF volume, but ICF volume is decreased because cells shrink. Hypervolemic hypernatremia usually occurs in the hospital setting because inadvertent or overzealous administration of hypertonic saline, the administration of hypertonic sodium bicarbonate solutions during cardiopulmonary resuscitation, or dialysis against a hypertonic dialysate can lead to hypervolemic hypernatremia in the clinical setting.

In *normovolemic hypernatremia*, a pure water deficit with no disturbance in body sodium content does not generally result in a clinically perceptible decrease in ECF volume because the predominant (approximately two thirds) origin of the water deficit is in the ICF rather than the ECF compartment. Thus, for example, a 3-L pure net water deficit will reduce ECF volume by only 1 L, approximately 300 mL of which emanates from plasma water. Yet a 3-L or greater deficit certainly increases body fluid tonicity and the measured plasma sodium concentration. Therefore, such pure net water deficits with no change in body sodium content often are considered to be approximately normovolemic. Clinical conditions that fit this category require a source of fluid loss that has a relatively low content of osmotically effective solutes (principally sodium and potassium and their accompanying anions), such as the various forms of diabetes insipidus or use of vaptan drugs without adequate monitoring. In these conditions, profuse volumes of low osmolality urine are excreted. However, hypernatremia is actually uncommon as long as thirst perception and availability of water remain intact. The principal clinical manifestation is polyuria and polydipsia (see later). Insensible evaporative losses from the skin and respiratory tract also are a source of hypotonic fluid loss. Increased fluid loss can occur in febrile patients (skin and respiratory tract), patients on mechanical ventilation (respiratory tract), and patients with profuse sweating. The sweat sodium concentration decreases with increasing volumes of perspiration. These conditions will lead to hypernatremia with body fluid hypertonicity only if the thirst mechanism or access to water is impaired.

Hypovolemic hypernatremia is by far the most common hypertonicity state. Patients with hypovolemic hypernatremia have lost both sodium and water, but the net loss of water is disproportionately greater than the net loss of sodium. The actual plasma sodium concentration resulting from loss of hypotonic fluid depends not only on the sodium concentration of the fluid lost but also on the concentration of other osmotically active solutes, such as potassium, and on the solute composition of concomitantly ingested or administered fluids. The extrarenal and renal causes of such fluid losses are similar to those of hypovolemia. Among gastrointestinal causes of hypovolemic hypernatremia, diarrhea is more common than vomiting, and osmotic diarrheas result in disproportionately greater loss of water than electrolytes, with a greater propensity to hypernatremia than for secretory diarrheas. Among the renal sources of sodium and water loss, the two most common causes are loop natriuretic medications and osmotic diuresis. Loop natriuretic agents interfere with the countercurrent mechanism and generate large volumes of urine with an iso-osmolar composition. Because some of the solutes are nonelectrolyte (urea), the impact on body tonicity may be to increase tonicity, unless there is concomitant intake or administration of hypotonic fluids. In contrast, thiazides do not interfere with the countercurrent mechanism and therefore rarely promote hypernatremia. The presence of nonelectrolyte solutes in urine causes an osmotic diuresis. Such solutes can

be of either endogenous origin (e.g., urea or glucose) or exogenous origin (e.g., mannitol or glycerol). The presence of these solutes in tubular fluid impairs both sodium and water reabsorption, but the excretion of urine that is relatively rich in nonelectrolyte solutes tends to promote body fluid hypertonicity, unless sufficient hypotonic fluids are ingested or administered concomitantly.

Failure to replace hypotonic fluid losses generally reflects either impairment in thirst, disability, or infirmity that prevents the patient from responding to thirst, or failure of the clinician to recognize the need for hypotonic fluid replacement. Rarely, impaired thirst in patients who are awake and alert can be caused by damage to the hypothalamic osmoreceptors that control thirst perception and response, a condition known as *primary hypodipsia*. Usually this condition tends to be associated with an abnormality in the osmotic regulation of AVP secretion. However, cases have been described in which the osmotic regulation of AVP secretion has been dissociated from the osmotic regulation of thirst. Such patients suffer hypernatremia only when extrarenal fluid losses exceed their habitual water intake, as might occur in settings of thermal stress or exercise.

CLINICAL MANIFESTATIONS

The clinical features of patients with hypernatremia can be divided into those associated with the underlying disease state, those associated with a concomitant disturbance in ECF volume, and those associated with an increase in body fluid tonicity. The main clinically relevant consequence of increased body fluid tonicity is decreased brain cell volume, with the attendant risk for intracerebral hemorrhage. Thus, the major symptoms are neurologic and include confusion, seizures, focal neurologic deficits, and a progressively decreasing level of consciousness that can progress to coma. In the absence of an underlying neurologic problem or disturbance in the thirst mechanism, the patient would be expected to complain of thirst unless the neurologic injury has disturbed consciousness.

In patients with hypernatremia of sufficient duration to enable brain cells to undergo osmotic adaptation, the risk for intracerebral hemorrhage from cell shrinkage is decreased, but a hypertonic intracellular environment with the accumulation of new intracellular solutes can perturb normal cellular function.

DIAGNOSIS

The diagnosis of hypernatremia is made by laboratory testing of the sodium concentration, which always should be repeated to confirm its accuracy, corroborated by measurement of plasma osmolality, which is expected to be elevated in all cases. The underlying cause of the hypernatremia is usually evident from the history and physical examination. The history should include a review of recent and current medication use and questions regarding exercise, heat exposure, sweating, vomiting, diarrhea, urine output, recent fluid intake, and the presence of thirst. Physical examination should include an assessment of ECF volume and a complete neurologic evaluation. Urine volume should be monitored, urine osmolality should be measured in several spot urine samples, and 24-hour urine osmolar excretion should be measured if polyuria is present. In the less common situation of hypervolemic hypernatremia, there is often an antecedent history of the administration of sodium-containing solutions, and the findings on physical examination are consistent with ECF volume expansion. In the absence of underlying intrinsic renal disease or diuretic action, urine osmolality should be high because of the hypertonic stimulus to AVP release, which overrides the attenuating effect of hypervolemia. In such patients, the urine sodium concentration should be elevated in response to hypervolemia.

In the more common condition of hypovolemic hypernatremia with extrarenal fluid loss, urine output should be reduced to less than 500 mL/day, and urine osmolality should be the maximum expected for age (urine osmolality >1000 mOsm/kg in young adulthood and decreasing to >600 mOsm/kg by the seventh decade of life and beyond). Polyuria with a submaximal urine osmolality in the presence of hypernatremia suggests impaired urine-concentrating ability, such as occurs with preexisting or underlying intrinsic renal disease or exposure to diuretic agents. A spot urine osmolality measurement less than 100 to 200 mOsm/kg or polyuria (>3 L/day), together with 24-hour urine solute excretion less than 600 mOsm/day in the face of hypernatremia, suggests diabetes insipidus. In contrast, daily solute excretion exceeding 800 to 1000 mOsm/day suggests an osmotic diuresis, which can be confirmed by measuring glucose and urea in urine.

TREATMENT

Rx

The main components of treatment are to treat the underlying disorder, correct the abnormality in ECF volume, replace the water deficit, and provide maintenance fluids to match continuing ongoing fluid losses if they persist.

The therapeutic approach to serious symptomatic hypovolemic hypernatremia is challenging and often controversial. It is best to divide the therapeutic approach into two separate phases: rapid correction of the depleted ECF volume, followed by gradual replacement of the water deficit, including provision for ongoing fluid losses. When ECF volume contraction is severe, as evidenced by tissue hypoperfusion and shock, administered fluid should have a sodium concentration as close as possible to that of the patient and should distribute to the ECF or even the intravascular compartment. Isotonic saline is generally the fluid of choice, and the volume and rate of administration should be guided by clinical parameters related to reversal of hypovolemia. After the patient's tissue perfusion has been restored, further fluid replacement should be aimed at correcting the estimated water deficit. This estimate begins with a simple calculation of the percent deficit based on the measured sodium concentration:

$$\text{Total body water deficit} = 0.6 \times \text{premorbid weight} \times (1 - [140/Na^+])$$

Total body water is used because the sodium concentration reflects tonicity in all body fluid compartments, including the ICF. Unlike the isotonic fluid replacement for ECF volume, the water replacement should be administered gradually over a period of hours to days, unless there is clear documentation that the hypernatremia has itself evolved over minutes to hours. The necessity for gradual replacement is dictated by the process of osmotic adaptation described previously, and ideally, the rate of water replacement should match the rate at which brain intracellular solutes can be adaptively extruded or removed. More rapid rates of administration could result in brain cell swelling with attendant dangerous neurologic consequences. It is recommended that the estimated volume of the water deficit be replaced at a rate that will lead to an approximately 0.5 to 1.0 mmol/L reduction in measured plasma sodium concentration per hour. In addition to the estimated water deficit, the estimated ongoing water loss during replacement should include at least 1 L per 24 hours of insensible fluid losses (greater volumes in patients who are febrile or mechanically ventilated), supplemented with any ongoing water losses (renal or gastrointestinal) resulting from continuation of the underlying disease process. Because of the need to distribute replacement of the initial water deficit, which can amount to several liters over a number of days during which ongoing water losses continue, it is not unusual for patients to require large volumes of water, sometimes reaching 5 to 10 L, over the duration of the correction period. This water deficit, together with ongoing losses, can be replaced by the dietary ingestion of tap water if the patient's condition is suitable or by an enteral feeding tube. If a gastrointestinal or other disease process precludes these preferred routes, a hypotonic intravenous solution such as D_5W or half-normal saline can be used. When D_5W is used, the glucose is either stored as glycogen or fat or metabolized into carbon dioxide and water, thus effectively providing the patient with solute-free water replacement. In the case of half-normal saline, for any given liter administered, only half can be considered as replacement of the water deficit, and the sodium content will either replace any remaining sodium deficit that has not been fully corrected in the first phase of treatment or be excreted if there is no impairment in urinary sodium excretion. In elderly patients with known or possible underlying cardiac, hepatic, or renal disease, caution should be exercised in the provision of excessive volumes of salt-containing solutions. In any case, the sodium concentration should be monitored at regular intervals of no less than every 4 hours to avoid too slow or too rapid correction, and ECF volume parameters should be monitored to avoid hypervolemic complications.

Special considerations apply for hypertonic states in the setting of uncontrolled diabetes with hyperglycemia (Chapters 236 and 237). The unusual cases of patients with hypervolemic hypernatremia in the hospital setting also need special attention and sometimes require continuous infusions of loop diuretics together with the administration of hypotonic solutions or, in some cases, extracorporeal means to remove both the sodium and water excess in a controlled and safe manner under careful monitoring, often in the intensive care unit.

The route of administration should change in accordance with the patient's response. Although an initial parenteral or nasogastric enteral route might be appropriate when the patient's neurologic status is compromised, subsequent therapy can consist of simple dietary intake of water. Once a patient is awake and alert and if thirst mechanisms are intact, the patient will generally correct the hypertonic state by spontaneous oral fluid intake.

Polyuria

Polyuria (Table 118-8), which is defined as a urine output greater than 3 L/day, should be distinguished from urinary frequency, which can occur with frequent voiding of small volumes totaling less than this amount per day. Polyuria occurs when urine-concentrating mechanisms are not being used at any time during the day (water diuresis) or urine solute excretion is excessive (solute diuresis).

SOLUTE DIURESIS

Solute diuresis is defined as the excretion of greater than 800 to 1000 mOsm of urinary solute per day. The composition of these excess solutes can be electrolyte or nonelectrolyte. Electrolyte solute diuresis usually occurs in response to the iatrogenic administration of high volumes of electrolyte-containing solutions, which are disposed by the kidney through normal physiologic mechanisms. Nonelectrolyte solute diuresis is equivalent to osmotic diuresis in which the presence of a nonreabsorbable nonelectrolyte solute in the tubule fluid prevents reabsorption of sodium and other electrolytes as well as water. The result is the excretion of large volumes of urine with a urine osmolality close to that of plasma osmolality.

WATER DIURESIS

When polyuria is associated with 24-hour urine solute excretion greater than 600 mOsm/day, a defect in urine concentrating ability is generally suggested. In some cases, this defect occurs in association with a more general state of intrinsic renal injury and can be part of the spectrum of interstitial injury in chronic renal disease. More specific defects in urine-concentrating ability fall into the category of the diabetes insipidus disorders (Chapter 232).

TABLE 118-8 REASONS FOR POLYURIA

WATER DIURESIS
Diabetes insipidus
Central (neurogenic)
Inherited
Acquired (e.g., tumors, trauma, hypoxia)

External loading (e.g., mannitol, glycerol)
Urea
Exogenous loading (e.g., urea, protein, amino acids)
Diuretic phase of acute kidney injury
Post-obstructive diuresis
Hypercatabolic states
Hemoglobin/myoglobin driven (post-rhabdomyolysis or reabsorption of a hematoma)
Other
Radiocontrast agents

TREATMENT

Rx

Once a patient with polyuria has been classified as having abnormally increased excretion of solute (solute diuresis) or water (water diuresis) (see Table 118-8), the clinical manifestations and treatment will be those of the underlying disease, and the consequences of changes in ECF volume and tonicity are the same as discussed earlier. Depending on the nature of fluid intake and medication used at the onset of polyuria, a significant percentage of polyuric patients will have alterations in serum sodium and ECF volume and will need attention to the underlying disease, as well as correction of fluid and electrolyte abnormalities. Thus, for example, although antihyperglycemic treatment effectively corrects the solute diuresis and polyuric state of uncontrolled diabetes mellitus, initial correction of the concomitant electrolyte and ECF volume disorders takes precedence (Chapters 236 and 237).

POTASSIUM DISORDERS

JULIAN L. SEIFTER

DEFINITION

Potassium is ubiquitous in both plant and animal sources of nutrition, so it is difficult to avoid eating potassium in a normal diet. Plant cells have cytosolic potassium concentrations of approximately 80 mmol/L, whereas animal cells may have as much as 140 mmol/L.

EPIDEMIOLOGY

Maintenance of a normal and narrow range of serum potassium, usually on the order of 3.5 to 5.0 mmol/L, is vital for health. The actual concentration may vary during the day, according to a circadian rhythm of decreased excretion in the morning and dietary intake. Insulin-deficient diabetic patients have a greater tendency to develop hyperkalemia, especially if other factors, such as a high-potassium diet, renal disease, or treatment with medications that interfere with renal excretion also are at work. Athletes may have chronically mild decreases in serum potassium. β-blockers may be associated with increased potassium during exercise, particularly in patients with renal failure.

PATHOBIOLOGY

Potassium Balance

Within the human body, potassium is not equally distributed in the total body water. Approximately two thirds of body water is intracellular, and within that compartment, potassium is the major cation. Most cells express sodium-potassium adenosine triphosphatase (Na^+, K^+-ATPase) on the cell plasma membranes and by this enzyme utilize metabolic energy in the form of adenosine triphosphate (ATP) to establish gradients of potassium and sodium. As a result, the potassium concentration of the cell may reach 140 mmol/L, compared with the extracellular potassium concentration of approximately 4 mmol/L. These established ion gradients, and the associated electrical gradients that follow, provide the essential mechanisms for electrical activity in excitable cells such as muscle and neural tissue, cellular nutrient uptake, and transcellular solute transport in polarized epithelial cells in the kidney and intestine.

If there is a ratio of 35:1 intracellular-to-extracellular potassium and a 2:1 ratio of intracellular-to-extracellular water, it is apparent that more than 98% of potassium resides within cells. The total amount of potassium is usually on the order of 50 mmol/kg of body weight, so a 70-kg individual has a store of about 3500 mmol of potassium. In the entire extracellular fluid, which is approximately 20% of body weight, or 14 L in a 70-kg person, the total potassium content is 50 to 60 mmol.

From these calculations, several important issues of potassium homeostasis emerge. First, total body potassium balance may be poorly reflected by the extracellular or serum potassium concentration. This fact dissociates hypokalemia from potassium depletion or hyperkalemia from potassium excess. Changes in the distribution between the cells and extracellular fluid can occur rapidly, within minutes, in contrast to the matching of dietary intake of potassium to potassium elimination from the body, which occurs within hours. It is also apparent that potassium ingestion at the time of a meal may be equal to a large fraction of the total extracellular potassium. An average daily consumption may be on the order of 50 to 100 mmol. Because this potassium cannot be eliminated instantaneously, there is the potential danger of rapid rises in extracellular potassium concentration after meals. Protection against this eventuality comes from the ability of potassium to distribute from the extracellular to intracellular spaces. The intracellular space, given its large volume and potassium content, can accommodate, or buffer, an extra load of potassium without significant changes in concentration. Distribution of potassium from extracellular to intracellular spaces is known as *internal balance*, and the matching of intake to losses from the body is known as *external balance*.

Importance of Potassium

Potassium is essential for a number of critical body functions, including enzymatic reactions that regulate protein synthesis, glycogen synthesis, cell growth, and cell division. The ability of cells to take up or extrude potassium contributes to the regulation of cell volume during periods of osmotic stress. In excitable cells, such as cardiac myocytes, the relationship of intracellular to extracellular potassium concentrations is critical in establishing the resting membrane potential, which normally may approach the Nernst equilibrium potential for potassium. Because larger percentage changes can occur in the extracellular potassium concentration compared with the intracellular concentration, changes in extracellular potassium have the greatest impact on the electrical potential difference across cell membranes. The serum potassium itself has effects on conductance of potassium through specific K^+ channels.

Potassium is also an important local mediator of vascular tone in muscle beds. During exercise, local extracellular potassium concentrations may rise to as high as 10 mmol/L, thereby causing local vasodilation to allow more blood supply to the exercising muscle. Very little of that potassium remains within the total extracellular fluid, so severe hyperkalemia does not usually occur with exercise. The trained athlete develops an adaptive increase in Na^+, K^+-ATPase to allow for efficient reuptake of potassium into muscle cells. The importance of adequate potassium stores to muscle function is well known to experienced marathoners, and overexertion of muscles in a state of potassium depletion can lead to rhabdomyolysis.

Renal Potassium Handling

In the kidney, potassium excretion begins with filtration. Because the extracellular potassium concentration is approximately 4 mmol/L, and that of sodium is 140 mmol/L, far less potassium is filtered than sodium (about 3%). The renal proximal tubule reabsorbs potassium in the process of reabsorbing sodium and water. In the thick ascending limb of the loop of Henle, potassium is reabsorbed both by the apical sodium-potassium-2-chloride cotransporter (NKCC) and, like calcium and magnesium, by paracellular reabsorption of the cation. The latter mechanism is a consequence of the luminal electropositivity created by recycling of potassium through K^+ channels from the cell to the lumen. Luminal ammonium (NH_4^+) can substitute for potassium on the NKCC cotransporter; the resulting increase in medullary interstitial fluid NH_4^+ concentrations enhances medullary collecting duct net acid excretion. In hyperkalemic states, less NH_4^+ appears in the urine because the high concentration of luminal potassium competes with NH_4^+ for reabsorption in the thick limb. As a consequence, a renal mechanism exists for metabolic acidosis to develop in hyperkalemic states, and this in part accounts for the success in treating acidosis by lowering the elevated serum potassium level.

In hypokalemia, whether through proximal tubule intracellular acidosis or other mechanisms, glutaminase enzymes are increased, and more ammonia is produced. This ammonia leads to greater medullary interstitial fluid concentrations and therefore to enhanced net acid elimination. Ammonium production in hypokalemia could be considered an adaptation to allow for potassium to be reabsorbed as NH_4^+ accompanies excreted anions into the urine. The increase in ammonia production can have a deleterious effect in that it may contribute to the chronic tubulointerstitial nephritis of chronic hypokalemia.

By the time the tubular fluid reaches the distal tubule and collecting duct, more than 90% of potassium has been reabsorbed. In potassium depletion, an increase in the apical membrane hydrogen-potassium H^+, K^+-ATPase of the collecting duct intercalated cell allows near-complete removal of potassium from the urine. However, potassium reabsorption is seldom as complete as that of sodium. It is unusual to see potassium concentrations in the urine lower than 5 to 10 mmol/L.

When dietary potassium is abundant, the reabsorption of 90% of filtered potassium by the proximal and distal nephron is followed by net potassium secretion. The urinary potassium most closely reflects potassium secreted by the distal nephron. The major regulatory site for potassium secretion resides in the principal cells of the cortical collecting duct. Three major mechanisms control overall potassium secretion (Fig. 119-1), which may vary depending on the need by as much as 400%: (1) development of a lumen-negative transepithelial potential difference that provides the driving force for potassium secretion into the lumen, (2) adequacy of a variety of apical membrane secretory potassium channels, and (3) flow-dependent movement of fluid through the lumen.

Mechanism of Potassium Secretion

First, sodium must be delivered in ample amounts (depending on the flow rate and sodium concentration of the tubular fluid) to result in sodium reabsorption through the apical epithelial sodium channel (ENaC) in the principal cell. In severely prerenal states of avid sodium reabsorption, sodium delivery may become rate limiting for potassium secretion. Low urinary sodium concentrations limit K^+ secretion in the hepatorenal syndrome or severe heart failure. Assuming that sodium delivery is not limiting, reabsorption of the sodium cation creates a lumen-negative transepithelial potential difference. The reabsorption of sodium in turn is dependent on the low intracellular sodium concentrations resulting from the energy-requiring Na^+, K^+-ATPase on the basolateral membrane. Although K^+ secretion is increased by Na^+ reabsorption, most of the potassium that enters the principal cell from the extracellular fluid through the Na^+, K^+-ATPase is recycled back to the extracellular fluid by basolateral potassium transport mechanisms.

Extracellular potassium is also a regulator of potassium secretion in the kidney. As plasma potassium increases, Na^+, K^+-ATPase increases, bringing more potassium into the cells for transepithelial secretion.

Another determinant of the transepithelial potential difference is the effect of anions in the collecting duct lumen. Non-reabsorbable anions maximize lumen negativity. To the extent that anions such as chloride are reabsorbed, the effect on luminal negativity will be reduced as sodium is reabsorbed. As a consequence, there will be less driving force for potassium (and hydrogen) secretion.

Aldosterone affects the transepithelial potential difference in several ways. The intracellular mineralocorticoid receptor functions to increase the density of ENaC and of basolateral Na^+, K^+-ATPase enzymes. Cortisol, which is normally present in higher concentrations than aldosterone, has equal affinity for the aldosterone receptor and therefore could lead to enhanced potassium secretion. However, the enzyme 11β-hydroxysteroid dehydrogenase type 2 is present in the collecting duct cells and converts cortisol to inactive cortisone.

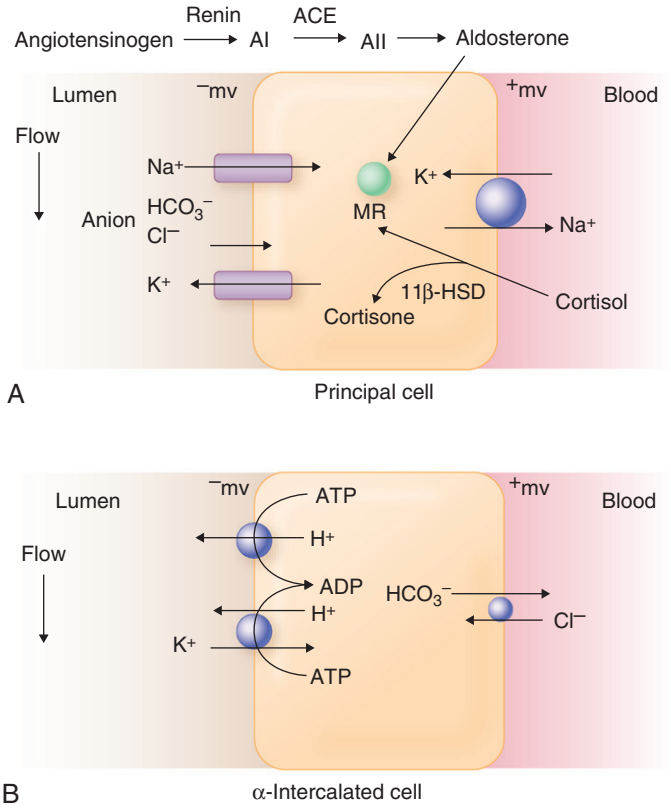

FIGURE 119-1. Two cell types in the cortical collecting duct. A, The principal cells mediate sodium (Na^+) reabsorption energized by the basolateral Na^+, K^+ pump. Entry from the lumen is through the epithelial Na^+ channel (ENaC), which renders the lumen negatively charged ($^-$mv). This transepithelial voltage stimulates secretion of potassium (K^+) through K^+ channels. Reabsorbable anions such as chloride (Cl^-) lessen the luminal negativity and decrease K^+ secretion. Bicarbonate (HCO_3^-) has an effect to increase K^+ secretion. High flow rates increase net K^+ secretion by preventing development of high lumen K^+ concentrations. The effects of the renin-angiotensin-aldosterone axis are shown: increased mineralocorticoid receptor (MR) activation increases ENaC, the Na^+, K^+ pump, and K^+ channels, thereby increasing Na^+ reabsorption and K^+ secretion. Cortisol would also increase MR activity, but it is inactivated by the enzyme, 11β-hydroxysteroid dehydrogenase (11β-HSD). AI = angiotensin I; AII = angiotensin II; ACE = angiotensin-converting enzyme; mv = millivolts. **B,** Intercalated cells are carbonic anhydrase–rich cells that secrete acid and reabsorb HCO_3^-. The H^+-ATPase secretes H^+ in a way favored by the negatively charged lumen in conjunction with the aldosterone-stimulated effect on Na^+ reabsorption in neighboring principal cells. The K^+, H^+-ATPase is an electroneutral pump. The K^+/H^+ exchanger, reabsorbing K^+, is important in states of K^+ depletion when urinary K^+ is decreased. ADP = adenosine diphosphate; ATP = adenosine triphosphate.

Role of Potassium Secretory Channels

The second mechanism for collecting duct potassium secretion is adequate function of several types of potassium secretory channels on the luminal membrane of the principal cell. Among many factors regulating these channels, antidiuretic hormone (ADH) and intracellular pH are likely of most significance. The increase in K^+ channel activity in response to ADH, combined with an ADH effect to increase ENaC, allows for the highest possible potassium concentration in the urine under circumstances of low flow that accompanies increased water reabsorption. Cellular acidification, as occurs in metabolic acidosis, inhibits potassium secretion through an effect on potassium secretory channels, thereby contributing to potassium retention in metabolic acidosis.

Flow Rate Dependence of Potassium Secretion

The third mechanism for regulating K^+ secretion in the collecting duct is the flow rate of urine. Increasing flow allows for greater sodium delivery and, hence, greater sodium reabsorption through ENaC; it also maintains optimal K^+ gradients for further secretion into the lumen. Conversely, in conditions of water diuresis, the decreased ADH diminishes the net amount of potassium secreted. Yet, because the urine cannot fully be free of potassium, polyuria over a prolonged period is likely to lead to significant potassium losses.

Because potassium excretion is highly dependent on flow rate, conditions in which high urine flow rates are accompanied by high aldosterone levels may result in substantial potassium losses. Such is the case with diuretic use (e.g., acetazolamide, thiazide, and loop diuretics). Increased urinary flow rates contribute to the hypokalemia in osmotic diuresis, Fanconi's syndrome, and metabolic alkalosis from vomiting. Conversely, low urinary flow rates make potassium excretion difficult and may contribute to hyperkalemic states. The increase in aldosterone and ADH that accompanies prerenal states may offset the K^+ retention that would otherwise accompany oliguria.

Excretion Mechanisms and Normal Function

Taken together, three feedback loops are relevant to normal function. First, drinking excessive water does not acutely lead to large losses of potassium because there is a simultaneous decrease in ADH. Second, expansion of the extracellular fluid with isotonic sodium chloride does not necessarily result in potassium depletion because the renin-angiotensin-aldosterone axis is suppressed. Third, in metabolic acidosis, intracellular acidification limits potassium secretion, favoring more acid secretion to compensate for the acidosis.

Diuretics such as furosemide and thiazides are well known and common causes of hypokalemia. The potassium-losing effects of thiazides are greater than those of loop diuretics.

Proximal tubule disorders associated with Fanconi's syndrome increase the delivery of solute, with an osmotic diuresis and bicarbonaturia that increase potassium secretion The volume depletion increases renin and aldosterone. Increased bicarbonate delivery from the proximal tubule overwhelms the capacity to reabsorb bicarbonate by the collecting duct. Bicarbonate acts as a non-reabsorbable anion that stimulates potassium secretion. For example, marked potassium wasting associated with vomiting is caused by renal losses when the urine is alkaline, not by lost potassium from the gastrointestinal tract.

The feedback mechanism coupling aldosterone with serum potassium is important in regulating the degree of potassium losses in the urine. For example, hyperaldosteronism results in K^+ loss, and then the resulting hypokalemia reduces aldosterone production and subsequent K^+ losses. Hyperkalemia has the opposite effect: it is an important stimulus of aldosterone synthesis and release. Thus, with volume expansion and low angiotensin II, the rise in K^+ stimulates aldosterone release from the zona glomerulosa of the adrenal cortex, thereby allowing for K^+ to be secreted into the urine.

Potassium Depletion and Excess

Potassium has critical effects on excitable tissues, especially cardiac and skeletal muscle. Low serum potassium not only hyperpolarizes most cells, thereby leading to an increase in the resting potential, but also alters potassium channels required for repolarization. Thus, hypokalemia decreases or slows potassium conductance.

Because of an increased potassium conductance, hyperkalemia antagonizes the normal slow depolarization of pacemaker tissue that is usually associated with a decrease in potassium conductance. Certain muscle-depolarizing anesthetic agents, such as succinylcholine, may potentiate effects of hyperkalemia, as may gentamicin, particularly in patients with renal failure.

Potassium is as important a body fluid osmole as sodium, and losses of potassium obligate sodium to replace it in the intracellular space, thereby resulting in hyponatremia. Hypokalemia contributes to the hyponatremia associated with thiazide diuretics. Isoosmotic losses of combined potassium and sodium salts in watery diarrhea may result in isotonic extracellular volume depletion. Similarly, if potassium chloride is added to isotonic saline, a hypertonic solution results, and potassium may enter cells as sodium exits, thereby contributing to hypernatremia.

Internal Potassium Balance

Because of the delay in hours before renal excretion matches dietary intake and because potassium first enters the extracellular fluid from the gastrointestinal tract, it is critical that the process of cellular buffering be effective (Table 119-1). Essentially, increases in postprandial blood potassium are minimized before potassium is eliminated from the body. A major factor in this regulation after meals is the feedback loop involving insulin and potassium. An increase in serum potassium stimulates insulin release from the β cells of the pancreatic islets. Insulin increases potassium uptake into cells, primarily muscle, independent of its effect on glucose uptake. Potassium uptake is chiefly the result of increased Na^+, K^+-ATPase trafficking to the plasma membranes in these cells.

Another important mechanism of regulating the distribution of potassium between extracellular and cellular spaces involves the sympathoadrenal system. β-Adrenergic activation, particularly through the β_2-receptor,

increases potassium uptake into muscle and fat cells. As with insulin, potassium uptake is the consequence of increased Na^+, K^+-ATPase activity associated with increased intracellular cyclic adenosine monophosphate (AMP). The adrenergic effect is important in regulating the serum potassium concentration during exercise and is independent of the additional effect that catecholamines may have on blood sugar with the expected increases in insulin. In the trained athlete, a chronic increase in Na^+, K^+-ATPase on cell membranes may cause a transient lowering of the serum potassium concentration after exertion. Conversely, a severe stress may contribute to hypokalemia, through both direct β_2 effects and insulin action secondary to the blood sugar rise.

Phenylephrine, an α-adrenergic agonist, increases serum potassium. Importantly, epinephrine, which also has α-adrenergic effects, is associated with a transient increase in potassium release from the liver before a more prolonged period of decreased serum potassium mediated by the β_2-receptor.

Metabolic acidosis raises the potassium level more than does respiratory acidosis; both metabolic alkalosis and respiratory alkalosis lower the potassium level. Anion gap acidosis does not raise the potassium level, probably because of the movement of the organic anion (e.g., lactate) from cells into the extracellular space with an accompanying proton, whereas the ingestion of chloride salts has the most profound effect on the potassium level because chloride is restricted to the extracellular space and protons enter cells in exchange for the exit of the potassium cation. The ingestion of excessive chloride salts of arginine and lysine is associated with hyperkalemic acidosis. ε-Aminocaproic acid has also been associated with hyperkalemia and is hypothesized to exchange for cellular potassium, much like the other cationic amino acids.

Just as multiple simultaneous acid-base disturbances lead to a single blood pH level, many processes that affect potassium can be simultaneously present. Metabolic acidosis may be associated with diarrheal or urinary losses of potassium, so that the potassium concentration is low, not high. Metabolic acidosis in diabetes can also be associated with insulin deficiency and renal failure, in which case the serum potassium level might be elevated despite osmotically driven urinary losses of potassium and total body potassium depletion.

Other hormonal effects on potassium include thyroid and growth hormone, but patients with disorders of these hormones do not usually have significant changes in their blood potassium levels. Some patients with hyperthyroidism may have mild hypokalemia, perhaps related to increased sympathetic activity. Growth states are associated with a greater need for potassium; for example, in normal pregnancy, the maternal potassium concentration may fall as the developing fetus grows.

Hypomagnesemia frequently accompanies hypokalemia. Both magnesium and potassium are found predominantly in cells, but Na^+, K^+-ATPase requires magnesium for function. If magnesium is deficient, potassium distributes more to the extracellular fluid, thereby masking the degree of potassium deficiency. Moreover, magnesium deficiency leads to renal potassium wasting, so potassium depletion is hard to correct until magnesium is repleted.

External Potassium Balance and Associated Disorders

Normally, no more than 10 to 20% of total potassium excretion is accomplished by the gastrointestinal tract, but colonic excretion is increased in renal failure, primarily through potassium-induced increases in epithelial Na^+, K^+-ATPase activity and aldosterone. In renal failure, the normal mechanisms to distribute potassium acquire increased importance.

Some conditions that cause the greatest losses of gastrointestinal potassium include secretory diarrheas of the colon, the result of infection or laxative abuse. Disorders of the small intestine, which may lead to large quantities of liquid stool with a low potassium concentration, engender favorable gradients for marked potassium secretion by the colon. A syndrome of watery diarrhea and hypokalemia is associated with neuroendocrine tumors (Chapter 211) that secrete vasoactive intestinal peptide. Rectosigmoid secretion of potassium may result in particularly high potassium losses, and potassium deficiency is seen in patients who have ureterosigmoidostomies. Potassium can be lost from a variety of other sources, including excess sweat or salivation, vomiting, and diarrhea.

Potassium can be depleted by vomiting or diarrhea. Urinary losses may exceed intake in renal tubular disorders, when excessive quantities of osmotic or anionic products are excreted in the urine, or in patients who take diuretics.

It is unusual for hyperkalemia to be caused by excessive potassium intake unless the patient has renal dysfunction. However, patients who have brisk hemolysis, internal hemorrhage, or rhabdomyolysis, particularly if the hemoglobinuria or myoglobinuria also results in acute kidney injury, can quickly develop life-threatening hyperkalemia owing to rapid release of cellular potassium stores.

CLINICAL MANIFESTATIONS

Hypokalemia

Clinical manifestations of potassium depletion include hypertension, decreased growth, and muscle symptoms such as weakness, cramps, fasciculations, and even paralysis. In severe cases, the diaphragm may be paralyzed, leading to respiratory failure. Cardiac arrhythmias are a critical component of low potassium states and are usually seen when the serum potassium falls below 3 mmol/L or when ischemia, hypercalcemia, or drugs such as digoxin are simultaneously present. A patient who has a chronically low potassium level (e.g., from diuretic use) may be particularly vulnerable to supraventricular and ventricular tachyarrhythmias during periods of stress, such as head trauma, or during the acute coronary syndrome, to which cardiac ischemia also contributes. The prolonged cardiac repolarization phase of hypokalemia accounts for the characteristic electrocardiographic findings of broad, flattened T waves. U waves are also indicative of this delay in repolarization (Fig. 119-2). In the intestine, hypokalemia may result in paralytic ileus, which may interfere with oral replacement. Hypokalemia may result in acute skeletal muscle weakness and even paralysis.

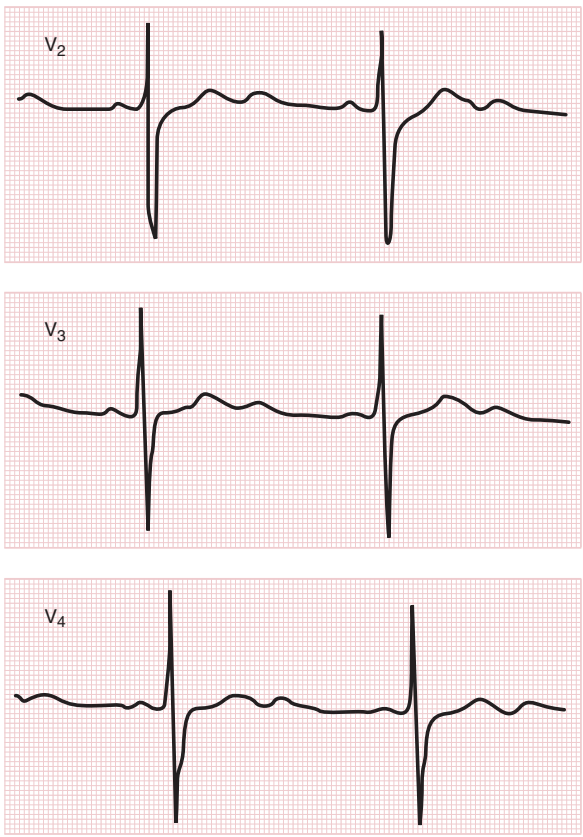

FIGURE 119-2. The electrocardiographic manifestations of hypokalemia. The serum potassium concentration was 2.2 mEq/L. The ST segment is prolonged, primarily because of a U wave following the T wave, and the T wave is flattened.

In addition to these systemic effects of potassium imbalance, the kidney is particularly sensitive to depletion of potassium. Structural changes in the glomeruli and tubules lead to a decreased glomerular filtration rate (GFR), increased proximal tubule ammoniagenesis, increased sodium bicarbonate reabsorption, and net acid excretion. A condition of nephrogenic diabetes insipidus results when potassium depletion decreases expression of vasopressin-dependent water channels (aquaporin-2) in the collecting duct luminal plasma membranes. Hypokalemia diminishes insulin secretion and may be associated with glucose intolerance.

Hyperkalemia

In hyperkalemia, the depolarizing effect on the resting membrane potential and increased potassium channel conductance lead to the classic electrocardiographic changes of hyperacute peaked T waves associated with rapid repolarization (Fig. 119-3). Hyperkalemia commonly results in sinus bradycardia. Heart block, loss of P waves on the electrocardiogram, and prolonged QRS intervals are all seen in cases of severe hyperkalemia, usually in excess of 6 mmol/L. The electrocardiogram, however, is not a sensitive indicator of severe hyperkalemia, and cardiac arrest may occur without warning. Like hypokalemia, severe hyperkalemia can cause skeletal muscle paralysis; unlike hypokalemic paralysis, it is often ascending in nature.

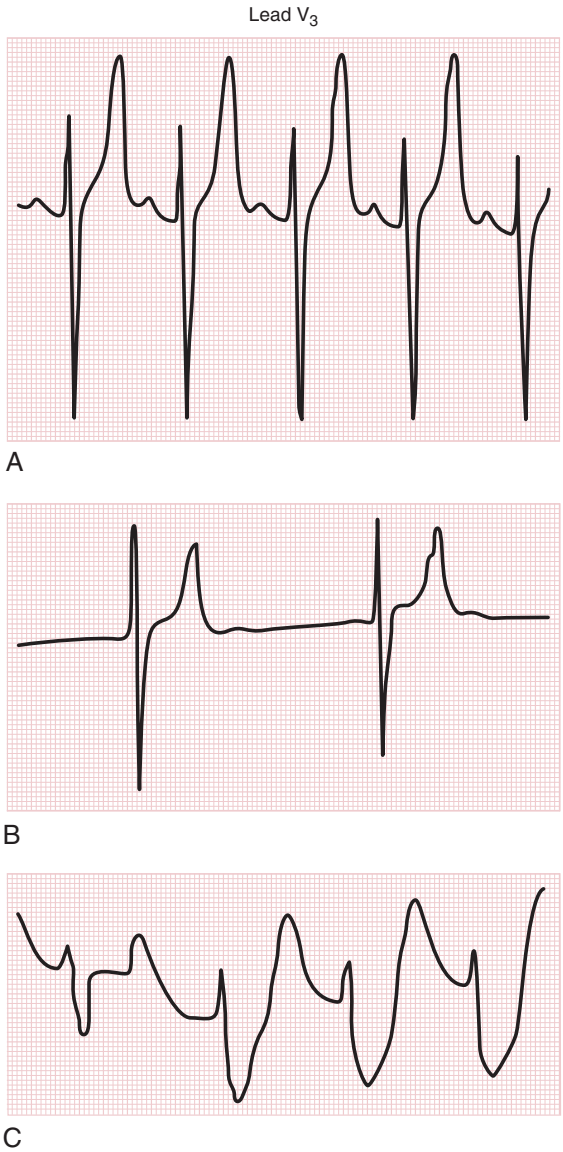

FIGURE 119-3. The effects of progressive hyperkalemia on the electrocardiogram. All of the illustrations are from lead V_3. **A,** Serum potassium concentration ($[K^+]$) = 6.8 mEq/L; note the peaked T waves together with normal sinus rhythm. **B,** Serum $[K^+]$ = 8.9 mEq/L; note the peaked T waves and absent P waves. **C,** Serum $[K^+]$ = >8.9 mEq/L; note the classic sine wave with absent P waves, marked prolongation of the QRS complex, and peaked T waves.

DIAGNOSIS

The first clue to a disorder in potassium balance usually is an abnormal serum potassium concentration obtained as part of a laboratory evaluation, not because an abnormal potassium level itself is suspected. When the potassium is elevated above normal, it is imperative to exclude common artifacts, known as pseudohyperkalemia. Hemolysis in the test tube is a common artifact; in cases of cold-induced hemolysis (Chapter 164), it is important to collect the blood and allow it to clot in a warm environment. Some patients have pseudohyperkalemia resulting from high platelet counts, usually in excess of 1 million/μL, or myelogenous leukemia (Chapters 189 and 190); in such cases, plasma potassium levels should be within the normal range. Sometimes the serum potassium level may be elevated because of local ischemia related to application of the tourniquet and clenching of the fist.

A detailed medical history should focus on medications, family history, and sources of potassium excess or loss. The physical examination should pay particular attention to blood pressure, extracellular volume status, heart rate and rhythm, and muscle strength and reflexes.

Laboratory testing should include a complete blood count as well as serum levels of sodium, chloride, bicarbonate, creatinine, and blood urea nitrogen. In more serious cases, arterial blood gases and levels of creatine kinase and magnesium should be obtained. A 12-lead electrocardiogram also should be obtained.

A low urinary potassium level is expected in hypokalemia. In a hypokalemic patient, a urinary potassium concentration greater than 30 mEq/L suggests renal potassium wasting, whereas extrarenal losses are usually reflected by concentrations lower than 20 mEq/L. In a state of potassium excess, urinary potassium excretion should exceed about 35 mEq/L, unless urinary underexcretion was the cause of the hyperkalemia. A high aldosterone level causes a high urinary potassium-to-sodium ratio, whereas hypoaldosteronism may cause the opposite. Another way to determine the appropriateness of urinary potassium content is to calculate the transtubular potassium gradient (TTKG) as follows:

$$\text{TTKG} = (\text{urinary potassium concentration} \div \text{plasma potassium concentration}) / (\text{urine osmolality} \div \text{plasma osmolality})$$

Correct use of the TTKG requires the urine Na^+ to be greater than 25 mEq/L and the urine osmolality as high as or higher than the serum osmolality.

In a hyperkalemic patient, a TTKG of more than 7 to 8 would be expected. Lower values suggest renal underexcretion as the cause of the hyperkalemia. In a hypokalemic patient, a healthy kidney should conserve potassium, so the TTKG should be less than 2 to 3; if it is more than 3, urinary potassium wasting would be suspected as the cause of the hypokalemia.

Hypokalemic Disorders

The most common cause of hypokalemia (Table 119-2) in medical practice is the use of thiazide diuretics or loop diuretics. Patients may have low, normal, or high blood pressures depending on their volume status and whether the diuretics were prescribed for hypertension or heart failure. The most common acute causes of hypokalemia are diarrhea or vomiting.

Hypokalemic Hypertensive Syndromes

If the renal collecting duct cells develop a transepithelial electrical gradient that is more lumen negative than is needed to maintain potassium balance, urinary potassium wasting, inappropriate to the blood potassium level, occurs. Because a parallel increase in H^+ secretion will occur, it is common to see an accompanying metabolic alkalosis. If the abnormality is related to a primary increase in sodium reabsorption, hypertension or extracellular volume expansion also will develop.

Evaluation of plasma renin and aldosterone levels can help distinguish among specific diagnoses (see Table 119-2). Primary hyperaldosteronism is associated with low renin levels owing to volume expansion. If corrected for serum potassium, an aldosterone-to-renin ratio of 30:1 suggests a primary adrenal cortical tumor (aldosteronoma) or hyperplasia (Chapter 234). The tubular delivery of large amounts of sodium chloride in a setting of volume expansion and nonsuppressible aldosterone results in hypokalemia, which improves after sodium restriction and worsens with the administration of intravenous saline. In congenital adrenal hyperplasia (Chapter 234), such as 11β-hydroxylase deficiency, hypokalemic alkalosis is associated with excessive androgen production. In patients with renin-secreting tumors or unilateral renal artery stenosis, high renin levels stimulate angiotensin and then

TABLE 119-2 CAUSES OF HYPOKALEMIA AND INCREASED POTASSIUM EXCRETION

CAUSES OF INCREASED K^+ EXCRETION AND HYPOKALEMIA	RENIN	ALDOSTERONE	EXTRACELLULAR VOLUME OR BLOOD PRESSURE	ACID-BASE STATUS
Increased ENaC: Liddle's syndrome	Low	Low	High	Alkalosis
Decreased β-OH steroid dehydrogenase: apparent mineralocorticoid excess, licorice	Low	Low	High	Alkalosis
Adrenal tumor or hyperplasia	Low	High	High	Alkalosis
Ectopic ACTH; Cushing's syndrome	Low	Low	High	Alkalosis
Congenital adrenal hyperplasia	Low	High	High	Alkalosis
Unilateral renal artery stenosis	High	High	High	Alkalosis
Renin-secreting tumor	High	High	High	Alkalosis
Diuretics:				
Acetazolamide	High	High	Variable	Acidosis
Furosemide, thiazides	High	High	Low	Alkalosis
Bartter's syndrome	High	High	Low	Alkalosis
Gitelman's syndrome	High	High	Low	Alkalosis
Fanconi's syndrome	High	High	Low	Acidosis
Distal RTA	High	High	Low	Acidosis

ACTA = adrenocorticotropic hormone; β-OH = β-hydroxy; ENaC = epithelial Na^+ channel; RTA = renal tubular acidosis.

aldosterone secretion, with a resulting increase in sodium reabsorption, hypertension, and hypokalemic metabolic alkalosis.

In some patients with overproduction of adrenocorticotropic hormone (ACTH), as in ectopic production from lung and other malignancies (Chapter 187), cortisol may overwhelm the aldosterone receptor and result in hypertensive hypokalemic alkalosis. The patient may not show signs of Cushing's syndrome, unless the syndrome is prolonged. In glucocorticoid-remediable aldosteronism, which is a familial disorder in which episodes of hypokalemia and hypertension develop, a chimeric gene duplication couples the ACTH-responsive 11β-hydroxylase promoter to the coding region of aldosterone synthase.

Glycyrrhizic acid, which is found in licorice or anisette, inhibits the renal enzyme 11β-hydroxysteroid dehydrogenase and thereby causes hypokalemia, metabolic alkalosis, and hypertension. A rare genetic disorder known as apparent mineralocorticoid excess syndrome produces the same effect owing to deficiency of 11β-hydroxysteroid dehydrogenase. The syndrome produces a high ratio of cortisol to cortisone; as a result, renin and aldosterone are suppressed by the volume expansion.

Activating mutations of ENaC cause increased Na^+ reabsorption (Liddle's syndrome; Chapter 130). The syndrome can be distinguished from primary or secondary hyperaldosteronism by a decrease in renin and aldosterone levels.

Hypokalemic Hypotensive Syndromes

In contrast to the hypokalemic hypertensive syndromes, in which an increased sodium reabsorption is a primary event, many hypokalemic alkaloses are associated with extracellular volume depletion. With a physiologic response to volume depletion, the K^+ losses may be a result of appropriate Na^+ reabsorption; signs of hypotension or extracellular volume depletion will be observed. Secretory diarrheas, whether associated with hypochloremic alkalosis or hyperchloremic acidosis, lead to extracellular volume depletion and secondary increases in renin and aldosterone; the result is both gastrointestinal and urinary K^+ losses.

Diuretic use, Bartter's syndrome (Chapter 130), and Gitelman's syndrome (Chapter 130) are renal tubular causes of extracellular volume depletion, hypotension, and hypokalemic alkalosis; sodium and chloride are lost in the urine, and secondary rises in renin and aldosterone occur. Increased urinary flow rates are important contributors to the increased potassium losses in each of these examples. Bartter's syndrome affects the function of the thick ascending limb through mutations in NKCC or in K^+ or Cl^- channels, whereas Gitelman's syndrome is characterized by inactivating mutations or dysregulation of the sodium-chloride cotransporter (NCC) in the distal tubule. The hypokalemia in Gitelman's syndrome may be caused by secondary hyperaldosteronism, bicarbonaturia, and, hypomagnesemia.

Classic type 1 distal renal tubular acidosis (Chapter 130) is often associated with hypokalemia, which may improve with correction of the acidemia. In contrast, proximal renal tubular acidosis, when corrected with bicarbonate, often results in worsening of the hypokalemia owing to greater bicarbonate wasting associated with increases in the filtered bicarbonate load.

Acetazolamide, when given to an alkalotic patient, is a particularly potent kaliuretic agent. Volume depletion and hyperaldosteronism contribute to the potassium losses, as does the bicarbonate wasting, which appears to have a direct effect on potassium secretion. Whenever the urine is alkaline, potassium will usually be present in significant amounts.

Tubular toxins that may be associated with severe potassium losses include aminoglycosides, cisplatinum, and ifosfamide. Amphotericin B results in significant potassium wasting accompanied by renal tubular acidosis. In many of these conditions, simultaneous use of amiloride may diminish potassium losses by as much as 50%.

Patients who present with unexplained hypokalemia and alkalosis with volume depletion should have urinary electrolytes measured to determine whether the urine chloride is low, as with vomiting or laxative abuse. If the urine contains chloride, a diuretic screen should be considered; Gitelman's syndrome and Bartter's syndrome are other possibilities.

Hyperkalemic Disorders

In clinical practice, acute hyperkalemia is seen most commonly with renal failure (Chapter 133), with acidosis (Chapter 120), and with acute muscle damage from rhabdomyolysis (Chapter 115) (Table 119-3). Chronic hyperkalemia is most commonly seen with medications that reduce potassium secretion and with renal tubular disorders.

Hyperkalemic Hypotensive or Normotensive Syndromes

Type IV renal tubular acidoses (Chapter 130) that are associated with an inability to acidify the urine are caused by diseases that disrupt distal nephron function, including systemic lupus erythematosus (Chapter 274), urinary tract obstruction (Chapter 125), amyloidosis (Chapter 194), the nephropathy associated with kidney and bone marrow transplantation (Chapters 133 and 181), and sickle cell nephropathy (Chapter 127). Males who present with hyperkalemia and renal insufficiency of unknown cause should be evaluated for possible prostatic obstruction (Chapter 131). Each of these conditions may also be associated with failure to concentrate the urine (nephrogenic diabetes insipidus) or with a hyperchloremic metabolic acidosis caused by abnormalities in acid secretion.

Primary selective hypoaldosteronism or complete adrenal cortical deficiency (Chapter 234) is associated with elevated renin and low aldosterone. Secondary hypoaldosteronism may be seen in hyporenin states caused by β-blockers, renin antagonists, or nonsteroidal anti-inflammatory drugs (NSAIDs). Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers increase renin and decrease aldosterone. Heparin, including low-molecular-weight and fractionated forms (Chapter 37), can lead to hyperkalemia even in small subcutaneous doses.

Disorders that affect the transepithelial potential difference and can result in hyperkalemia, acidosis, and extracellular volume depletion include

TABLE 119-3 CAUSES OF HYPERKALEMIA AND DECREASED POTASSIUM EXCRETION

CAUSE OF DECREASED K^+ EXCRETION AND HYPERKALEMIA	RENIN	ALDOSTERONE	EXTRACELLULAR VOLUME OR BLOOD PRESSURE	ACID-BASE STATUS
Decreased ENaC: Drugs: amiloride, triamterene, trimethoprim, lithium Pseudohypoaldosteronism type 1 autosomal recessive ENaC mutation	High	High	Low or normal	Normal or acidosis
Pseudohypoaldosteronism type 1 autosomal dominant MR mutation	High	High	Low	Acidosis
MR blockade: spironolactone, eplerenone, progesterone	High	High	Low	Acidosis
Hypoaldosteronism: Adrenal insufficiency	High	Low	Low	Acidosis
Hyporenin-hypoaldosteronism: NSAIDs, β-blockers, autonomic neuropathy	Low	Low	Low	Acidosis
Pseudohypoaldosteronism type 2	Low	Low	High	Acidosis

ENaC = epithelial Na^+ channel; MR = mineralocorticoid receptor; NSAIDs = nonsteroidal anti-inflammatory drugs.

inactivating mutations of ENaC (autosomal recessive pseudohypoaldosteronism type 1), which may be accompanied by high renin and aldosterone levels. The ENaC may also be inhibited by the potassium-sparing diuretics (i.e., amiloride and triamterene) and certain medications secreted by the proximal tubule organic cation transporters, such as trimethoprim and pentamidine, as well as by lithium. Inhibition of the aldosterone receptor may be the result of antagonists such as spironolactone and eplerenone.

Hyperkalemic Hypertensive Syndromes

NSAIDs can cause hyperkalemia, particularly in patients with renal disease, by decreasing sodium delivery, increasing water reabsorption, and decreasing renin and aldosterone. Hypertension with the NSAIDs is most likely caused by renal salt and water retention.

Cyclosporine or tacrolimus may produce a hyperkalemic acidosis. The mechanism may involve inhibition of cyclooxygenase 2 (COX2) and therefore hyporenin-hypoaldosteronism. There may also be a decrease in apical potassium secretion in the collecting duct. Gordon's syndrome is a genetic disorder (pseudohypoaldosteronism type 2) associated with hyperkalemia, volume expansion, and metabolic acidosis; it is highly responsive to thiazide diuretics.

TREATMENT

Rx

It may be difficult to determine the exact state of total body potassium stores from the serum potassium level because as much as 100 to 300 mmol of potassium may be lost from the body with a fall in serum potassium of only 1 mmol/L.

Hypokalemia

The goal of acute therapy for hypokalemia is to prevent or manage potentially life-threatening arrhythmias or paralysis. Patients at greatest risk are elderly patients, patients with known liver disease or cardiac disturbances, and patients who have had an abrupt fall in serum K^+ to less than 2.5 mEq/L. Potassium must traverse the extracellular space before repleting intracellular stores, so it is dangerously easy to replete potassium too quickly. Oral potassium should be given, if possible. If the K^+ is greater than 3 mEq/L, increasing dietary K^+ can be considered, along with removing the underlying cause of hypokalemia. Usual oral replacement is with KCl at a dose of 40 to 100 mmol per day. The Cl salt has the advantage of treating concomitant metabolic alkalosis, but other available forms include K citrate (in the acidotic patient) and K phosphate (in patients with a phosphate deficit). Giving potassium with a nonreabsorbable anion, such as gluconate, may not replace the potassium deficit adequately. Intravenous potassium is reserved for patients who are unable to take enteral potassium and patients with symptomatic hypokalemia, paralysis, or cardiac arrhythmias. It is usually given as a solution of 20 to 40 mmol of K^+ in 1 L of solution at a rate that does not exceed 10 to 20 mmol/hour. In some cases of severe hypokalemia (<2.5 mEq/L) and in symptomatic patients, higher concentrations (up to 40 mmol in 100 mL) have been used. If the potassium level is less than 3 mmol/L or if more than 10 mmol/hour is to be delivered, it may be best to treat the patient in a monitored setting to observe for cardiac complications. A central venous catheter may be required for these higher concentrations. In these unusual circumstances, it is best to consult with a renal specialist and the pharmacy.

In patients who have prerenal azotemia associated with hyperglycemia or severe metabolic alkalosis, volume expansion with sodium chloride solutions alone can result in life-threatening potassium losses, despite improvement in the extracellular volume. Potassium must be given in anticipation of such events.

In a hypokalemic patient, care must be exercised when glucose-containing solutions are given because the resulting increase in insulin may further decrease the blood potassium level. Attention to the urine output and ongoing losses is crucial. If ongoing losses of potassium are severe, it may be necessary to provide a potassium-sparing diuretic (e.g., amiloride, 5 to 10 mg orally) and to treat the cause of the ongoing losses (e.g., diarrhea). Magnesium should be measured and replaced, if necessary, in any hypokalemic patient.

In the outpatient setting, hypokalemia is a common side effect of diuretic therapy. The serum potassium level should be maintained within the normal range (>3.5 mEq/L), especially in high-risk patients. Addition of 40 to 100 mmol of K^+ per day as the chloride salt is the usual treatment, depending on the patient's response.

Hyperkalemia

If hyperkalemia is severe, the goal is to achieve a rapid reduction in potassium concentration. If hyperkalemia is associated with cardiac arrhythmias, however, the cardiac effects of the hyperkalemia require interim treatment in a monitored setting, before the serum potassium can be expected to decline, even with aggressive therapy. Calcium gluconate, 10 mL of a 10% solution (8.9 mg calcium) over 10 to 20 minutes, is often indicated to stabilize electrical effects on cardiac excitation. Calcium chloride (3 to 4 mL of a 10% solution) is used as another alternative, but it should be administered through a central access line because extravasation of the chloride salt may result in tissue necrosis.

However, calcium does not lower the potassium concentration. Nebulized or inhaled β-agonists and intravenous insulin and glucose, either alone or the two in combination, are the best treatments. To lower the potassium within 15 minutes, 10 units of regular insulin should be given, with glucose given as a 10% solution over 1 hour for a total of 30 to 50 g in the normoglycemic patient. The blood glucose level should be monitored. Albuterol by nebulizer (10 to 20 mg in 4 mL saline over 10 minutes) can redistribute potassium acutely but should not be the sole treatment because some patients are not responsive. In some cases, intravenous β-adrenergic agonists (e.g., albuterol, 0.5 mg in 100 mL of 5% dextrose over 15 minutes) have been used to lower the serum potassium level by about 1 mmol/L within minutes to hours. Sodium bicarbonate, as an isotonic mixture calculated to correct acid-base status, should be reserved for acidemic patients who otherwise require alkalinization, while being careful to avoid hypocalcemia; complications of sodium bicarbonate infusions include hypernatremia, volume expansion, and decreased ionized calcium, potentially resulting in tetany. Diabetic patients may be potassium depleted even though they present with hyperkalemia; as they are volume repleted, they typically require potassium replacement (Chapter 236).

Over the longer term, potassium loss can be sustained by using cation exchange resins such as sodium polystyrene sulfonate, given orally or as an enema (Chapter 133). A dose of 30 to 50 g can reduce potassium levels over several hours. This resin will also provide a sodium load and bind calcium, thereby resulting in volume expansion and hypocalcemia. These resins may interfere with the absorption of lithium and thyroxine. A serious complication of sodium polystyrene sulfonate resins when used in combination with sorbitol is colonic ulceration and necrosis. These resins also should not be given in combination with aluminum-based antacids because the resulting concretions can obstruct the gastrointestinal tract. If the patient is volume expanded, furosemide (40 to 100 mg), chlorothiazide (500 mg) or, if the patient is also

alkalotic, acetazolamide (250 to 500 mg) may enhance renal potassium clearance. If the patient is volume depleted, isotonic saline expansion may improve urine output and, with it, potassium excretion.

Specific Clinical Syndromes

Hypokalemia

Patients with pernicious anemia who receive vitamin B_{12} to stimulate erythropoiesis may deplete extracellular potassium and suffer from hypokalemia as a cost of producing new red blood cells. Leukemias with rapid growth rates (Chapter 189) also may cause a drop in the serum potassium level, and some forms of myelogenous leukemia are associated with a high level of lysozyme, which leads to urinary potassium loss as well (Chapter 190).

Familial hypokalemic periodic paralysis is caused by a variety of mutations in a cellular calcium channel, with resulting reduced activity of an ATP-regulated K^+ channel that extrudes potassium from skeletal muscle cells. Without the ability to recycle potassium to the extracellular space, the hypokalemic effect of the Na^+, K^+-ATPase is unopposed. The presentation is usually in the teenage years or early adulthood. In some cases, a progressive proximal myopathy may develop. A form is seen in Asian patients with hyperthyroidism; it manifests as episodic paralysis brought out by high-carbohydrate meals (insulin secretion). Another aggravating factor is rest after exercise, a time when blood potassium falls owing to reuptake of potassium by the ATPase pumps. The condition is treated by a high potassium diet as well as with β_2-blockers (e.g., propranolol, 20 to 40 mg twice daily) and carbonic anhydrase inhibitors (e.g., acetazolamide, 125 to 500 mg), which in part work by creating a hyperchloremic acidosis that offsets the urinary potassium wasting they cause.

Hyperkalemia

The abnormal distribution of potassium between cells and the extracellular space results in the hyperkalemia that is associated with acidosis, insulin-deficient states, and β_2-adrenergic blockade. Although it is not always possible, it is best to know the levels of serum glucose and potassium in an unconscious diabetic patient before infusing concentrated glucose solutions, because of the risk for aggravating an already elevated potassium concentration.

Familial hyperkalemic periodic paralysis is a myopathy caused by a genetic defect in voltage-gated Na^+ channels in skeletal muscle. Exercise or dietary increases in plasma potassium result in mild depolarization of skeletal muscle that then unmasks the sodium channel defect, rendering the cells unexcitable. Treatment is frequent meals and acetazolamide (125 to 500 mg).

Potassium competes with digoxin-binding sites on the Na^+, K^+-ATPase, so that, if hypokalemia coexists, digoxin will have an intensified effect and may lead to drug toxicity. In extreme cases of digitalis overdose, severe hyperkalemia develops owing to generalized blockade of Na^+, K^+-ATPase.

PROGNOSIS

The prognosis of patients with hypokalemia and hyperkalemia depends on the severity and underlying illness. Most hypokalemic cases are mild (K^+, 3 to 3.5 mEq/L). However, mortality of hospitalized patients with hypokalemia is increased ten-fold. Hyperkalemia is reported in 1 to 10% of hospitalized patients, of whom 10% have severe hyperkalemia (K^+, >6.0 mEq/L). Hyperkalemia is associated with increased mortality (14 to 41%), and it accounts for 2 to 5% of deaths in patients with end-stage renal disease.

ACID-BASE DISORDERS

JULIAN L. SEIFTER

DEFINITION

The pH is defined as the negative log of the hydrogen ion concentration. At a pH of 7.40, the hydrogen ion concentration is 40 nanoequivalents (nEq) per liter, a very small concentration in comparison to serum sodium at 140 mEq/L. The hydrogen ion concentration of body fluids is in equilibrium with each of multiple buffers, such as proteins, phosphate, and hemoglobin (the isohydric principle), but acid-base equilibria in the body are often analyzed by using the CO_2/HCO_3^- system and the relationship of the proton concentration (thus pH) to the ratio of HCO_3^- to CO_2. The Henderson-Hasselbalch equation is a logarithmic expression of the relationship.

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

$$pH = pK + \log[HCO_3]/0.03(P_{CO_2})$$

In this equation, pK, or the dissociation constant, is 6.1; 0.03 (mM/mm Hg) is the solubility factor for CO_2 in solution. The product of $0.03 \times P_{CO_2}$ represents dissolved CO_2; the "total CO_2" in plasma is the sum of HCO_3^-, normally about 25 mM, and $0.03 \times P_{CO_2}$, normally about 1.2 mM. It is important to note that pH is a function of the *ratio* of HCO_3^- to P_{CO_2}. The HCO_3^- concentration in the numerator is regulated by the kidney, and P_{CO_2} is regulated by the lung, the major organ systems involved in acid-base balance.

EPIDEMIOLOGY

If the production of acid exceeds elimination, a state of acidosis exists, whereas if elimination exceeds production, alkalosis will develop. In metabolic acidosis, production could exceed excretion through a marked excess in the production rate, as might be seen with diabetic ketoacidosis (Chapter 236) or lactic acidosis, or it could develop even with a normal rate of metabolic acid production if the kidney were unable to eliminate acid normally, as in kidney failure (Chapters 122 and 132).

In most humans, particularly those who eat animal protein or an acid-ash diet, the requirement for net acid excretion dominates. However, vegetarians can have an overall alkaline-ash diet, for which net alkali must be excreted to match intake.

Hypochloremic alkalosis might be anticipated in a patient with a history of vomiting or the use of thiazide or loop diuretics. Metabolic acidosis might be anticipated in hypotensive shock, sepsis, diarrhea, and renal failure. Chronic lung disease can be associated with respiratory acidosis, whereas fever, infection, stroke, or acute pulmonary disease may be a cause of acute respiratory alkalosis.

PATHOBIOLOGY

Normal Acid-Base Physiology

Many of the body's metabolic and physiologic functions are pH dependent or pH sensitive. The range of normal arterial pH is 7.38 to 7.42. Intracellular pH is lower than extracellular pH because cells are electronegative with respect to extracellular fluid and metabolically produced acids are constantly being transported to extracellular fluid for eventual elimination from the body. Net acid production must equal net acid excretion. When the diet calls for excretion of acids, urine pH will fall to a value as low as 5.0, and the urine will become nominally free of bicarbonate. When there is an alkaline load, the kidney will reject the excess filtered HCO_3^-, and urine pH may approach a maximal value of 8.0 to 8.5.

In severe disease states, arterial pH may fall as low as 6.8 and rise as high as 7.8. Strenuous exercise with the metabolic production of lactate may transiently but severely lower pH, even in normal healthy individuals.

Production of Acids and the Elimination of CO_2 by the Lung

Volatile acid is the term used for the carbon dioxide produced by metabolic processes in all tissues, an amount that approximates 20,000 mmol/day. This CO_2 is carried from tissues to the lung, where it is eliminated by alveolar ventilation. Steady-state P_{CO_2} is normally 38 to 42 mm Hg.

Nonvolatile acid is a term used to describe acids other than carbonic acid that are formed primarily from protein metabolism. The usual amount of formation is approximately 1 to 2 mEq of H^+ per kilogram of body weight per day. Most diets that contain animal protein have a net positive quantity of nonvolatile acids, primarily from the sulfur-containing amino acids cysteine and methionine; phosphates from phosphoproteins, phospholipids, and phosphonucleotides; nonmetabolizable organic acids, such as uric acid, and inorganic sources; and HCl derived from chloride salts of lysine, arginine, and histidine. The addition of protons to body fluids by these acid end products consumes bicarbonate, which then must be replenished by the kidney as it eliminates the proton. The kidney must excrete any nonvolatile acid or alkali load to maintain a steady-state serum HCO_3^- concentration in the 22- to 28-mM range.

Oxidation of carbohydrates and fats results in the production of water and CO_2, but not nonvolatile acids. To maintain a steady state, any acid or base produced per day must be equivalent to what is excreted. If CO_2 production exceeds CO_2 excretion by the lungs, respiratory acidosis characterized by a high P_{CO_2} will develop. If the rate of CO_2 excretion exceeds production, respiratory alkalosis develops. By the equation,

$$\text{alveolar ventilation} \sim CO_2 \text{ elimination} \div P_{CO_2}$$

the inverse relationship of alveolar ventilation to P_{CO_2} is obvious. At steady state, CO_2 production by tissues must equal CO_2 elimination by the lungs for a constant P_{CO_2} to be maintained. The changes in P_{CO_2} are almost always caused by changes in alveolar ventilation rather than production of CO_2. Thus, respiratory acidosis is nearly always a consequence of decreased pulmonary ventilation because of lung or central nervous system (CNS) disease and not a consequence of increased production of CO_2. Similarly, respiratory alkalosis develops because of hyperventilation rather than decreased CO_2 production. In either case, when the elimination rate of CO_2 (alveolar ventilation × P_{CO_2}) again equals CO_2 production, a new steady state will prevail, with no net retention or loss of carbonic acid.

Bicarbonate and the Kidney in Acid-Base Balance

The first role of the kidney in acid-base balance is to reabsorb all filtered HCO_3^- (Fig. 120-1). At a normal glomerular filtration rate (i.e., ~180 L/day in an adult) and serum HCO_3^- concentration of 25 mEq/L, about 4500 mEq of HCO_3^- is filtered in 1 day. Loss of even a small fraction of that amount would result in metabolic acidosis if not replaced by intake.

The Proximal Tubule

About 80 to 90% of HCO_3^- reabsorption is accomplished in the proximal tubule by a proton secretory process. The brush border membranes facing the lumen of the proximal tubule cell contain transporters known as Na/H exchangers (NHE3 is the abundant isoform). Through the normal function of basolateral membrane Na^+,K^+-adenosine triphosphatase (ATPase), cell Na^+ is kept at low concentration so that filtered Na^+ in the lumen will be favored to enter the cell in exchange for H^+ secreted into the lumen. This H^+ rapidly combines with filtered HCO_3^- to form H_2CO_3, which then dehydrates in the lumen to form CO_2 and H_2O. This last process is greatly facilitated by luminal carbonic anhydrase (CA_{IV}). The CO_2 diffuses into the proximal cell, where it reforms HCO_3^-, a reaction catalyzed by intracellular carbonic anhydrase (CA_{II}). The HCO_3^- is then transported back to the blood by a sodium bicarbonate cotransporter (NBC), which couples 1Na and $3HCO_3^-$, thereby completing net Na^+ and HCO_3^- reabsorption. The entire process requires a mitochondrial source of adenosine triphosphate (ATP) for the Na/K pump, intact NHE3 and NBC, and two isoforms of carbonic anhydrase. Additionally, there must be favorable ion gradients for luminal Na^+ entry, H^+ secretion, and basolateral HCO_3^- transport. A disturbance in any of these factors may disrupt proximal HCO_3^- reabsorption enough to cause loss of HCO_3^- in urine. Another 10 to 15% of HCO_3^- is reabsorbed in the thick ascending limb of Henle through a similar mechanism so that only small amounts of the filtered HCO_3^- are normally delivered to more distal nephron segments.

The Cortical Collecting Duct

The cortical connecting tubule and collecting duct reabsorb less than 10% of the filtered HCO_3^-. In principal cells, Na^+ is reabsorbed from lumen to cell by the epithelial Na^+ channel (ENaC), driven by the inwardly directed Na^+ gradient and favorable electrical potential. With the reabsorption of Na^+, the lumen becomes electronegative, thus favoring the secretion of both K^+, through K^+ channels, and H^+, through vacuolar H^+-ATPases on the luminal

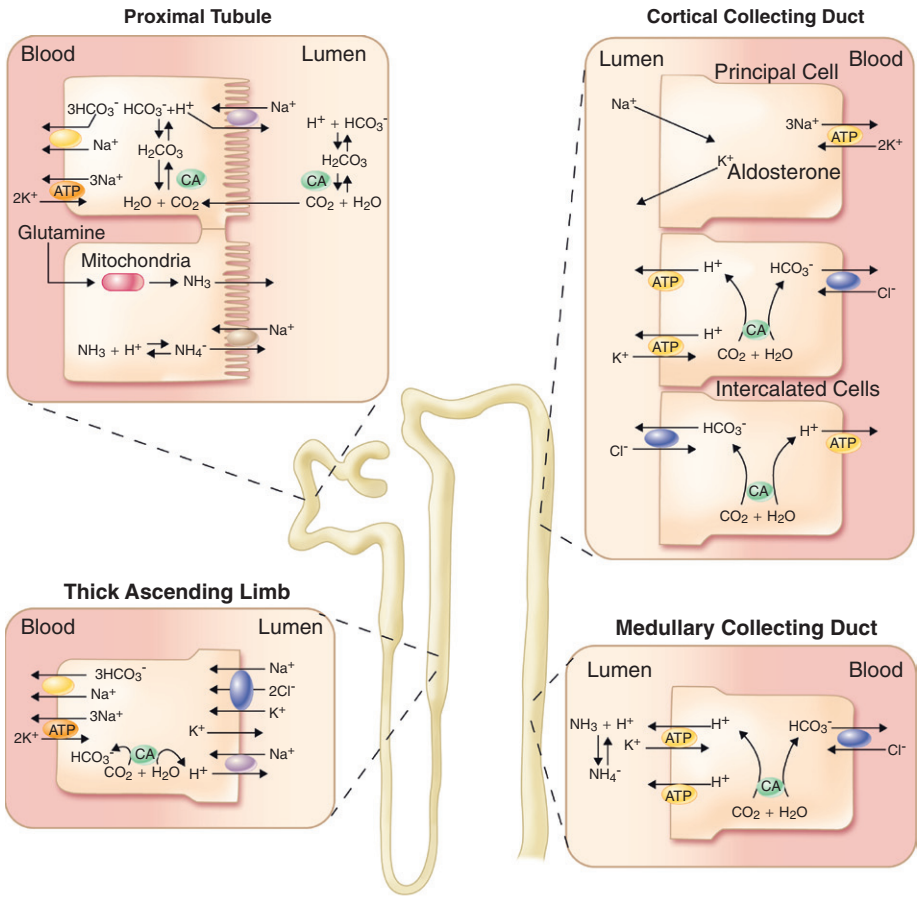

FIGURE 120-1. Renal acidification mechanisms. ATP = adenosine triphosphate; CA = carbonic anhydrase.

surface of neighboring α-intercalated cells, which are acid-secreting cells. The secreted H^+ will combine with the remaining HCO_3^- in the lumen to generate CO_2, with subsequent reabsorptive diffusion of CO_2, re-formation of cellular HCO_3^- with the help of cellular carbonic anhydrase (CA_{II}), and then exchange of HCO_3^- from cell to blood for entry of Cl^- through Cl/HCO_3 exchangers. It is at this distal site that tubular fluid pH starts to fall to levels below pH 6.0.

Some collecting duct cells have reverse polarity and secrete HCO_3^- into the lumen in exchange for Cl^- entry into the cell. In these cells, the H^+-ATPase faces the blood side of the cell (β-intercalated cells). An elevated extracellular HCO_3^- concentration, as seen with an alkaline-ash diet or alkalosis, will increase HCO_3^- secretion by these cells.

The Medullary Collecting Duct

The medullary collecting duct continues to secrete protons into the luminal fluid, where the pH reaches its lowest values of close to 5.0. The mechanism is based on continued function of H^+-ATPases with an additional role of an ATP-dependent K/H exchanger, a member of the family of K^+, H^+-ATPases found in the stomach and colon.

Once the filtered HCO_3^- is fully reabsorbed, the kidney is still required to eliminate an additional net amount of acid equivalent to that produced in metabolism. Most of this net acid excretion is in the form of ammonium (NH_4^+), which is derived from the renal synthesis of ammonia from glutamine in the proximal tubule and the titration of filtered phosphate to acid phosphate (titratable acidity).

$$NH_3 + H^+ \rightarrow NH_4^+ \text{ pK 9.1, and}$$

$$HPO_4^{2-} + H^+ \rightarrow H_2PO_4^- \text{ pK 6.8}$$

Urinary Buffers

As the collecting duct cells continue to secrete H^+ into urine with a diminishing luminal HCO_3^- concentration and decreasing pH, H^+ is captured by the urinary buffers. The resulting alkalinization of the cells after H^+ leaves results in the formation of HCO_3^- ready for transport into blood. This process generates "new" HCO_3^- that is not a result of the reabsorption of filtered HCO_3^-. The amount of new HCO_3^- matches the amount of net acid eliminated and is also equal to each of the following: the amount of acid produced, the amount of body buffer consumed by that acid, and the amount of fixed acid anions, such as sulfate, phosphate, and Cl^-, that accompanied the H^+. The result is maintenance of normal acid-base equilibrium.

The ability of the kidney to lower urinary pH to values as low as 5.0 enables the buffers to capture a proton. Net acid excretion in urine is accomplished not simply by a decrease in urine pH but mostly by titration of these important urinary buffers. For example, a typical daily urine volume of 1 liter at pH 5.0 contains only 10^{-5} molar hydrogen ion, or 0.01 mmol, a trivial amount compared with the amount of produced acid (~1 mmol/kg/day). In chronic kidney disease, it is the failure to produce enough ammonium that leads to a poorly buffered, though acid, urine and an inability to excrete enough net acid to stay in normal balance.

Regulation of Urinary Acid Secretion

Renal mechanisms of urinary acidification are adaptable. Transport processes such as H^+-ATPases, Na/H exchange, and Cl/HCO_3 exchange can increase or decrease their capacity to handle acid-base equivalents, depending on the challenge presented. Renal ammoniagenic mechanisms are also critically regulated to serve the acid-base needs of the individual. Metabolic acidosis and respiratory acidosis increase the capacity to reabsorb HCO_3^-, including increased expression of the transporters involved in acidifying the urine. At the same time, increased glutamine uptake into proximal cells and ammonia production enables increased acid excretion and the generation of new HCO_3^- in the distal nephron. Metabolic alkalosis and respiratory alkalosis have the opposite effects.

Carbonic anhydrase is important in acid-secreting epithelia as well as in other cells, such as red blood cells, in which rapid interconversion of large quantities of CO_2 to HCO_3^- is required. In the proximal tubule, carbonic anhydrase exists not only within cells but also on the luminal brush border membrane, where it accelerates the dehydration of carbonic acid to CO_2, thereby allowing the large amount of HCO_3^- reabsorption in that segment. The distal nephron, which has a smaller requirement for bicarbonate reabsorption, lacks luminal carbonic anhydrase. However, intracellular carbonic anhydrase is present in all cells that transport CO_2 and HCO_3^-.

In acid-secreting cells, bicarbonate exits back to blood across the basolateral membrane as protons exit across the apical membrane. These processes are reversed in bicarbonate-secreting cells. In addition, the mechanisms of proton secretion and bicarbonate reabsorption may vary in different cell types.

Ammoniagenesis, which is a key element in urinary acid excretion, provides the major acceptor for protons. Ammonia is produced predominantly in the proximal tubule cell by mitochondrial glutaminase enzymes. Production is increased by increasing the metabolic acid load in the body, respiratory acidosis, and hypokalemia. NH_4^+ can preserve potassium in the hypokalemic state by serving as a counter-ion for anion excretion. Similarly, in response to metabolic acidosis, the kidney would ideally excrete chloride with ammonium and preserve Na^+ and K^+.

Ammonia can be secreted by nonionic diffusion into the proximal fluid, where it will pick up a proton and form ammonium (NH_4^+), or it could form ammonium within the proximal tubule cell and be secreted by Na/NH_4 exchange, a mode of operation of the Na/H exchanger. Ammonium may be reabsorbed by the thick ascending limb of Henle on the Na/K/2Cl transporter, where it can substitute for K^+. By countercurrent multiplication, NH_4^+ concentrates in the medullary interstitial fluid rather than remaining in the ascending limb fluid as it reaches the highly perfused renal cortex, where it could otherwise dissipate into renal venous blood. The countercurrent mechanism also allows for ammonia to diffuse into the lumen of the medullary collecting duct, where it will be trapped as ammonium in the acid tubular fluid. Collecting duct cells also secrete NH_3 by way of glycoproteins that are in the family of the Rh factor, red blood cell ammonia transporters.

Regulation is accomplished at a number of levels. Hormones such as angiotensin II and catecholamines stimulate Na^+ reabsorption in the proximal tubule by increasing Na/H exchange. Aldosterone increases H^+-ATPase in the distal collecting duct cell and stimulates Na^+ reabsorption, thereby increasing proton secretion. Low extracellular fluid volume increases proximal HCO_3^- reabsorption, as does hypokalemia and high P_{CO_2}. Hyperkalemia (Chapter 119) may limit urinary acidification by several mechanisms, including decreased ammonia synthesis, decreased NH_3 entering the countercurrent multiplier in the loop of Henle, and decreased H^+ secretion by ATPases in the collecting duct as the need to secrete K^+ predominates.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

An acid-base disturbance never should be considered an isolated problem but always should alert the clinician to the possible presence of an important underlying condition. Anion gap acidoses usually represent important underlying metabolic conditions, ranging from sepsis (Chapter 108) to uremia (Chapter 132) to diabetic ketoacidosis (Chapter 236) to serious poisonings (Chapter 110). Specific renal abnormalities as well as diarrhea (Chapter 142) can cause hyperchloremic acidosis (Table 120-1). Metabolic alkaloses are commonly caused by renal abnormalities or the loss of acid from the stomach owing to vomiting or nasogastric suction (Table 120-2). Respiratory acidosis and alkalosis are related to ventilation, which is increased by conditions such as sepsis (Chapter 108) and anxiety and decreased in many pulmonary conditions (Chapter 86).

Assessment of clinical acid-base disturbances usually begins with measurement of arterial blood gases (Fig. 120-2 and Table 120-3). In some situations, venous blood can be used as an alternative, accounting for the fact that the normal venous pH is approximately 0.05 pH units more acid than arterial pH, and P_{CO_2} is 5 to 6 mm Hg higher than that of arterial blood. Venous bicarbonate concentrations are normally greater than arterial concentrations.

If arterial pH is below 7.35, acidemia is said to exist. If pH is greater than 7.45, alkalemia exists. However, several processes may simultaneously drive the pH upward or downward; these individual processes are known as *acidoses* or *alkaloses*. Because multiple processes may coexist, an abnormal pH is not always noted in acid-base disturbances. Because pH is related to the ratio of HCO_3^- to P_{CO_2}, the finding of an abnormal bicarbonate level alone also cannot define acidemia or alkalemia.

It is customary to define acid-base balance in terms of the hydrogen ion concentration, bicarbonate, and P_{CO_2}, where

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

The addition of CO_2, as in respiratory acidosis, will increase the hydrogen and bicarbonate concentrations. Removal of CO_2, as in respiratory alkalosis, will decrease CO_2, protons, and bicarbonate. The addition of protons with an anion other than HCO_3^-, as in metabolic acidosis, will lead to increased

TABLE 120-1 CAUSES OF HYPERCHLOREMIC ACIDOSIS

TYPE	CAUSE
Renal with hypokalemia	Proximal RTA, type 2 Distal RTA, type 1 Some anion gap acidoses with high anion clearance
Renal with hyperkalemia	Type 4 RTA; hyporenin-hypoaldosteronism
Nonrenal with hypokalemia	Diarrhea Urinary diversions: ureteroileostomy, ureterosigmoidostomy
Nonrenal with hyperkalemia	NaCl, KCl, NH_4Cl, $CaCl_2$, Arg-HCl, Lys-HCl

RTA = renal tubular acidosis.

TABLE 120-2 CAUSES OF METABOLIC ALKALOSIS

TYPE	CAUSES
Renal, hypochloremic alkalosis: Cl responsive with urine Cl > 20	Loop and distal tubule diuretics Bartter's syndrome Gitelman's syndrome Posthypercapnic status
Nonrenal, hypochloremic alkalosis: Cl responsive with urine Cl < 20	Vomiting, nasogastric suction Chloridorrhea Villous adenoma
Renal, alkalosis with extracellular expansion: Cl unresponsive with urine Cl > 20	Hyperaldosteronism, primary and secondary Liddle's syndrome
Nonrenal alkalosis, Cl unresponsive	$NaHCO_3$, acetate, citrate, lactate
Other causes of metabolic alkalosis	Excessive non-reabsorbable anion excretion Hypoproteinemia

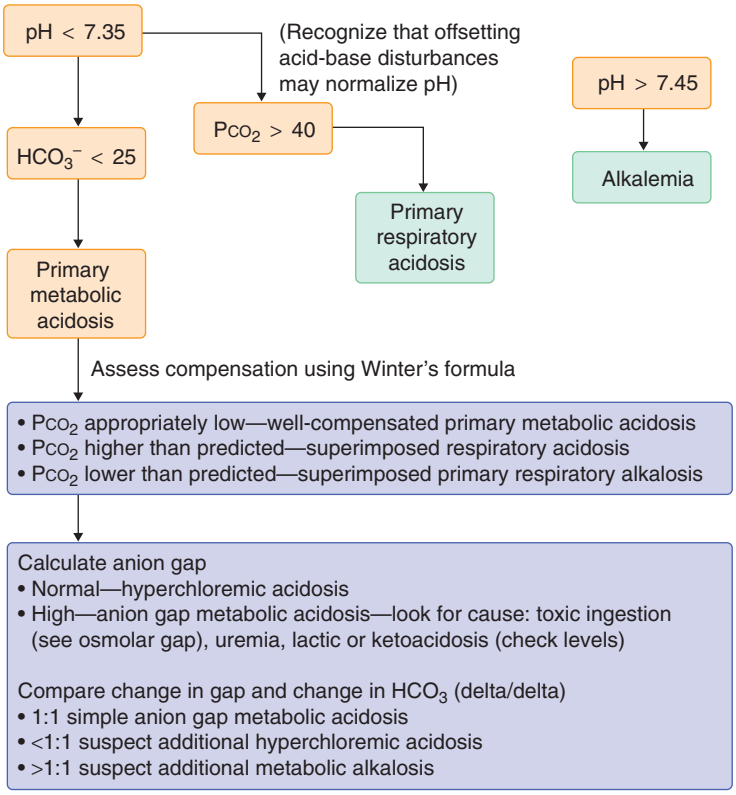

FIGURE 120-2. Evaluation of acidemia.

concentrations of protons and a decreased bicarbonate concentration. This increase in CO_2 can be rapidly removed by the lungs because it constitutes a small additional amount of CO_2 over the usually produced quantities. Removal of HCO_3^- with a cation such as Na^+, also a cause of metabolic acidosis, will increase the proton concentration and lower the HCO_3^- concentration. Metabolic alkalosis might be caused by the addition of $NaHCO_3$ with a resulting decrease in the proton concentration or by removal of H^+ with chloride, thereby leading to a decreased proton concentration and increased HCO_3^-.

TABLE 120-3 LABORATORY STEPS IN IDENTIFYING ACID-BASE DISORDERS

EVALUATE pH	ACIDEMIC	ALKALEMIC
Elevated P_{CO_2}	Respiratory acidosis	Metabolic alkalosis
Elevated HCO_3	Respiratory acidosis	Metabolic alkalosis
Decreased P_{CO_2}	Metabolic acidosis	Respiratory alkalosis
Decreased HCO_3	Metabolic acidosis	Respiratory alkalosis

EVALUATE FOR EXPECTED COMPENSATION

Meets expectation: simple disorder with compensation or could be offsetting metabolic alkalosis and acidosis
Does not meet expectation: complex disorder, but pH indicates whether acidosis or alkalosis is dominant
If a metabolic disorder is dominant, a P_{CO_2} greater than predicted indicates an additional respiratory acidosis. A P_{CO_2} less than predicted indicates an additional respiratory alkalosis.
If a respiratory disorder is dominant, an HCO_3 concentration greater than predicted indicates additional metabolic alkalosis. An HCO_3 concentration less than predicted indicates an additional metabolic acidosis.

ASSESS ANION GAP

Elevated: metabolic acidosis is present whether acidemic or alkalemic. If alkalemic, an additional metabolic or respiratory alkalosis is present.
If the gap is greater than the fall in HCO_3, consider an additional metabolic alkalosis or respiratory acidosis.
If the gap is less than the fall in HCO_3, consider an additional nongap acidosis or respiratory alkalosis.

Compensatory Changes

Few patients have an isolated acid-base disturbance. In nearly all cases, a respiratory or renal compensation (or both) occurs in response to counteract a primary acid-base disturbance.

With normal organ function, the lungs may maintain a normal pH and P_{CO_2} during changes in volatile acid production. The kidneys will also help maintain normal acid-base balance during changes in fixed acid production. Only excesses beyond the capacity to eliminate an acid or alkali load will lead to clinical disturbances. It follows that patients with renal or lung disease may do less well in response to metabolic and respiratory disorders.

When an acid-base disturbance develops, the initial response to modulate its severity depends on the titration of various body buffer pairs. For example, phosphate, hemoglobin, and albumin change their protonated and unprotonated concentrations. The body will then further attempt to correct the extracellular pH toward normal but usually not to normal. For metabolic disturbances caused by increased or decreased nonvolatile acid, the response is respiratory; for primary respiratory acidosis and alkalosis, the compensation is renal (Table 120-4). The direction of change in HCO_3^- and P_{CO_2} is the same when the primary disturbance is compensated; the ratio of HCO_3^- to P_{CO_2} and thus pH becomes more normal. These compensations tend to take time, so acid-base disturbances, particularly the respiratory conditions, are classified as acute (lasting less than 24 to 48 hours) or chronic.

Peripheral blood does not demonstrate complete compensation for most acid-base disturbances, with the occasional exception of chronic respiratory alkalosis. Yet the CNS closely regulates its pH, with nearly full correction within 1 to 2 days. Before this compensation occurs, acute alkalemia may be associated with cerebral vasoconstriction and ischemia, whereas acidemia may result in vasodilation and cerebral edema. Rapid changes in P_{CO_2} affect the CNS chemosensors more quickly than do changes in HCO_3^- because of the more rapid movement of nonionic CO_2 across the blood-brain barrier. Increases in CNS CO_2 lead to acidification of the medullary center interstitial fluid and an increased ventilatory drive. Decreases in CNS CO_2 lead to hypoventilation.

In metabolic acidosis, peripheral chemosensors in the carotid body stimulate the CNS to increase ventilation to reduce P_{CO_2}. The fall in peripheral P_{CO_2} will lead to dissolved CO_2 leaving the CNS ahead of HCO_3^-; the alkalinization of the medullary center interstitial fluid will then slow the hyperventilatory response until a new steady state of hypocapnia is achieved.

TABLE 120-4 EXPECTED DEGREES OF COMPENSATION IN ACID-BASE DISORDERS

DISORDER	EXPECTED COMPENSATION
Metabolic acidosis	Steady state in 12-36 hr Expected P_{CO_2} = 1.5 (measured HCO_3) + 8 ± 2
Metabolic alkalosis	Less predictable Expected P_{CO_2} increases 0.5 mm Hg per 1-mEq/L increase in HCO_3
Respiratory acidosis	
Acute	Expected 1-mEq/L increase in HCO_3 per 10-mm Hg rise in P_{CO_2}
Chronic, 24-36 hr	Expected 3- to 5-mEq/L increase in HCO_3 per 10-mm Hg rise in P_{CO_2}
Respiratory alkalosis	
Acute	Expected 1- to 2-mEq/L fall in HCO_3 per 10-mm Hg fall in P_{CO_2}
Chronic, after 24-36 hr	Expected 5-mEq/L fall in HCO_3 per 10-mm Hg fall in P_{CO_2}

Patients may sense dyspnea or air hunger acutely with rapid and shallow respirations. In severe cases of metabolic acidemia, the respirations are deep and gasping, typical of Kussmaul breathing.

When the bicarbonate concentration increases as a result of metabolic alkalosis, a hypoventilatory response, signaled from the peripheral chemosensors, raises P_{CO_2}. As P_{CO_2} rises, the dissolved CO_2 will enter the cerebrospinal fluid (CSF) and will acidify the medullary respiratory center. The stimulus to breathe will, in part, antagonize the peripheral signal until a steady state of hypoventilation is reached.

The acute stimulus of hypercapnia to increase net renal acid excretion disappears in chronic respiratory acidosis when, at the elevated P_{CO_2}, carbonic acid production and elimination are again equal. However, the hypochloremia, brought about by the compensatory early excretion of NH_4Cl, and elevated serum HCO_3^-, maintained by the high P_{CO_2}, persist.

In respiratory alkalosis, the primary event is a fall in P_{CO_2} because of increased alveolar ventilation. Upon transition from acute to chronic respiratory alkalosis, the compensatory mechanisms that initially helped maintain a more normal systemic pH are no longer required as CO_2 production and elimination become equal. Thus, the initial compensatory decrease in renal acid excretion brought about by increased loss of filtered $NaHCO_3$ ceases, but low serum HCO_3^- and high serum Cl^- concentrations are still maintained.

In identifying whether an acid-base disturbance is simple (a single disturbance with its compensation) or complex (multiple processes simultaneously present), it is useful to compare the expected compensation with the observed parameters of the blood gases (see Table 120-3). For example, if P_{CO_2} is lower than would be predicted in a patient with a simple, compensated metabolic acidosis, an additional respiratory alkalosis must be driving the P_{CO_2} down. If P_{CO_2} is higher than what would be predicted for a low bicarbonate level in a patient with metabolic acidosis, a coexistent respiratory acidosis is present.

METABOLIC ACIDOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

In metabolic acidosis, the primary change is a fall in serum bicarbonate. The compensatory response is to increase ventilation to reduce P_{CO_2}. Worsening acidosis elicits increasing alveolar ventilation.

Primary metabolic acidosis results from an imbalance between net acid production and net acid excretion (NAE) in the form of urinary ammonium and acid phosphate. Consider the following relationship, where U_x represents the urinary concentration and $\dot{V}$ the urinary flow rate:

$$NAE = (U_{NH_4^+}\,\dot{V}) + (U_{phos}\,\dot{V}) - (U_{bicarb}\,\dot{V})$$

In a normal steady-state condition, the rate of excretion of net acid must be equal to the rate of production. The normal production rate depends on diet. If net acid production is normal, metabolic acidosis could occur because of a failure to reabsorb bicarbonate or a failure to elaborate enough urinary buffers, as is the case in renal failure and renal tubular acidosis. An inequality also could develop if net acid production were excessive or if large extrarenal bicarbonate losses were unable to be matched by maximal adaptive increases in net acid excretion. Endogenous sources of acid include ketoacidosis and lactic acidosis, whereas exogenous sources are metabolic products of ingested ethylene glycol or methanol. On occasion, strong inorganic acids may be ingested. When net acid is retained in body fluids, the serum bicarbonate concentration falls. However, maintenance of a constant serum HCO_3^- concentration does not guarantee that there is a new steady state in which net acid production is equal to net acid excretion because body buffers such as carbonate salts of bone may become depleted by relentless acid retention, as in renal failure and distal renal tubular acidosis.

The causes of metabolic acidosis are usually categorized according to the presence of either a normal or an elevated serum anion gap. The serum anion gap is the net charge difference when the sum of chloride and bicarbonate is subtracted from the serum sodium concentration.

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-)$$

The normal anion gap is due to the unmeasured anionic charge associated predominantly with albumin. When acidemia is present, albumin is in a more protonated form, which lowers the normal gap. In alkalemia, the effect of pH is to increase the gap attributed to albumin. Each 1 g/dL of albumin contributes approximately 2.8 mEq/L to the normal anion gap. The anion gap may be low with hypoalbuminemia or with an increase in unmeasured cations, such as immunoglobulin G myeloma paraproteins, calcium, lithium, or magnesium. When the anion gap is increased above the normal value of approximately 10 to 12 mEq/L by a nonchloride acid anion, an anion gap metabolic acidosis exists. The accompanying proton is responsible for lowering the serum bicarbonate concentration. The degree of increase in the anion gap, sometimes referred to as the *gap delta*, may be estimated by the difference between the observed anion gap and a normal value of 10 to 12 mEq/L. A similar calculation for a change in serum HCO_3^- can be made by subtracting the observed HCO_3^- from the normal value of about 25 mEq/L. Comparison of the two values (the *delta-delta*) may help identify more complicated acid-base disorders. If the increase in the anion gap is larger than the decrease in serum HCO_3^-, a process is raising the HCO_3^- level. The patient may have a coexisting metabolic alkalosis or be compensating for chronic respiratory acidosis. If the decreases in serum HCO_3^- are larger than the increases in the anion gap, a sign that another process is lowering the HCO_3^- level, the patient may have an additional hyperchloremic acidosis or respiratory alkalosis.

CLINICAL MANIFESTATIONS

The effects of metabolic acidosis depend on its rapidity of onset and severity. Patients often complain of fatigue and dyspnea, particularly on exertion. Nausea and vomiting are common. On examination, deep respirations, often labored with the use of accessory muscles, may be detected acutely, but hyperventilation may be less notable with long-standing metabolic acidemia. Metabolic acidemia also may be associated with vasodilation, tachycardia, and hypotension (Chapter 106). The negative inotropic effect of acidemia on the heart can exacerbate septic shock (Chapter 108). The stress of either an underlying illness or an increase in adrenergic and corticosteroid activity associated with acidemia may elevate the peripheral white blood cell count and cause hyperglycemia. Other laboratory findings include variable degrees of hyperkalemia, hyperphosphatemia, and hyperuricemia, as well as hypocalcemia as a result of decreased renal synthesis of 1,25-dihydroxyvitamin D.

Anion Gap Metabolic Acidoses

A variety of abnormalities can cause anion gap acidosis (Table 120-5). Other organic anions that may be detectable by special screening include hereditary disorders of methylmalonic aciduria or 5-oxoprolinuria. In patients who ingest acetaminophen and deplete intracellular glutathione, acquired 5-oxoprolinuria anion gap acidosis may occur.

UREMIC ACIDOSIS

The metabolic acidosis of advanced chronic kidney disease (Chapter 132) may be due to tubular leakage of HCO_3^-, but it is often present when inadequate ammonia production is unable to facilitate excretion of the normal metabolic acid load. Many patients with renal failure can acidify their urine, but the lack of buffering capacity diminishes net acid excretion. Many organic and inorganic anions, such as phosphate and sulfates, are retained at glomerular filtration rates of less than 25 mL/minute and constitute an increased anion gap in association with the metabolic acidosis. The magnitude of the gap is usually less than 20 mEq/L.

The systemic acid-base disturbance in renal diseases that particularly target the renal tubules is attributable to the kidney's inability to secrete hydrogen

TABLE 120-5 CAUSES OF INCREASED ANION AND OSMOLAL GAPS

ANION GAP METABOLIC ACIDOSIS	OSMOLAL GAP
Uremia	No
Lactic acidosis	Variable/no
D-Lactic acidosis	No
Diabetic ketoacidosis	No
Starvation ketoacidosis	No
Alcoholic ketoacidosis	If ethanol is present
Ethylene glycol	Yes
Methanol	Yes
Salicylates	No
5-Oxoprolinuria (acetaminophen)	No

and to reabsorb and generate HCO_3^-. It is particularly pronounced in oliguric acute renal failure and is exacerbated by hypercatabolic states such as infection. A significant metabolic acidosis in a patient with chronic kidney disease of unknown cause should raise the possibility of urinary tract obstruction (Chapter 125) or chronic tubulointerstitial diseases (Chapter 124), including amyloidosis (Chapter 194), myeloma (Chapter 193), autoimmune disorders and analgesic nephropathy (Chapter 124).

The presentation and approach to uremia are discussed in Chapters 132 and 133. It is important to treat the metabolic acidosis of chronic kidney disease. Maintaining the serum HCO_3^- concentration above 20 to 22 mEq/L, by administering $NaHCO_3$ at a rate of 1 mEq HCO_3^-/kg/day, will slow the progression of chronic kidney disease, delay end-stage renal failure, and improve nutritional state.■

OVERPRODUCTION OF ENDOGENOUS ACIDS

Lactic Acidosis

EPIDEMIOLOGY AND PATHOBIOLOGY

Lactic acidosis is caused by an imbalance in the rates of lactate production and its clearance, primarily in the liver. Lactic acidosis, which increases the anion gap, is most often due to impaired lactate clearance owing to circulatory failure, hypoxia, and mitochondrial dysfunction that increase anaerobic glycolysis and the rate of conversion of pyruvate to lactate. Other causes are thiamine deficiency (Chapter 221), hypophosphatemia (Chapter 121), isoniazid toxicity (Chapter 110), and hypoglycemic states (Chapter 238). Metformin may cause lactic acidosis, particularly in elderly patients with cardiac, hepatic, or renal dysfunction. Nucleoside antivirals (Chapter 396), including zidovudine, may cause lactic acidosis and abnormal liver function as a result of toxic mitochondrial effects. Abnormal mitochondrial function is also a feature of aspirin overdose (Chapter 36) or toxicity with hypoglycin from ingestion of the unripe akee fruit (Jamaican vomiting sickness).

Lactic acidosis can also be caused by the overproduction of lactate, which may occur with severe exertion and malignancies, particularly with a large tumor burden from lymphoma or widely metastatic cancer. Malignant cells can upregulate glycolytic activity, which may increase their uptake of glucose and decrease their dependence on mitochondrion-derived energy.

Lactate, the final product in the anaerobic pathway of glucose metabolism, is produced from pyruvate by the following reaction catalyzed by lactate dehydrogenase:

$$\text{NADH} + \text{pyruvate} + \text{H}^+ \rightarrow \text{lactate} + \text{NAD}$$

CLINICAL MANIFESTATIONS

Symptoms and signs are related to the underlying cause as well as to the metabolic acidosis itself (see earlier). Sepsis (Chapter 108) is associated with an elevated lactate level because of poor clearance and impaired gluconeogenesis. Lactic acidosis can also result from seizure activity (Chapter 410) when lactate is released from muscle cells that have sustained a period of anaerobic metabolism.

A high reduced nicotinamide adenine dinucleotide (NADH)/NAD ratio will favor lactate formation. Conversion of ethanol to acetaldehyde and conversion of β-hydroxybutyrate to acetoacetate uses NAD and produces NADH. Alcohol metabolism may be associated with excessive β-hydroxybutyrate and lactic acidosis.

DIAGNOSIS

In any patient with an anion gap acidosis, the serum lactate level should be directly measured. Glucose, creatinine, and blood urea nitrogen levels also should be obtained. In cases in which a toxic ingestion is suspected (see Table 120-5), a screen for such toxins in the serum should be performed.

TREATMENT Rx

Treatment of lactic acidosis is aimed at correcting the underlying cause. Tissue perfusion and ventilation should be restored if possible. Sodium bicarbonate therapy should be considered when the arterial pH is below 7.0 or when acidemia has resulted in decreased cardiac inotropy or systemic vasodilation and shock. It is preferable to give $NaHCO_3$ as an isotonic mixture in 5% dextrose and water, rather than as a hypertonic bolus, because the latter carries the risk of pulmonary edema and hypernatremia. The quantity of administered sodium bicarbonate to raise arterial pH to 7.2 should be estimated by multiplying the desired minus observed bicarbonate concentration by the estimated total body water. Full correction should be avoided. Bicarbonate treatment of less severe lactic acidosis is controversial. In a randomized trial of patients with lactic acidosis (pH 6.9 to 7.2 and an average 7.8-mM lactate level) in an intensive care unit, sodium bicarbonate infused at a rate of 2 mEq/kg per 15 minutes did not improve hemodynamics, despite improvement in pH, but adversely lowered ionized serum calcium compared with saline.■

In patients with a metabolic acidosis after seizures (Chapter 410), the lactate is quickly metabolized to HCO_3^- by the liver and kidneys, and the acidosis often resolves within 60 minutes. The administration of HCO_3^- is usually unnecessary and may precipitate an overshoot metabolic alkalosis as the lactate is metabolized, which lowers the seizure threshold.

In patients with intestinal bacterial overgrowth (Chapter 142), a syndrome of disorientation, ataxia, and anion gap metabolic acidosis may develop after a carbohydrate meal because of bacterial production of D-lactate. This isomer of the mammalian L-lactate can be measured only by a specific D-lactate assay. The condition is treated with oral antibiotics and appropriate diet.

PROGNOSIS

Lactic acidosis when severe is associated with a high early mortality. When the pH is less than 7.2, only 17% of patients who are admitted to an intensive care unit are ultimately discharged from the hospital.

Diabetic Ketoacidosis

EPIDEMIOLOGY AND PATHOBIOLOGY

Diabetic ketoacidosis is defined as hyperglycemia with metabolic acidosis resulting from generation of the acid anions β-hydroxybutyrate and acetoacetate in response to insulin deficiency and elevated counter-regulatory hormones such as glucagon. It is most commonly seen in cases of type 1 diabetes mellitus (Chapter 236) but can occasionally be seen in type 2 diabetes mellitus (Chapter 237).

The lack of insulin increases lipolysis in adipose tissue; free fatty acids are transported to the liver, where hepatic mitochondria produce ketone bodies, including acetoacetate, from acetyl coenzyme A. In the presence of high NADH/NAD ratio, the more reduced form of β-hydroxybutyrate is produced.

CLINICAL MANIFESTATIONS

Symptoms include nausea, vomiting, anorexia, polydipsia, and polyuria. Patients often exhibit Kussmaul respirations and volume depletion. Neurologic symptoms include fatigue and lethargy with depression of the sensorium. CSF exhibits a change in acid-base status with treatment of diabetic ketoacidosis. Even without bicarbonate administration, CSF pH falls as a result of the ventilatory response to the correction of acidosis and the sudden rise in P_{CO_2}. However, no correlation between decreased CSF pH and depression of sensorium has been established. Ketoacidosis is also seen in cases of starvation, in which it is generally mild and not associated with hyperglycemia.

Ketoacids in the urine may be accompanied by cations, including sodium and potassium, thereby contributing to volume depletion, potassium depletion, relative chloride retention, and a mixed anion gap and hyperchloremic

acidosis. The "delta HCO_3^-" will exceed the "delta anion gap," especially if the glomerular filtration rate and the filtered load of ketoacids are high. The serum anion gap in general will be greatest when renal failure is present because the additional anions cannot be cleared from extracellular fluid.

DIAGNOSIS

The urinary dipstick nitroprusside test for ketones may underestimate the degree of ketosis because it does not detect β-hydroxybutyrate; in fact, the ketone test may become more positive as treatment helps metabolize β-hydroxybutyrate to acetoacetate. This problem should be addressed by direct measurement of serum β-hydroxybutyrate. Diabetic patients also are more prone to lactic acidosis because an increase in NADH favors the formation of lactate from pyruvate, and pyruvate dehydrogenase is inhibited in the absence of insulin.

TREATMENT Rx

Treatment of diabetic ketoacidosis (Chapter 236) consists of volume repletion, insulin administration with dextrose if necessary to avoid hypoglycemia, and potassium replacement (Chapter 119). Bicarbonate administration should be considered only if ketoacidosis is accompanied by shock or if arterial pH is less than 7.0 or 7.1, and bolus infusion should be avoided. The administration of bicarbonate occasionally results in cerebral edema significant enough to lead to loss of consciousness and even death.

PROGNOSIS

Most patients with diabetic ketoacidosis recover. In the less than 0.5% of patients who present with coma from cerebral edema, the mortality rate ranges from 20% to as high as 90%. The cerebral edema may be exacerbated by bicarbonate administration, which is discouraged in this situation.

Salicylate Intoxication

EPIDEMIOLOGY AND PATHOBIOLOGY

Salicylate intoxication can be caused by accidental overdose, therapeutic overdose, or a suicide attempt (Chapters 36 and 110). Salicylate functions as an uncoupler of oxidative phosphorylation and consequently results in increased oxygen consumption and CO_2 production. However, the increase in alveolar ventilation resulting from stimulation of central chemoreceptors overcomes this increase in CO_2.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common clinical manifestation is a combined anion gap metabolic acidosis and respiratory alkalosis, although the condition also can be manifested as either one or the other only. Children are often seen with metabolic acidosis, whereas adults often have predominant respiratory alkalosis. Hypoglycemia, ketoacidosis, and lactic acidosis may result. Other manifestations of intoxication include hemorrhage, fever, nausea and vomiting, hyperventilation, diaphoresis, tinnitus, and occasionally polyuria followed by oliguria. Severe cases may lead to seizures, respiratory depression, and coma. Noncardiogenic pulmonary edema is sometimes seen in adults.

Respiratory alkalosis is the result of a direct stimulatory effect of salicylate on the medullary respiratory control center. Salicylate intoxication also increases the metabolic rate. Diagnosis is suspected by the clinical presentation and confirmed by the salicylate level (Chapters 36 and 110).

Treatment of salicylate intoxication (Chapter 110) is aimed at correcting the metabolic acidosis and removing salicylate. Bicarbonate as a sodium salt should be administered according to an estimated calculation of the deficit if metabolic acidosis predominates. Salicylates are removed by alkaline diuresis because the less reabsorbable salicylate anion will predominate when the urine pH increases. Urinary alkalinization with acetazolamide is not advised because carbonic anhydrase inhibition may impair CO_2 transport from tissue to blood and potentially worsen acidosis in the respiratory center. In severe intoxication (salicylate concentrations greater than 35 mg/dL) or when renal failure is present, dialysis may be required.

PROGNOSIS

The prognosis of salicylate toxicity is better with early diagnosis and prompt management, in which case most patients do well. Patients who ingest oil of wintergreen (methylsalicylate) may have more severe deterioration because of the highly lipid soluble form of the drug.

Alcoholic Ketoacidosis

EPIDEMIOLOGY AND PATHOBIOLOGY

Alcoholic ketoacidosis occurs in a patient who has been drinking very heavily without eating. The pathophysiology is based on the overproduction of β-hydroxybutyrate and, to a lesser extent, acetoacetate because of an increased production of free fatty acids. Alcohol inhibits the conversion of lactate to glucose in the liver. The oxidation of ethanol increases the ratio of NADH to NAD^+ and favors the production of β-hydroxybutyrate. Damage to mitochondria by alcohol can further elevate the ratio of β-hydroxybutyrate to acetoacetate by preventing reoxidation of NADH to NAD. The oxidative metabolism of ethanol favors the reaction of dehydrogenase enzymes to form β-hydroxybutyrate and lactate (opposing glucose production).

CLINICAL MANIFESTATIONS

Alcoholic ketoacidosis usually follows binge drinking and may be associated with withdrawal symptoms (Chapters 32 and 425) and the associated hyperadrenergic state. Alcoholic ketoacidosis is associated with abdominal pain, vomiting, starvation, and volume depletion. In contrast to diabetic ketoacidosis, coma is rare. Blood glucose levels are generally low or normal, and the insulin level is frequently low, with elevated glucagon and cortisol levels. Some patients have hyperglycemia because of the increased catecholamine response.

DIAGNOSIS

Patients typically have a high osmolal gap initially (defined as the difference between the measured and the calculated serum osmolality).

$$\text{Calculated osmolality} = 2(Na^+) + (\text{Glucose [mg/dL]} \div 18) + (\text{Blood urea nitrogen [mg/dL]} \div 2.8)$$

Blood alcohol levels may be absent or elevated on initial evaluation. A clue to the diagnosis of toxic alcohol ingestion is the simultaneous presence of an anion gap metabolic acidosis and an osmolal gap. This osmolal gap, if secondary to ethanol, should be equal to the ethanol concentration in milligrams per deciliter divided by 4.6. If this calculation does not yield the expected gap based on the ethanol concentration, ingestion of another alcohol such as methanol, isopropanol, or ethylene glycol should be suspected (see Table 120-2).

The serum osmolality should be measured by a freezing point depression technique and compared with the calculated osmolality. If possible, ethanol, ethylene glycol, propylene glycol, and methanol levels should be measured directly; each is associated with a metabolic acidosis. In contrast, isopropanol metabolizes to acetone and causes ketosis without acidosis.

TREATMENT Rx

Treatment of alcoholic metabolic acidosis consists of volume repletion with normal saline in dextrose; the administration of thiamine (50 to 100 mg intravenously) and enough glucose to treat hypoglycemia; and the correction of any hypophosphatemia (Chapter 121), hypokalemia (Chapter 119), and hypomagnesemia (Chapter 121) that may be present. The acid-base disturbance usually resolves after several hours. Both hypophosphatemia and thiamine deficiency, which may not be apparent until 12 to 24 hours after the initiation of treatment in an undernourished patient, are exacerbated by glucose administration.

PROGNOSIS

The prognosis of alcoholic ketoacidosis is usually favorable. The long-term outlook is more closely tied to other complications of continued alcohol abuse.

Ethylene Glycol

Ethylene glycol (Chapter 110) is commonly found in antifreeze and is used as an industrial solvent. It has a sweet taste, and patients occasionally ingest it as a substitute for ethanol. Although ethylene glycol itself is not particularly damaging, its highly toxic metabolites include glyoxylate, glycolate, oxalic acid, and ketoaldehydes. Glycolic acid appears to be primarily responsible for the metabolic acidosis observed in this condition.

Intoxication is characterized by profound CNS symptoms, including seizures and coma, severe metabolic acidosis, and cardiac, pulmonary, and renal

failure. Patients are often dehydrated because of osmotic diuresis from the renal excretion of the alcohol.

An increased anion gap is attributable to ethylene glycol metabolites. A high osmolal gap will also be present because of the uncharged alcohol. However, an osmolal gap may not be present if all of the alcohol has been converted to the toxic anionic forms. Calcium oxalate crystals in the urine may cause intratubular obstruction and acute renal failure. Treatment is aimed at rehydration with saline and correction of acidosis with $NaHCO_3$ based on an estimate of the bicarbonate deficit. When an osmolal gap exists, competitive inhibition of alcohol dehydrogenase should be initiated with fomepizole at a loading dose of 15 to 20 mg/kg intravenously in 100 mL normal saline over 30 minutes to 1 hour, followed by a maintenance dose of 10 mg/kg every 12 hours (Chapter 110). If ethanol is used, a solution of 10% ethanol in 5% dextrose can be given as a loading dose of 0.6 g/kg intravenously followed by a maintenance dose of 150 mg/kg per hour in alcoholic patients, or 65 mg/kg per hour in nonalcoholic patients. The ethanol level should be maintained at a 100 to 200 mg/dL. The goal of therapy is early recognition to prevent metabolism of the uncharged glycol to acidic products. Hemodialysis is required in severe cases. If the diagnosis is made promptly and appropriate therapy is instituted, outcomes are favorable. Renal failure may be reversible.

Methanol

Methanol, wood alcohol, is a component of shellac and windshield wiper fluid and is highly toxic to the CNS after metabolism to formaldehyde and formic acid. Optic papillitis may cause blindness. Treatment consists of competitive inhibitors for alcohol dehydrogenase, including ethanol or fomepizole, in similar amounts as for ethylene glycol poisoning, to reduce the formation of acid anions and the anion gap while maintaining a higher level of methanol in the blood (Chapter 110). Hemodialysis may be necessary to increase elimination.

Early diagnosis and treatment are associated with a favorable outcome, but visual loss may be permanent. Late presentation is associated with a poor prognosis, particularly if the amount consumed exceeds 30 mL. As with ethylene glycol, the simultaneous presence of ethanol on presentation may help slow the metabolism of methanol and improve outcome.

Isopropyl Alcohol

Toxic ingestion of isopropyl alcohol, as in rubbing alcohol, does not cause an increased anion gap or ketoacidosis because the metabolite is acetone, but tests for ketones are positive and a high osmolal gap will be present.

Propylene Glycol

Occasionally, patients in the intensive care unit setting are given high doses of intravenous benzodiazepines, such as lorazepam or diazepam, that contain propylene glycol as a diluents. Other intravenous medications that also contain this diluent include phenobarbital, phenytoin, nitroglycerine, and esmolol. Propylene glycol has also been used as a less toxic substitute for methanol in windshield wiper fluid. A high osmolal gap may develop because of the propylene glycol and lead to a clinical picture of sedation, failure to wean from the respirator, and an increased lactate level. Propylene glycol metabolites include lactate and pyruvate. Treatment, which consists of early recognition and withdrawal of the offending agent, usually results in a favorable prognosis.

Hyperchloremic (Normal Anion Gap) Acidosis

Hyperchloremic metabolic acidoses (see Table 120-1) can be caused by renal or nonrenal mechanisms and can be associated with an elevated, normal, or low serum potassium level.

Hyperchloremic Metabolic Acidosis of Nonrenal Origin Associated with Normal or Increased Potassium

Hyperchloremic metabolic acidoses with a normal or elevated potassium concentration can develop as a result of the addition of chloride salts such as NaCl, KCl, $CaCl_2$, NH_4Cl, arginine and lysine hydrochlorides, or HCl itself. If the quantity of Cl^- introduced exceeds the ability of the kidney to eliminate Cl^- salts in urine, hyperchloremia will develop. Electroneutrality is maintained by a decrease in the serum HCO_3^- concentration, and a hyperchloremic acidosis ensues. Renal production of NH_3 increases in an attempt to improve HCl excretion. Hyperkalemia can occur because the acidemia favors the exit of K^+ from cells. Hyperkalemia also inhibits K^+ secretion in the renal collecting duct.

Hyperchloremic Metabolic Acidosis of Nonrenal Origin Associated with Hypokalemia

Hypokalemic, hyperchloremic acidosis may result from loss of a body fluid that is low in Cl^- relative to Na^+ and K^+ when compared with the ratio of Cl^- to Na^+ in extracellular fluid. For example, stool losses of Na^+, K^+, and HCO_3^- in small bowel diarrhea or organic acid anions of bacterial origin in colonic diarrhea lead to hyperchloremic acidosis (Chapter 142). Pancreatic secretions (Chapter 201) or heavy losses from ileostomy sites may lead to loss of bicarbonate-containing fluids. Secretagogues such as vasoactive intestinal peptide (VIP), which is associated with neoplasms of the pancreas or sympathetic chain (Chapter 201), cause large losses of HCO_3^- in stool, with a resulting hypokalemic, hyperchloremic metabolic acidosis. Concomitant gastric achlorhydria is part of the syndrome known as *watery diarrhea, hypokalemic, hypochlorhydric acidosis*. Urinary diversions, such as ureterosigmoidostomies and ileal loops, may increase chloride absorption in exchange for bicarbonate in the intestinal segment and lead to hyperchloremic acidosis.

RENAL TUBULAR ACIDOSIS TYPES 1 AND 2

Proximal Renal Tubular Acidosis

Renal tubular acidosis causes the cations Na^+ and K^+ to be lost in the urine with HCO_3^- rather than Cl^-, thereby leading to hyperchloremia. Proximal renal tubular acidosis (type 2) is characterized by a decreased threshold for bicarbonate reabsorption. HCO_3^- wasting and concomitant urinary losses of potassium occur until a lower level of serum bicarbonate reduces the filtered HCO_3^- to a level that the renal tubule can completely reabsorb.

Isolated proximal renal tubular acidosis may result from mutations of specific transporters of the proximal tubule, such as the $NaHCO_3$ cotransporter, or from hereditary deficiency of carbonic anhydrase. More commonly, proximal renal tubular acidosis is associated with generalized proximal tubule dysfunction. Causes (Table 120-6) include genetic diseases such as glucose-6-phosphatase deficiency (Chapter 164), cystinosis (Chapter 130), hereditary fructose intolerance (Chapter 212), and Wilson's disease (Chapter 218). Multiple myeloma (Chapter 193) and Sjögren's syndrome (Chapter 276) should be considered in an adult patient. Primary hyperparathyroidism (Chapter 253) results in proximal renal tubular acidosis and hypophosphatemia secondary to inhibition of Na/H exchange and sodium phosphate cotransport in the proximal tubule. Drug toxicity with aminoglycosides, tenofovir, cisplatin, and ifosfamide may cause proximal tubule dysfunction. The syndrome also may be seen after kidney transplantation (Chapter 133).

Distal Renal Tubular Acidosis

In distal renal tubular acidosis (type 1), failure to produce ammonia leads to an inability to excrete net acid, thereby leading to continuous retention of acid in the body. The degree of acidemia is often severe, with pH reaching values as low as 7.2, whereas urine pH usually exceeds 5.3.

Kindreds have been described in which mutations in genes for the distal vacuolar H^+-ATPase cause an autosomal recessive distal renal tubular acidosis with deafness. Mutations resulting in defective Cl/HCO_3 exchange protein (AE1) have been linked to an autosomal dominant form of distal renal tubular acidosis.

Distal renal tubular acidosis (see Table 120-6) is also associated with autoimmune disorders, including systemic lupus erythematosus (Chapter 274) and Sjögren's syndrome (Chapter 276), and genetic diseases, including sickle cell anemia (Chapter 166), Wilson's disease (Chapter 218), Fabry's disease (Chapter 215), cystic kidney diseases (Chapter 129), and hereditary elliptocytosis (Chapter 164). Hypercalciuria and hyperoxaluria may cause distal renal tubular acidosis; nephrocalcinosis may be present. Amyloidosis (Chapter 194) may be manifested as severe acidemia and other tubular dysfunction, including nephrogenic diabetes insipidus. Tubulointerstitial disease of the kidney (Chapter 124), including reflux nephropathy and urinary obstruction, may result in renal tubular acidosis with hypokalemia or hyperkalemia. Drugs such as amphotericin B can cause hypokalemic distal renal tubular acidosis.

HYPERCHLOREMIC METABOLIC ACIDOSIS OF RENAL ORIGIN ASSOCIATED WITH HYPERKALEMIA

Hyperkalemic, hyperchloremic acidosis (type 4) suggests dysfunction of the cortical collecting duct, where acidification of urine and disorders in potassium secretion may occur. Some patients with high blood potassium and hyperchloremic acidosis can lower urinary pH below 5.3, whereas others appear to have defects in both potassium balance and urinary acidification. Hyperkalemia itself may worsen metabolic acidosis by decreasing NH_3 accumulation by countercurrent multiplication in the medullary interstitium.

TABLE 120-6 CAUSES OF RENAL TUBULAR ACIDOSIS*

HYPOKALEMIC DISTAL (TYPE 1) RTA
Hereditary tubule disorders
Vacuolar H^+/ATPase β-subunit gene mutations
Carbonic anhydrase type II deficiency
Cl/HCO_3 exchanger (AE-1) mutations
Genetic causes
Sickle cell
Fabry's disease
Wilson's disease
Elliptocytosis
Paroxysmal nocturnal hemoglobinuria
Medullary cystic kidneys
Autoimmune disorders
Systemic lupus erythematosus
Sjögren's syndrome
Multiple myeloma and amyloidosis
Drugs: amphotericin, cisplatinum, aminoglycosides
Nephrocalcinosis and hypercalcemic disorders
Tubulointerstitial diseases
Acute tubulointerstitial nephritis
Reflux nephropathy
Analgesic nephropathy
PROXIMAL (TYPE 2) RTA
Hereditary tubule disorders
Na HCO_3 cotransport (NBC) mutations
Carbonic anhydrase deficiency
Generalized proximal tubular dysfunction
Hereditary Fanconi's syndrome
Genetic diseases: cystinosis, glycogen storage disease (glucose-6-phosphatase deficiency), Wilson's disease
Hormonal: hyperparathyroidism, vitamin D deficiency
Multiple myeloma, lysozymuria
Sjögren's syndrome
Renal transplantation
Heavy metals: cobalt, mercury, lead
Drugs: ifosfamide, outdated tetracycline, tenofovir, tacrolimus, aminoglycosides
HYPERKALEMIC (TYPE 4) RTA
Renal diseases-aldosterone resistance
Diabetes mellitus
Amyloidosis
Systemic lupus erythematosus
Urinary tract obstruction
Hyporeninism
Autonomic neuropathy (diabetic)
Sickle cell anemia
Primary hypoaldosteronism
Adrenal insufficiency: Addison's disease,
Tubular mutations: pseudohypoaldosteronism
Drugs: K-sparing diuretics, amiloride, triamterene, spironolactone, nonsteroidal anti-inflammatory drugs, lithium, trimethoprim, cyclosporine, tacrolimus, renin inhibitors, angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists

*Type 3 renal tubular acidosis (RTA) is not listed separately because it is an overlap of proximal and distal dysfunction.

Causes include hyporenin-hypoaldosteronism, as seen in diabetic renal disease (Chapter 126); other tubulointerstitial diseases (Chapter 124), usually with some renal impairment; sickle cell anemia (Chapter 166); or the use of drugs such as β-blockers and nonsteroidal anti-inflammatory drugs. Low renin and aldosterone levels can also be found in cases of volume expansion with hypertension. Cyclosporine and tacrolimus may lead to decreased electrical driving forces for K^+ and H^+ secretion. Hyperkalemic acidosis with elevated renin and low aldosterone is found in adrenal insufficiency (Chapter 234), isolated hypoaldosteronism (Chapter 234), and the use of angiotensin-converting enzyme inhibitors, renin inhibitors, and angiotensin II receptor blockers. High renin and aldosterone levels are anticipated when the renal collecting duct cell is insensitive to aldosterone, as in urinary tract obstruction, sickle cell anemia, amyloidosis, and systemic lupus erythematosus. Inhibition of aldosterone action with spironolactone or eplerenone may cause hyperkalemic acidosis, as does ENaC inhibition by amiloride and triamterene.

Pseudohypoaldosteronism type 1 is due to autosomal recessive, inactivating mutations of the Na^+ channel ENaC, whereas autosomal dominant pseudohypoaldosteronism type 1 is due to mutations of the mineralocorticoid receptor. Both cause hypovolemia, metabolic acidosis, and hyperkalemia with secondary increases in renin and aldosterone. In Gordon's syndrome (pseudohypoaldosteronism type 2), increases in Na^+ and Cl^- reabsorption through increased activity of the distal thiazide-sensitive NaCl transporter lead to hypertension, hyperkalemic acidosis, volume expansion, and consequently, low renin and aldosterone. Type 3 renal tubular acidosis is the syndrome of combined proximal and distal renal tubular acidosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The urinary anion gap helps distinguish renal tubular acidosis from extrarenal bicarbonate loss (e.g., from diarrhea). Because the normal renal response to metabolic acidosis is an increase in ammoniagenesis, the urine should contain large amounts of NH_4Cl while the kidney retains sodium and potassium; the urinary anion gap, which is $(Na^+ + K^+) - Cl^-$, should be strongly negative because of the unmeasured NH_4^+.

In renal diseases such as distal renal tubular acidosis, however, the urinary anion gap will be zero or positive because of either the failure of ammoniagenesis or the excretion of sodium plus potassium with bicarbonate. With type 2 (proximal) renal tubular acidosis, patients often have Fanconi's syndrome with glycosuria, phosphaturia, aminoaciduria, and uricosuria. In proximal renal tubular acidosis, the steady-state urine pH is usually less than 5.3, the acidosis is not severe (i.e., HCO_3^- usually not less than 16), and acid excretion may balance acid production at this new steady state.

In contrast to proximal renal tubular acidosis, distal renal tubular acidosis (type I) is generally a more severe metabolic disorder that may be accompanied by hypercalciuria, nephrocalcinosis, calcium phosphate kidney stones (Chapter 128), and bone disease that includes rickets in children and osteomalacia in adults. Although rarely necessary to perform, the NH_4Cl loading test can confirm the diagnosis of distal renal tubular acidosis. In this test, the plasma bicarbonate is lowered by an acid challenge. If urine pH remains above 5.3, a distal abnormality is suspected. Proximal and distal renal tubular acidoses usually can be distinguished by a careful clinical evaluation (Fig. 120-3). Helpful findings include the presence of a urine pH greater than 5.3 in distal but not proximal renal tubular acidosis during acidemia; a fractional excretion of bicarbonate as high as 10 to 15% in proximal renal tubular acidosis; and the lowering of serum potassium upon correction of proximal but not distal tubular acidosis.

In patients with an elevated serum anion gap, unmeasured anions such as ketoacids and lactate, rather than NH_4^+, are present in urine, so a positive urinary anion gap does not indicate renal tubular acidosis. On occasion, however, the prompt renal excretion of organic anions with sodium and potassium may minimize the increase in the serum anion gap. In the metabolic acidosis of glue sniffers, hippurate, which is a product of toluene, is rapidly excreted, thus giving the appearance of a nongap metabolic acidosis with a positive urinary anion gap.

TREATMENT

Rx

If possible, treatment of metabolic acidosis should focus on correcting the underlying cause and permitting the body's homeostatic mechanisms to correct the acid-base disturbance. Patients whose pH is less than 7.2 are typically treated with infusions of sodium bicarbonate, guided by the estimated base deficit in milliequivalents, calculated using the serum HCO_3^- concentration in milliequivalents per liter:

$$\text{Amount of } HCO_3^- = (25 - [HCO_3^-]) \times \text{wt (kg)}/2$$

In general, the correction of metabolic acidemia should be based on a calculated amount, with not more than 50% of the estimate given before recalculation. Moreover, this equation is used for deficit correction only; the ongoing losses of 1 to 2 mEq/kg per day, equivalent to the daily acid load, should be replaced in distal renal tubular acidosis with $NaHCO_3$, $KHCO_3$, or citrate salts in divided doses. Hypokalemia may accompany distal renal tubular acidosis and may improve with treatment.

Proximal renal tubular acidosis in children may affect growth and require large quantities of bicarbonate in excess of 1 to 2 mEq/kg per day to correct the acidosis because ingested alkali is promptly excreted in alkaline urine. In adults, treatment is often deferred because the steady state acidosis allows for a normal acid excretion rate. Hypokalemia may worsen with bicarbonate treatment of proximal tubular acidosis.

In type 4 renal tubular acidosis, treatment of hyperkalemia with a low potassium diet, thiazide, or loop diuretics or sodium polystyrene sulfonate often improves urinary acidification without the use of bicarbonate salts.

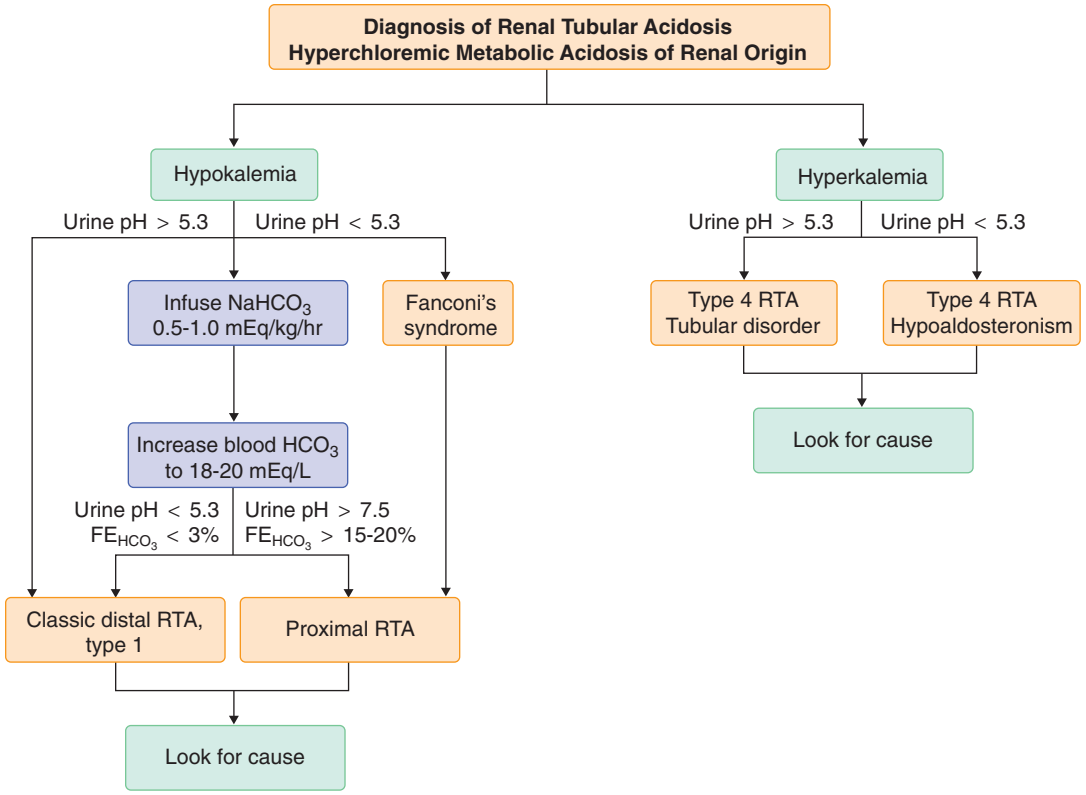

FIGURE 120-3. Diagnosis of renal tubular acidosis (RTA). FE = fractional excretion; $NaHCO_3$ = sodium bicarbonate.

PROGNOSIS

The prognosis of renal tubular acidosis generally depends on the presence of an underlying systemic disease, such as myeloma (Chapter 193). In children, disorders such as medullary cystic kidney disease (Chapter 129) or cystinosis (Chapter 130) usually result in renal failure by the teenage years. These patients are candidates for renal replacement therapy, including transplantation. Chronic metabolic acidosis in children, if not well treated, is associated with rickets (Chapter 252) and short stature.

METABOLIC ALKALOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

In metabolic alkalosis, the primary event is elevation of the plasma bicarbonate concentration. In response to increased systemic pH, alveolar ventilation is decreased to increase P_{CO_2} and thereby decrease pH. However, respiratory compensation is generally less effective in cases of metabolic alkalosis than in cases of metabolic acidosis. Contributing factors may include the fact that hypoventilation also decreases P_{O_2}, which is a potent stimulus for the peripheral chemoreceptors to increase alveolar ventilation when P_{O_2} falls below about 60 mm Hg. A second mechanism that may blunt respiratory compensation is intracellular acidosis in the brain in the setting of hypokalemia. In acute metabolic alkalosis, an initial paradoxical acidotic shift in CSF pH secondary to a sudden increase in P_{CO_2}, similar to the alkaline shift in CSF pH in acute metabolic acidosis, may activate central chemoreceptors and increase ventilatory drive despite peripheral stimulation to decrease alveolar ventilation. In chronic metabolic alkalosis, CSF pH may return to normal, so respiratory drive is controlled entirely by the peripheral chemoreceptors. The result is that the ventilatory response to metabolic alkalosis is highly varied: many patients with metabolic alkalosis maintain nearly normal P_{CO_2} levels, and the level rarely rises above 60 mm Hg.

Metabolic alkalosis requires a generation phase, in which new HCO_3^- is added to the extracellular fluid, and a maintenance phase, in which the new elevated serum HCO_3^- concentration is sustained. Without the latter phase, a kidney with normal filtration and tubular function has a high capacity to excrete HCO_3^-, thereby preventing alkalosis. Maintenance of a high HCO_3^- concentration usually occurs because of volume depletion, a reduced glomerular filtration rate, hypokalemia, or low chloride levels.

Metabolic Alkalosis of Renal Origin Associated with Volume Depletion

Metabolic alkalosis of renal origin may be the result of excessive urinary chloride excretion, most commonly related to diuretics that inhibit reabsorption of Cl^-. The Cl^- loss results in hypochloremia, with a compensatory increase in plasma HCO_3^- to maintain electroneutrality. Extracellular volume depletion stimulates the renin-angiotensin-aldosterone pathway, and high aldosterone levels superimposed on increased distal urinary flow rates results in increased K^+ excretion and hypokalemia. The volume depletion and hypokalemia enhance proximal HCO_3^- reabsorption, thereby maintaining the alkalosis, and the prerenal fall in the glomerular flow rate limits HCO_3^- filtration.

Important but rare genetic syndromes characterized by urinary chloride wasting include Bartter's syndrome and Gitelman's syndrome. Bartter's syndrome is an autosomal recessive salt-losing state associated with extracellular volume depletion and excessive urinary chloride loss that results in hypokalemia and hypochloremic metabolic alkalosis. Secondary increases of plasma renin and aldosterone occur, as does renal juxtaglomerular cell hyperplasia. The syndrome resembles the effects of furosemide on the thick ascending limb of Henle; gene mutations in the Na-K-2Cl cotransporter, K^+ channel, and Cl^- channels have been described. Because calcium reabsorption occurs in the thick ascending limb of Henle, Bartter's syndrome, like furosemide, causes hypercalciuria as well as polyuria.

Gitelman's syndrome is an autosomal recessive cause of extracellular volume depletion, urinary chloride wasting, and hypokalemic metabolic alkalosis. It is due to inactivating mutations in the *SLC12A3* gene encoding the thiazide-sensitive NaCl cotransporter of the renal distal tubule. Urinary concentrating ability is preserved, and patients are hypocalciuric because decreased NaCl reabsorption in the distal tubule is associated with a decrease in calcium excretion. Hypomagnesemia may also be severe.

Metabolic Alkalosis of Nonrenal Origin with Extracellular Volume Depletion

Metabolic alkalosis may develop as a result of gastrointestinal Cl^- loss from vomiting, nasogastric suctioning, or secretory diarrhea. In such cases, extracellular volume is usually contracted, hypochloremia develops, and the urinary chloride level is usually less than 20 mEq/L.

In Zollinger-Ellison syndrome (Chapter 201), excessive gastrin-induced gastric acid secretion may result in an acidic stool with high chloride content. Diarrhea does not cause metabolic alkalosis unless the stool electrolytes $[(Na^+ + K^+) - Cl^-]$ are less than plasma HCO_3^-.

Infectious gastroenteritis, congenital chloridorrhea, and villous adenomas also cause chloride losses in stool. Congenital chloridorrhea is an autosomal recessive disorder of defective colonic, apical Cl/HCO_3 exchange associated with the downregulated adenoma *(DRA)* gene.

With vomiting, the initiating event is loss of HCl. This secretion of HCl into the stomach lumen by the parietal cell is coupled to the absorption of HCO_3^- in exchange for chloride at the basolateral membrane. When gastric acid is normally secreted, a mild increase in serum HCO_3^- spills into urine and causes an "alkaline tide." With vomiting, however, the net loss of HCl generates the alkalosis. Initially, this increased HCO_3^- is filtered by the glomeruli and excreted in urine accompanied by Na^+ and K^+; volume depletion begins to develop. As vomiting continues, extracellular volume depletion worsens, glomerular filtration falls, HCO_3^- filtration is limited, volume depletion increases the renin-angiotensin II–aldosterone system, proximal fluid and HCO_3^- reabsorption increase, distal Na^+ reabsorption increases under the influence of aldosterone, and greater H^+ secretion enhances HCO_3^- reabsorption. These effects reduce renal Na^+ loss but at the expense of maintaining the metabolic alkalosis. Significant K^+ losses, which occur as a result of the bicarbonaturia and hyperaldosteronism, lead to hypokalemia, which is actually due to renal, not gastrointestinal, losses as a consequence of attempts to maintain extracellular volume. The hypokalemia further increases proximal $NaHCO_3$ reabsorption, distal H^+ secretion, and K^+ reabsorption, all at the expense of further reabsorption of HCO_3^-. At the new steady state after vomiting or nasogastric suctioning ceases, the paradoxical aciduria of metabolic alkalosis develops as HCO_3^- reabsorption is complete, and the urine contains low levels of Na^+, K^+, and Cl^-. The patient may be hypovolemic, hypokalemic, and alkalemic, but because Na^+, K^+, and acid-base balance are intrinsically linked, life-threatening volume depletion, K^+ depletion, and alkalemia are usually avoided.

Most nonrenal metabolic alkaloses with volume depletion are due to gastrointestinal losses. However, some patients with cystic fibrosis (Chapter 89) may develop hypochloremic alkalosis as a consequence of excessive sweat chloride content related to the *CFTR* gene mutation.

Metabolic Alkalosis of Renal Origin with Volume Expansion and Hypertension

The renal conditions that cause metabolic alkalosis and volume expansion are due to a proportionately greater increase in Na^+ reabsorption above what is required to maintain a steady state of Na^+ balance, rather than primary loss of the Cl^- anion. As Na^+ is reabsorbed, electroneutrality is maintained by an increase in plasma HCO_3^-. The plasma Na^+ concentration may be increased, and Cl^- balance is normal; Cl^- appears in urine, and hypochloremia is not present. In the kidney, the loss of net acid as NH_4Cl in excess of the acid produced generates a metabolic alkalosis, in which the new bicarbonate generated is due to proton secretion by the distal nephron through H^+-ATPases. The H^+ then combines with NH_3 to form NH_4^+ in urine.

Na^+ is reabsorbed independently of Cl^- in the cortical collecting duct through the aldosterone-sensitive cells containing the ENaC. When Na^+ is reabsorbed by the principal cells of the cortical collecting duct, the tubule lumen becomes electronegative and stimulates both K^+ and H^+ secretion by the electrogenic H^+-ATPases. To the extent that HCO_3^- remains in the lumen, the secreted protons complete HCO_3^- reabsorption. Additional secreted protons combine with NH_3 and phosphates and lead to net acid excretion. Any increase in the distal H^+ secretory mechanism will produce more urinary net acid; more "new" HCO_3^- will be generated and returned to the now expanded extracellular fluid, and metabolic alkalosis will develop. The increased plasma HCO_3^- will be filtered, but in the absence of a stimulus to increase proximal HCO_3^- reabsorption, the HCO_3^- will flow distally to be reabsorbed by the increased H^+ secretion of the collecting duct. At first, the alkalosis is mild, but increased cortical collecting duct Na^+ reabsorption will also lead to increased K^+ secretion and hypokalemia. Hypokalemia increases the capacity for proximal HCO_3^- reabsorption, thereby opposing the effect of volume expansion, so that distal delivery of HCO_3^- decreases. The higher than normal distal H^+ secretion titrates urinary buffers so further "new" HCO_3^- is formed and the alkalosis worsens. Metabolic alkaloses in the hypermineralocorticoid syndromes are sustained by hypokalemia.

Metabolic Alkalosis of Nonrenal Origin Associated with Normal or Expanded Volume

If an alkalotic patient is not hypochloremic, electroneutrality must be maintained either by depletion of an alternative anion or by an excessive concentration of a cation. An example of a metabolic alkalosis associated with depletion of a nonchloride anion is hypoproteinemic alkalosis, with hypoalbuminemia and a small anion gap. Chloride balance is normal and chloride appears in urine.

Alkalosis also may result from the addition of alkali salts of organic anions. The normal response to the ingestion of $NaHCO_3$ is rapid urinary alkalinization because of an unaltered threshold for HCO_3^- reabsorption. However, a marked excess of HCO_3^-, as may be administered in an attempt to alkalinize a patient's urine, expands volume and causes an alkalemia, especially in the presence of volume depletion or low glomerular filtration. Milk-alkali syndrome, usually seen when patients in renal failure ingest milk or calcium antacids, is associated with hypercalcemia, alkalemia, and normal Cl^-.

Other situations in which intake of alkali salts results in metabolic alkalosis include infusion of large quantities of sodium salts of metabolizable organic compounds such as acetate, citrate, lactate, or bicarbonate; hyperalimentation with acetate salts; chronic peritoneal dialysis with acetate or lactate dialysate; or excessive transfusions or plasmapheresis, in which large quantities of citrate, used as an anticoagulant, are delivered.

CLINICAL MANIFESTATIONS

Mild metabolic alkalosis up to a pH of 7.50 *is* usually asymptomatic. When the pH exceeds 7.55, however, the alkalosis itself and the compensatory hypoventilation are frequently associated with metabolic encephalopathy. Symptoms include confusion, obtundation, delirium, and coma. The seizure threshold is lowered; tetany, paresthesias, muscular cramping, and other symptoms of low calcium are seen. In patients with hypocalcemia, these signs may be seen at pH values above 7.45. Other findings include cardiac tachyarrhythmias and hypotension. Lactate production increases as a result of the increased anaerobic glycolysis.

DIAGNOSIS

In diagnosing the cause of metabolic alkalosis, it is important to distinguish whether the condition is chloride responsive or chloride unresponsive. Metabolic alkalosis is generally divided into two categories based on its responsiveness to chloride (see Table 120-2). Chloride-responsive metabolic alkalosis is associated with extracellular fluid and chloride depletion and is seen in cases of gastric fluid loss and diuretic use. A diagnostic clue comes from the serum electrolytes. HCO_3^- is increased with a corresponding fall in serum chloride (hypochloremic alkalosis). Chloride-unresponsive metabolic alkalosis is seen in patients with extracellular fluid expansion in conditions such as primary aldosteronism and hypokalemia. Entry of hydrogen ions into cells can also lead to metabolic alkalosis in patients with hypokalemia.

Vomiting, nasogastric suction, and diarrhea are usually obvious sources of metabolic alkalosis. However, the Zollinger-Ellison syndrome (Chapter 201), villous adenomas (Chapter 199), and VIPomas (Chapter 201) may be more difficult to diagnose unless the index of suspicion is high.

Patients who present with hypokalemic metabolic alkalosis with normal or low blood pressure and have urinary chloride concentrations above 25 mEq/L may be taking diuretics such as furosemide or thiazides surreptitiously; a diuretic screen can document the presence of the drug. If the screen is negative, Bartter's or Gitelman's syndrome (Chapter 130) should be considered. Bartter's syndrome is less common, usually more severe, and presents in young patients. The presence of hypercalciuria favors Bartter's syndrome, whereas hypocalciuria suggests Gitelman's syndrome.

Specific causes of renal alkalosis with volume expansion and hypertension can be classified according to levels of renin and aldosterone. Primary increases in renin with secondary increases in aldosterone can be seen in patients with unilateral renal artery stenosis (Chapter 127), renin-secreting tumors of the kidney (Chapter 67), and malignant hypertension (Chapter 67). Low renin and elevated aldosterone levels are characteristic of primary hyperaldosteronism from adrenal adenoma or hyperplasia (Chapter 235). A high cortisol level with volume expansion is seen in hypercortisolism (Chapter 234) and adrenocorticotropic hormone-secreting tumors (Chapter 186). Inhibition of the intracellular enzyme 11β-hydroxysteroid dehydrogenase, which normally inactivates cortisol to form cortisone in the cortical collecting duct, will also result in low renin levels, low aldosterone levels, and hypokalemic alkalosis. Both genetic mutations (the apparent

mineralocorticoid excess syndrome) and an excess consumption of glycyrrhizic acid found in licorice or anisette are causes of this enzyme block. Another cause of hypertension with hypokalemic alkalosis but with low renin and aldosterone levels is Liddle's syndrome (Chapter 130), in which an activating mutation in the cortical collecting duct Na^+ channel (ENaC) leads to increased Na^+ reabsorption.

Metabolic alkalosis may also develop without volume expansion when a non-reabsorbable anion is presented to the cortical collecting duct lumen. Nitrates, sulfates, and certain antibiotics such as nafcillin, carbenicillin, and ticarcillin may obligate K^+ and H^+ secretion as Na^+ is reabsorbed. Topical administration of silver nitrate to burn victims may result in alkalosis.

TREATMENT

In chloride-responsive patients (see Table 120-2), treatment is directed at increasing urinary excretion of bicarbonate. In patients with mild to moderate alkalosis, liberalizing salt intake and administering potassium chloride is effective in increasing renal HCO_3^- excretion. The K deficit is likely to be at least 100 mEq for every 1 mEq/L decrease in serum potassium. Unless KCl is also replenished, the improvement in filtration and proximal reabsorption will result in severe K^+ wasting as bicarbonaturia develops and aldosterone's effects remain. In addition, complete resolution of alkalosis will not occur until K^+ is normalized. In a patient with renal failure and vomiting, the elevation in HCO_3^- may be more severe because of poor HCO_3^- filtration. In cases of volume expansion and alkalosis, acetazolamide may be administered carefully while monitoring its potential for losing K^+. If this agent fails to work, dilute solutions of HCl (0, 1N HCl) may be cautiously administered. The amount of H^+, in milliequivalents, to be given may be calculated as the product of the desired change in serum HCO_3^- concentration (mEq/L) times the estimated total body water (L). It is likely that the this calculation will overestimate the amount of acid needed for correction, so no more than one third of the amount should be given before recalculating to avoid metabolic acidosis. Full correction of HCO_3^- should not be the goal. In the absence of renal failure, intravenous acetazolamide (250 to 500 mg every 8 hours) may be effective but may greatly increase K^+ losses.

Chloride-unresponsive patients (see Table 120-2) include those with mineralocorticoid excess. In these patients, the metabolic alkalosis can be lessened by potassium replacement or by blocking Na^+ reabsorption with aldosterone antagonists such as spironolactone, starting with 25 mg orally, or amiloride, beginning with 5 mg orally. Indomethacin effectively treats Bartter's syndrome (Chapter 130) by interfering with prostaglandin E_2 to allow greater Na-Cl reabsorption in the thick ascending limb. Gitelman's and Bartter's syndromes are best treated with combinations of KCl, a potassium-sparing diuretic, and magnesium if needed.

RESPIRATORY ACIDOSIS

Respiratory acidosis is characterized by a primary elevation in P_{CO_2} as reflected by reduced arterial pH with variable elevation in the HCO_3^- concentration. It is most frequently caused by a decrease in alveolar ventilation owing to pulmonary disease (Chapter 104), respiratory muscle fatigue (Chapter 99), or abnormalities in ventilatory control (Chapter 86).

CLINICAL MANIFESTATIONS

Clinical findings in respiratory acidosis are related to the degree and duration of the respiratory acidosis and whether hypoxemia is present. A precipitous rise in P_{CO_2} can lead to confusion, anxiety, psychosis, asterixis, seizures, and myoclonic jerks, with progressive depression of the sensorium and coma at an arterial P_{CO_2} greater than 60 mm Hg (CO_2 narcosis). Hypercapnia, which increases cerebral blood flow and volume, can lead to symptoms and signs of elevated intracranial pressure, including headaches and papilledema. Other findings in acute respiratory acidosis include signs of catecholamine release, such as skin flushing, diaphoresis, and increased cardiac contractility and output. Symptoms of chronic hypercapnia include fatigue, lethargy, and confusion, in addition to the findings seen in acute hypercapnia.

The slow time course of many of these diseases allows the kidney to compensate adequately as the disease progresses by increasing its excretion of hydrogen ion as ammonium and generating and reabsorbing bicarbonate to restore systemic pH toward normal values. This compensatory process is not maximal until 3 to 5 days after the onset of respiratory acidosis.

DIAGNOSIS

Disorders that cause a respiratory acidosis include central effects of drugs, stroke, and infection; airway obstruction; primary parenchymal processes such as chronic obstructive pulmonary disease (Chapter 88) and acute respiratory distress syndrome (Chapter 104); disorders of ventilation (Chapter 105); and neuromuscular diseases such as myasthenia gravis (Chapter 430) and muscular dystrophies (Chapter 429). Permissive hypercapnia has been used clinically in patients with acute respiratory distress syndrome to limit pulmonary damage secondary to mechanical ventilation (Chapter 105).

It can be difficult to distinguish the signs of hypercapnia from those of hypoxemia because the two often appear together. If correction of the hypoxemia does not improve the clinical picture, however, it can be surmised that hypercapnia is responsible.

TREATMENT

Treatment of both chronic and acute respiratory acidosis is aimed primarily at correcting the underlying cause and ensuring adequate ventilation. In acute respiratory acidosis, measures to relieve severe hypoxemia and acidemia should be instituted immediately, including intubation and assisted mechanical ventilation (Chapter 105) if necessary.

In patients with chronic respiratory acidosis, however, ventilation may be driven by hypoxemia; oxygen must be carefully titrated because correction of the hypoxemia can worsen the hypercapnia. In patients with compensated chronic respiratory acidosis, rapid and complete correction of hypercapnia can also result in posthypercapnic metabolic alkalosis. Patients recovering from an acute-on-chronic respiratory acidosis should be monitored carefully to correct hypokalemia, hypochloremia, and hypovolemia so that adequate renal excretion of bicarbonate can occur.

Bicarbonate therapy is not indicated for respiratory acidosis unless the pH falls below 7.0 and the patient is about to be intubated. There is a role for bicarbonate therapy in patients with renal failure (Chapter 132), in whom adequate compensatory acid excretion cannot take place.

RESPIRATORY ALKALOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

In respiratory alkalosis, a primary decrease in P_{CO_2} is reflected by increases in arterial pH and variable decreases in plasma bicarbonate concentration. The most common cause is alveolar hyperventilation, not underproduction of CO_2.

Acute hypocapnia results in an initial increase in the pH of both the CSF and the brain's intracellular environment. However, this increase is quickly offset by a decrease in bicarbonate levels. In acute respiratory alkalosis, one of the primary mechanisms of this fall in bicarbonate appears to be the generation of lactate as a result of vasoconstriction, hypoxia, and increased hemoglobin affinity for oxygen. The combination of increased oxygen demand and decreased oxygen delivery may contribute to adverse clinical outcomes in hypocapnic alkalosis.

Cerebral blood flow is significantly decreased by hypocapnia, which is a potent vasoconstrictor. As in respiratory acidosis, the CNS is immediately affected by decreases in systemic P_{CO_2} because of the blood-brain barrier's permeability to CO_2. In addition, as in respiratory acidosis, CSF and intracellular pH show an initial short-lived response that parallels the systemic increase in pH.

Renal compensation for sustained hypocapnia is complete in 36 to 72 hours. The mechanism rests primarily in the kidney's net reduction of hydrogen ion excretion, which it accomplishes largely by decreasing ammonium and titratable acid excretion. The threshold for bicarbonate excretion is also lowered, and bicarbonaturia develops. As a result, systemic bicarbonate levels decrease, and arterial pH returns toward normal values.

CLINICAL MANIFESTATIONS

The clinical manifestations of respiratory alkalosis depend on the degree and duration of the condition but are primarily those of the underlying disorder. Chronic hypocapnia does not appear to be associated with any significant clinical symptoms.

Symptoms of acute hypocapnia are largely attributable to the alkalemia and include dizziness, perioral or extremity paresthesias, confusion, asterixis, hypotension, seizures, and coma. Most symptoms, which are manifested only when the P_{CO_2} falls below 25 or 30 mm Hg, can be related to decreased cerebral blood flow or reduced free calcium because alkalosis increases calcium's protein-bound fraction. Shortness of breath and chest wall pain, which frequently may be seen when patients hyperventilate because of pain or anxiety, do not appear to be related to hypocapnia.

Adaptation to High Altitude

Acute exposure to high altitude (Chapter 94) results in hypoxia-induced hyperventilation. Compensation requires at least several days and is characterized by a gradual further increase in hyperventilation, a steadily decreasing P_{CO_2}, and an increasing P_{O_2}. The effect of the hypoxic stimulus to ventilate is initially modulated by the effects of alkalosis, both peripherally and centrally. However, as HCO_3^- in CSF falls, inhibition of the central stimulus to ventilate decreases. Once a steady state is achieved, the drive to ventilate is determined by the effects of hypoxemia and alkalemia on the peripheral chemoreceptors.

DIAGNOSIS

Alveolar hyperventilation leading to respiratory alkalosis is seen with hypoxemia from pulmonary disease (Chapter 83), heart failure (Chapter 58), high altitudes (Chapter 94), or anemia. Mechanical ventilation (Chapter 105) is also a common cause of respiratory alkalosis.

Another common cause of respiratory alkalosis is primary stimulation of the central chemoreceptor, as seen in sepsis (Chapter 108), hepatic cirrhosis (Chapter 156), salicylate intoxication (Chapters 36 and 110), correction of metabolic acidosis, hyperthermia (Chapter 109), and pregnancy, as well as cortical hyperventilation from anxiety and pain. In these situations, central signals override peripheral chemoreceptors until the primary stimulus is removed.

Primary neurologic diseases that can stimulate alveolar hyperventilation include acute stroke, infection, trauma, and tumors. Two patterns of respiration are seen: central hyperventilation and Cheyne-Stokes respiration (Chapter 86). Central hyperventilation, which is associated with lesions at the pontine-midbrain level, is regular, but with an increased rate and tidal volume. Cheyne-Stokes breathing, which is characterized by periods of hyperventilation alternating with apnea, is seen in patients with bilateral cortical and upper pontine lesions and in patients with heart failure.

TREATMENT

Rx

Treatment of respiratory alkalosis must address the underlying cause of the disturbance. Hyperventilation syndrome is a diagnosis of exclusion, but patients who exhibit symptoms, such as tetany and syncope, and who do not have more serious causes of hyperventilation can be treated with a rebreathing mask. Hypophosphatemia can be seen in these patients, but it usually improves with treatment of the alkalosis. Patients with respiratory alkalosis associated with mountain sickness can be pretreated with acetazolamide to induce a metabolic acidosis, thereby preventing extreme elevations in pH (Chapter 94).

DISORDERS OF MAGNESIUM AND PHOSPHORUS

ALAN S. L. YU

MAGNESIUM METABOLISM

Magnesium is an important mineral component of the bony skeleton, a cofactor for many metabolic enzymes, and a regulator of ion channels and transporters in excitable tissues.

Normal Magnesium Metabolism

The majority of total body magnesium is intracellular or in bone, with only 1% in extracellular fluid. The normal serum magnesium concentration is 1.8 to 2.3 mg/dL (1.5 to 1.9 mEq/L). The average daily intake of magnesium is 300 mg, the main sources of which are green vegetables, nuts, whole grain cereals, milk, and seafood. Magnesium is absorbed mainly in the jejunum and ileum. In the kidney, 70 to 80% of serum magnesium is filtered at the glomerulus, with the majority being reabsorbed along the length of the tubule, particularly in the thick ascending limb of Henle. In states of magnesium deficiency or excess, renal tubule reabsorption is tightly regulated so that magnesium excretion is adjusted accordingly.

Magnesium Deficiency

PATHOBIOLOGY

Magnesium deficiency is usually detected when hypomagnesemia becomes evident. However, because magnesium is stored primarily intracellularly, substantial depletion of total body magnesium can occur before serum magnesium levels drop appreciably.

Magnesium deficiency may be due to nutritional deficiency, intestinal malabsorption, redistribution into bone, or losses via cutaneous, lower gastrointestinal, or renal routes (Table 121-1). The recommended daily allowance of magnesium is 420 mg for males and 320 mg for females. Approximately 25% of alcoholics are chronically hypomagnesemic because of a combination of poor nutritional intake and increased renal loss. Magnesium deficiency can rarely occur in protein-calorie malnutrition and may be associated with acute hypomagnesemia during refeeding because of rapid cellular magnesium

*Common causes.

uptake. Fat malabsorption in conditions such as celiac disease, Crohn's disease, and small intestinal resection causes magnesium deficiency because free fatty acids accumulate in the intestinal lumen, where they combine with magnesium to form insoluble soaps. Proton pump inhibitors can also cause hypomagnesemia, which is thought to be due to inhibition of intestinal absorption. Lower gastrointestinal secretions are rich in magnesium, so diarrhea of colonic origin is a common cause of hypomagnesemia. Sweat contains significant amounts of magnesium, and transient hypomagnesemia can occur after prolonged, intense exercise such as marathon runs. Magnesium is also lost from burned skin surfaces, and 40% of patients with severe burns (Chapter 112) are hypomagnesemic.

In patients with severe hyperparathyroidism (Chapter 253) and high bone turnover, continued sequestration of minerals within bone may continue for several days after parathyroidectomy and cause transient hypocalcemia, hypomagnesemia, and hypophosphatemia. Renal magnesium losses can occur in any polyuric state, including the recovery phase of acute tubular necrosis or urinary tract obstruction. Hypomagnesemia is common in diabetes mellitus (Chapters 236 and 237), where it is thought to be due to a combination of poor intestinal absorption owing to autonomic neuropathy, osmotic diuresis, and decreased renal tubule reabsorption. Failure of sodium reabsorption in the thick ascending limb of Henle as a result of the use of loop diuretics and in the distal convoluted tubule as a result of thiazide diuretics inhibits tubular magnesium reabsorption and leads to urinary magnesium wasting. Drugs that are tubular toxins are also common causes of renal magnesium wasting. Such drugs include cisplatin, amphotericin B, and aminoglycosides, which are commonly associated with hypokalemia and rarely with renal tubule acidosis, as well as calcineurin inhibitors such as cyclosporine and tacrolimus, which also cause hyperkalemia. Antibodies to the epidermal growth factor receptor, such as cetuximab and panitumumab, which are used to treat metastatic colorectal cancer, downregulate a distal tubule magnesium channel and are an increasing cause of isolated severe hypomagnesemia.

Inherited hypomagnesemia is usually caused by renal magnesium loss and can be subdivided into three main types, depending on the coexistence of other electrolyte disturbances: Bartter's and Gitelman's syndromes, which are associated with renal salt wasting and hypokalemic metabolic alkalosis; familial hypomagnesemia with hypercalciuria and nephrocalcinosis; and isolated hypomagnesemia, which is usually associated with hypocalcemia.

CLINICAL MANIFESTATIONS

Mild to moderate hypomagnesemia or magnesium deficiency is frequently asymptomatic. Manifestations of increased neuronal excitability are the most common symptoms, including paresthesias, tetany, and seizures. These may be associated with Chvostek's sign (twitching of the cheek muscles in response to tapping the facial nerve in front of the ear) or Trousseau's sign (carpal spasm induced by compressing the upper arm with a tourniquet or blood pressure cuff). Cardiac disturbances may also occur and range in severity from mild electrocardiographic abnormalities (nonspecific T wave changes, U waves, prolonged QT interval, and repolarization alternans) to ventricular tachycardia, torsades de pointes, and ventricular fibrillation (Chapter 65).

Coexistent hypokalemia is very common, for two reasons: many of the causes of hypomagnesemia are also causes of potassium loss, and hypomagnesemia itself causes renal potassium wasting. Severe hypomagnesemia also impairs parathyroid hormone secretion and induces tissue resistance to its actions, thereby leading to hypocalcemia.

DIAGNOSIS

The cause of the magnesium deficiency is often obvious from the history. In difficult diagnostic cases, 24-hour urinary magnesium excretion should be measured. With extrarenal magnesium loss (usually malabsorption or laxative abuse), urinary magnesium excretion is appropriately suppressed (<25 mg/day). Higher urinary magnesium levels indicate renal magnesium wasting, often secondary to surreptitious diuretic use or one of the familial magnesium-wasting disorders.

TREATMENT Rx

It is unclear whether mild, asymptomatic hypomagnesemia needs to be treated. Magnesium repletion is recommended in hypomagnesemic patients if they are symptomatic, have underlying cardiac or seizure disorders, exhibit concurrent severe hypocalcemia or hypokalemia, or have severe hypomagnesemia (<1.4 mg/dL). In mild cases or in the outpatient setting, oral magnesium salts such as magnesium oxide (250 to 500 mg four times daily) can be used for repletion, but these substances frequently cause diarrhea, particularly at high doses. In the inpatient setting, intravenous magnesium sulfate (1 to 2 g every 6 hours) can be used for repletion. Because the redistribution of magnesium from extracellular to intracellular compartments is relatively slow, the serum magnesium concentration may normalize before total body magnesium stores are replete. It is therefore prudent to continue intravenous magnesium for an additional 1 to 2 days after restoration of normomagnesemia. In patients with normal renal function, any excess magnesium is simply excreted renally. Adverse effects from intravenous magnesium administration are primarily due to transient hypermagnesemia and include flushing, hypotension, and flaccid paralysis. Amiloride (10 to 20 mg orally once daily) abrogates renal magnesium wasting in some patients with this problem, but the mechanism is unknown.

PROGNOSIS

In patients with a self-limited cause of magnesium deficiency, repletion is easily accomplished. However, in patients with persistent magnesium wasting, such as in Gitelman's syndrome (Chapter 119), it can be difficult to keep up with the ongoing losses with oral therapy. Fortunately, these individuals tend to adapt to their chronic hypomagnesemia and tolerate it fairly well.

Hypermagnesemia

Transient hypermagnesemia can occur in patients given large doses of intravenous magnesium, for example, in the setting of preeclampsia. It has also been reported in individuals taking large doses of magnesium-containing antacids or cathartics, particularly in settings in which intestinal absorption is enhanced, such as inflammatory bowel disease and intestinal obstruction. However, the kidney has a very large capacity to excrete excess magnesium. Thus, persistent hypermagnesemia is seen almost exclusively in patients who have chronic renal insufficiency (Chapter 132) who are also taking excessive amounts of magnesium in the form of antacids, cathartics, or enemas.

CLINICAL MANIFESTATIONS

Magnesium toxicity is a serious and potentially fatal condition. Mild hypermagnesemia (serum magnesium level >4 to 6 mg/dL) causes hypotension, nausea, vomiting, facial flushing, urinary retention, and ileus. Above serum levels of 8 to 12 mg/dL, flaccid skeletal muscle paralysis and hyporeflexia may ensue, along with bradyarrhythmias, respiratory depression, coma, and cardiac arrest. A low or even negative serum anion gap is sometimes seen.

TREATMENT Rx

Mild hypermagnesemia in a patient with good renal function usually requires no treatment because renal clearance is rapid and the normal serum half-life of magnesium is about 1 day. In the event of serious toxicity, the effects of magnesium can be temporarily antagonized by the administration of intravenous calcium salts (5 to 10 mL of 10% calcium chloride). Renal magnesium excretion can be enhanced by administering furosemide (20 to 40 mg every 4 hours) together with a saline infusion (0.9% NaCl at 150 mL/hour, titrated to replace urinary losses). In patients with advanced renal insufficiency, the most effective method of magnesium removal is hemodialysis.

PROGNOSIS

Severe hypermagnesemia is potentially fatal. Lesser degrees of hypermagnesemia usually respond well to treatment.

PHOSPHORUS METABOLISM

Phosphorus has many critical roles. It is a major component of bone mineral, of phospholipids in cell membranes, and of nucleic acids. It forms high-energy phosphate bonds in compounds such as adenosine triphosphate (ATP), is post-translationally bound to proteins as an intracellular signal, and acts as a major pH buffer in serum and urine.

Normal Phosphorus Metabolism

Of the total body phosphorus content, 85% is in bone, 14% is in intracellular compartments, and only 1% is in extracellular fluid. The normal concentration of phosphorus in plasma is 3 to 4.5 mg/dL (1 to 1.5 mM). Daily intake of phosphorus is 800 to 1500 mg. Phosphorus is present in many foods, including dairy products, meats, and grains, and it is absorbed in the small

intestine. The kidneys excrete excess phosphorus, which is the principal mechanism by which the body regulates extracellular phosphate balance. Ninety percent of serum phosphate is filtered at the glomerulus, of which 80 to 97% is reabsorbed along the nephron, primarily in the proximal tubule. Parathyroid hormone increases renal phosphate excretion by inhibiting the sodium-phosphate cotransporter in the proximal tubule, whereas vitamin D enhances intestinal phosphate absorption.

Hypophosphatemia

PATHOBIOLOGY

Hypophosphatemia may be caused by decreased intake, impaired intestinal absorption, redistribution into cells or bone, and renal losses (Table 121-2). Phosphate is frequently depleted in alcoholism (Chapter 32) because of the intake of a carbohydrate-rich, phosphate-poor diet, as well as renal phosphate wasting. Divalent cation-containing antacids bind phosphate in the intestinal lumen to form insoluble salts, thereby preventing their absorption. Vitamin D deficiency also leads to decreased intestinal phosphate absorption and hence to hypophosphatemia. Respiratory but not metabolic alkalosis (Chapter 120) may cause transient hypophosphatemia. In this disorder, intracellular pH is increased, thereby stimulating glycolysis, which depletes the intracellular inorganic phosphate pool and leads to a shift of phosphate into cells.

Insulin is also a strong stimulus for shifting phosphate into cells. Patients with diabetic ketoacidosis (Chapter 120) are often hyperphosphatemic because of a shift of phosphate out of cells under insulinopenic conditions, but their total body phosphate is actually depleted as a result of urinary losses. Subsequent treatment with insulin may uncover severe hypophosphatemia. Similarly, in malnourished patients (Chapter 222), whose total body phosphate stores may be depleted, overzealous intravenous refeeding with carbohydrate-rich fluids may stimulate insulin release and cause acute hypophosphatemia. The tyrosine kinase inhibitors imatinib and sorafenib, which are used in the treatment of various cancers (Chapter 190), can cause profound hypophosphatemia, which appears to be due to inhibition of bone resorption.

Renal phosphate wasting is usually due to impaired proximal tubule phosphate reabsorption. In primary hyperparathyroidism (Chapter 253), hypercalcemia is typically associated with hypophosphatemia. Fanconi's syndrome is a generalized proximal tubule disorder characterized by hypophosphatemia in association with glycosuria, aminoaciduria, hypokalemia, and type II renal tubular acidosis; it can be caused by a variety of inherited metabolic disorders, multiple myeloma (Chapter 193), heavy metal intoxication (Chapter 21), and drugs such as ifosfamide, cidofovir, and tenofovir. Phosphaturia can also occur with diuretics, particularly carbonic anhydrase inhibitors, and with antimicrobial agents such as pentamidine and foscarnet.

Oncogenic osteomalacia is a paraneoplastic syndrome (Chapter 187) associated primarily with mesenchymal tumors that secrete a variety of phosphaturic factors collectively known as phosphatonins. A similar phenotype is found in X-linked and autosomal dominant hypophosphatemic rickets; these inherited disorders are characterized by an increase in a circulating phosphatonin called fibroblast growth factor-23. Phosphatonins inhibit both renal tubular phosphate reabsorption and 1α-hydroxylation of 25-hydroxycholecalciferol, thereby leading to hypophosphatemia, rickets or osteomalacia (Chapter 252), and inappropriately low serum levels of 1,25-dihydroxycholecalciferol.

*Common causes.

CLINICAL MANIFESTATIONS

Clinical complications, which are usually observed only with severe hypophosphatemia (<1 mg/dL), are thought to be due to the disruption of cell membrane composition, depletion of ATP (which particularly affects high energy-consuming tissues such as skeletal and cardiac muscle), and depletion of 2,3-diphosphoglycerate in erythrocytes, with impaired tissue oxygen delivery. Manifestations of severe hypophosphatemia include encephalopathy, dilated cardiomyopathy, generalized muscle weakness that can lead to respiratory failure, rhabdomyolysis, and hemolysis. Hypophosphatemia also impairs renal ammoniagenesis and reduces the availability of urinary buffer, thereby impairing renal acid excretion and causing metabolic acidosis. Chronic hypophosphatemia leads to resorption of bone and osteomalacia.

DIAGNOSIS

The cause of hypophosphatemia is often evident from the history and physical examination. If not, measurement of either 24-hour urinary phosphate excretion or fractional excretion of phosphate (F_EPO_4) in a spot urine sample is often helpful.

$$F_EPO_4 = \frac{\text{Urine phosphate} \times \text{Serum creatinine}}{\text{Serum phosphate} \times \text{Urine creatinine}}$$

In the setting of hypophosphatemia, the normal response of the kidney is to reduce urinary phosphate excretion to less than 100 mg/day or to reduce F_EPO_4 to less than 5%. Higher values suggest one of the causes of renal phosphate wasting.

TREATMENT

Rx

Patients with asymptomatic mild to moderate hypophosphatemia, normal total body phosphorus stores, and minimal ongoing phosphorus losses (e.g., a patient with hypophosphatemia as a result of acute respiratory alkalosis) do not require treatment. Phosphate should be repleted in patients who are symptomatic, are suspected of having severely depleted intracellular phosphorus stores (malnourished or alcoholic patients), have ongoing gastrointestinal or renal losses, or have severe hypophosphatemia (<1 mg/dL). Oral repletion can be accomplished with sodium or potassium phosphate salts (1 to 2 g/day) or with skimmed milk. Intravenous phosphorus repletion at a dose of 0.16 to 0.64 mmol/kg over 4 to 8 hours is recommended for severe hypophosphatemia but is contraindicated in patients with renal insufficiency or hypercalemia. Complications of phosphate therapy include hypocalcemia, metastatic calcification, hypotension, acute renal failure, and arrhythmias, as well as concomitant hypernatremia or hyperkalemia, depending on which salt is administered.

PROGNOSIS

Most patients with hypophosphatemia respond well to treatment.

Hyperphosphatemia

PATHOBIOLOGY

Pseudohyperphosphatemia may occur in blood specimens that are hemolyzed or hyperglobulinemic, such as in multiple myeloma (Chapter 193). True hyperphosphatemia is caused by excessive phosphate intake, increased intestinal absorption, redistribution from intracellular stores, or impaired renal excretion (Table 121-3). Overzealous phosphate repletion can obviously cause hyperphosphatemia. The phosphorus in some laxatives and enemas may be absorbed and cause hyperphosphatemia. Intoxication with vitamin D or its analogues increases intestinal absorption of both calcium and phosphorus. Conditions associated with massive cell lysis, such as rhabdomyolysis (Chapter 115) and tumor lysis syndrome (Chapter 182), cause the release of intracellular phosphate into the extracellular fluid. Patients with diabetic ketoacidosis (Chapters 236 and 237) are often hyperphosphatemic at initial evaluation because of the redistribution of phosphate out of cells in the insulin-deficient state. Decreased phosphate excretion is most commonly

TABLE 121-4 MEDICATIONS FOR HYPERPHOSPHATEMIA

MEDICATION	USUAL DOSE WITH EACH MEAL	COMMENTS
CALCIUM SALTS		
Calcium acetate	1334 mg	Calcium level will increase about 0.5 mg/dL
Calcium carbonate	500-1000 mg	Calcium level will increase about 0.5 mg/dL
MAGNESIUM SALTS		
Magnesium hydroxide	311-622 mg	Can cause diarrhea or hypermagnesemia
Magnesium carbonate	63-126 mg	Can cause diarrhea or hypermagnesemia
ALUMINUM SALTS		
Aluminum hydroxide	300-600 mg	Encephalopathy and osteomalacia with prolonged use
OTHERS		
Sevelamer hydrochloride	800-1600 mg	Gastrointestinal side effects
Sevelamer carbonate	800-1600 mg	Gastrointestinal side effects
Lanthanum carbonate	250-500 mg	Monitor serum bicarbonate and chloride levels as well as folic acid and vitamin D, E, and K levels

due to acute or chronic renal failure (Chapter 132). With a normal diet, serum phosphate levels can be maintained within the normal range until the glomerular filtration rate falls below 25 mL/minute. However, even mild degrees of renal insufficiency may predispose to hyperphosphatemia if there is a concurrent excessive intake of phosphate-containing compounds such as laxatives. Finally, because parathyroid hormone stimulates proximal tubule phosphate excretion, primary hypoparathyroidism (Chapter 253) is often associated with mild hyperphosphatemia together with hypocalcemia.

CLINICAL MANIFESTATIONS

Acute hyperphosphatemia increases the risk of precipitation of calcium phosphate and subsequent metastatic calcification in soft tissues, including the kidney, where it can cause acute renal failure. The resultant hypocalcemia (Chapter 253) can cause tetany, hypotension, seizures, and cardiac arrhythmias. In the chronic hyperphosphatemia of chronic renal insufficiency, patients with a serum phosphate concentration greater than 6.5 mg/dL have higher mortality. Hyperphosphatemia in this setting is a risk factor for coronary and other vascular calcification, which is associated with increased mortality.

TREATMENT

Rx

Acute hyperphosphatemia in an asymptomatic patient with normal renal function often resolves spontaneously as excess phosphate is excreted. In symptomatic patients and those with impaired renal function, phosphate should be removed by extracorporeal therapy. Because of the slow rate of phosphate mobilization from intracellular stores, continuous venovenous hemodiafiltration is considerably more effective than intermittent hemodialysis. Chronic hyperphosphatemia (Chapter 132) can be managed by minimizing dietary phosphorus intake and administering oral phosphate binders such as calcium salts (e.g., calcium acetate 1334 mg with each meal), lanthanum carbonate (500 mg with each meal), or sevelamer (800 to 1600 mg with each meal) (Table 121-4). Aluminum hydroxide (300 to 600 mg with meals) is also a very effective phosphate binder, but prolonged use leads to aluminum accumulation and results in encephalopathy and osteomalacia. Cinacalcet (30 to 180 mg/day), a calcimimetic used in patients with chronic renal insufficiency to treat secondary hyperparathyroidism, also reduces the serum phosphate concentration and calcium-phosphate product.

PROGNOSIS

Severe acute hyperphosphatemia can be life-threatening owing to metastatic calcification and multiorgan failure, but it generally responds well to prompt therapy. Chronic hyperphosphatemia in patients with chronic kidney failure (Chapter 132) is often fairly resistant to treatment, particularly in poorly compliant individuals, and is associated with increased long-term mortality.

122 ACUTE KIDNEY INJURY

BRUCE A. MOLITORIS

DEFINITION

Acute kidney injury (AKI) describes the clinical syndrome formerly called acute renal failure (ARF). This nomenclature defines AKI as a functional or structural abnormality of the kidney that manifests within 48 hours, as determined by blood, urine or tissue tests or by imaging studies. Diagnostically, the reduction in kidney function in AKI is associated with either an absolute increase in serum creatinine of 0.3 mg/dL or a percentage increase in serum creatinine of 50%. In addition, a reduction in urine output with oliguria (<0.5 mL/kg/hour) for more than 6 hours also fulfills the diagnostic criteria for AKI.

EPIDEMIOLOGY

Most episodes of AKI occur in the hospital, with an incidence ranging from 5 to 7% among all hospitalized patients and 15 to 40% among patients in intensive care units (ICUs). By contrast, the incidence of community-acquired AKI is no more than 1%.

Both conceptually and diagnostically, the various causes of AKI are divided broadly into three anatomic categories: prerenal, intrarenal or intrinsic, and postrenal (Fig. 122-1). Each of the categories represents a unique pathophysiologic process with distinctive diagnostic parameters and prognosis.

Prerenal Azotemia

Prerenal azotemia, which is the most common cause of AKI, accounts for approximately 60 to 70% of community-acquired and 40% of hospital-acquired cases. Decreased renal perfusion is seen in disease states that reduce intravascular volume, such as sepsis (Chapter 108), heart failure (Chapter 58), or liver failure (Chapter 157). Additionally, medications that reduce glomerular capillary perfusion, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin-receptor blockers (ARBs), and nonsteroidal anti-inflammatory drugs (NSAIDs), can also cause prerenal AKI.

Intrinsic Acute Kidney Injury

Intrarenal AKI is often the result of untreated or untreatable prerenal azotemia that leads to ischemic AKI. The diverse causes of intrinsic AKI can involve any portion of the renal vasculature, nephron, or interstitium (Fig. 122-2). Ischemic and septic injury are major causes. Renal toxins also can damage tubules both directly and indirectly (Table 122-1). Fortunately, AKI does not develop in every patient exposed to these agents, but elderly patients with diabetes mellitus, hypotensive patients, and patients with a reduced effective arterial volume (heart failure, burns, cirrhosis, hypoalbuminemia) are the most susceptible to toxic renal injury. In fact, the incidence of aminoglycoside antibiotic nephrotoxicity increases from 3 to 5% to 30 to 50% in these high-risk patients.

AKI secondary to injury to the renal interstitium is termed *acute interstitial nephritis*. Commonly implicated medications for interstitial nephritis include penicillins, cephalosporins, sulfonamides, and NSAIDs (Table 122-2) (Chapter 124). Bacterial and viral infections can be the causative agents. Interstitial nephritis is also associated with a kidney-confined or systemic autoimmune process, such as systemic lupus erythematosus (Chapter 274), Sjögren's syndrome (Chapter 276), cryoglobulinemia (Chapter 193), and primary biliary cirrhosis (Chapter 156).

Postrenal Acute Kidney Injury

Postrenal AKI can occur in the setting of bilateral urinary outflow obstruction or in a patient with a solitary kidney when a single urinary outflow tract is obstructed (Chapter 125). Most commonly, this type of outflow obstruction is observed in patients with prostatic hypertrophy (Chapter 131), prostatic or cervical cancer (Chapter 205), or retroperitoneal disorders. A functional obstruction can be observed in patients with a neurogenic bladder. In addition, intraluminal obstruction can be seen in patients with bilateral renal calculi (Chapter 128), papillary necrosis, blood clots, and bladder carcinoma, whereas extraluminal obstruction can develop in connection with retroperitoneal fibrosis, colon cancer, and lymphomas. Finally, intratubular crystallization of compounds such as uric acid, calcium oxalate, acyclovir, sulfonamide,

and methotrexate, as well as myeloma light chains, can result in tubular obstruction.

PATHOBIOLOGY

The etiology of AKI is diverse, and it can arise from a number of physiologic insults that injure the kidney and reduce the glomerular filtration rate (GFR). Decreased kidney perfusion and a reduced GFR can occur with or without cellular injury; toxic, ischemic, or obstructive injury to the renal tubule; inflammation and edema of the tubulointerstitium; and a primary glomerular disease process.

Prerenal Acute Kidney Injury

The precipitating event for prerenal AKI is renal hypoperfusion (see Fig. 122-2), which can be caused by a reduction in the volume of extracellular fluid or disease states associated with normal or even increased extracellular fluid volumes but decrements in effective arterial volume, such as in sepsis, heart failure, and advanced cirrhosis. Prerenal azotemia is also divided functionally into volume responsive and nonresponsive azotemia, based on the etiology. For example, in severe heart failure (Chapter 58), additional intravascular volume may not improve kidney perfusion, whereas afterload reduction may. Early in the course of prerenal AKI, the renal parenchyma remains intact and functional. During this initial phase, the GFR remains largely intact because renal hypoperfusion initiates a neurohormonal cascade that results in afferent arteriolar dilation and efferent arteriolar constriction. Because prerenal azotemia is often easily reversible and mortality rates are low, early diagnosis and correction of the underlying pathophysiology are of critical importance. However, without early medical corrective intervention, prerenal azotemia progresses, ischemia worsens, and the resulting injury to tubular epithelial cells further decreases the GFR. This progression from prerenal azotemia to ischemic AKI is a continuum that depends on the severity and duration of the physiologic insult.

Intrarenal Acute Kidney Injury

Intrinsic AKI is classified according to the primary histologic site of injury: tubules, interstitium, vasculature, or glomerulus. Renal tubular epithelial cell injury, commonly termed *acute tubular necrosis* (ATN), occurs more commonly in the setting of ischemia, although the renal tubules can also be damaged by specific renal toxins. Ischemia can arise from a number of different clinical scenarios, but the common underlying pathogenesis is reduced renal blood flow (Table 122-3) with progression from prerenal azotemia to ischemic AKI in four distinct clinical and cellular phases: initiation, extension, maintenance, and recovery. Each of these phases encompasses distinct cellular events and declines in GFR as the kidneys respond to the insult and attempt to maintain and reestablish function (Fig. 122-3). The initiation phase, which marks the transition from prerenal to tubular cell injury and dysfunction, is characterized by severe cellular depletion of adenosine triphosphate. Renal tubular epithelial cell injury is a prominent feature during this phase; however, endothelial and vascular smooth muscle cell injury has also been documented. During the extension phase, microvascular congestion with continued hypoxia and inflammation are most pronounced in the corticomedullary junction of the kidney, where reperfusion is limited owing to endothelial dysfunction at the capillary and postcapillary venule levels, with white blood cell adhesion. The GFR is at its ebb during the maintenance phase, but cells continue to undergo repair, migration, and proliferation, as the kidney attempts to reestablish cellular and tubular integrity. Finally, during the recovery phase, the GFR begins to improve as cellular differentiation continues and normal cellular and organ function returns. This last phase is often heralded by increasing urine output.

The S3 segment of the proximal tubule is located in the outer stripe of the medullary region of the nephron. This region is particularly susceptible to continued reduced perfusion following injury, and ongoing or worsening hypoxia results in continued cellular injury. Proximal tubular cell injury during the initiation phase of renal ischemia is first manifested as bleb formation in the apical membranes, with loss of the brush border. Proximal tubule cells also lose the polarity of the surface membrane and the integrity of their tight junctions. As the injury progresses, both live and necrotic proximal cells detach and enter the tubular lumen, where they ultimately form casts in the distal tubule. Casts contribute to a reduction in GFR by obstructing tubular urine flow, thereby preventing further filtration into that nephron. In addition, loss of the epithelial cell barrier and cell tight junctions allows backleak of the glomerular filtrate into the interstitium, thus further compromising GFR (see Fig. 122-2).

Common agents that can cause direct tubular cell toxicity (see Table 122-1) include the aminoglycoside antibiotics, intravenous radiocontrast agents, and cisplatin. Other agents such as radiocontrast dyes, NSAIDs, and cyclosporine induce vasoconstriction and reduce renal perfusion. Cocaine and the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors can damage skeletal muscle and cause *rhabdomyolysis* (Chapter 115), which results in the release of myoglobin that is toxic to the tubular epithelium. Finally, the precipitation of some compounds or their metabolites can cause intratubular obstruction; agents in this category include acyclovir, sulfonamides, ethylene glycol (calcium oxalate metabolite; Chapter 110), methotrexate, and the light chains of multiple myeloma (Chapter 193).

In AKI caused by the interstitial injury, a mixed inflammatory infiltrate composed of T lymphocytes, monocytes, and macrophages, is seen. These inflammatory lesions can be diffuse or patchy in distribution. Granulomas can also occasionally be observed, especially in drug hypersensitivity reactions. Acute interstitial nephritis that persists and becomes chronic is characterized by interstitial fibrosis and tubular atrophy, although foci of inflammatory cells can persist. This process can lead to chronic and even end-stage kidney disease requiring chronic dialysis.

Vascular causes of intrinsic AKI can include microvascular and macrovascular processes. Classic microvascular disorders, which include thrombotic thrombocytopenic purpura (Chapter 175), sepsis (Chapter 108), hemolytic-uremic syndrome (Chapter 127), and the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count; Chapter 153), cause AKI as a

TABLE 122-3 CONDITIONS THAT LEAD TO ISCHEMIC ACUTE RENAL FAILURE

MECHANISM	CONDITION
Intravascular volume depletion and hypotension	Hemorrhage; gastrointestinal, renal, and dermal losses
Decreased effective intravascular volume	Heart failure, cirrhosis, hepatorenal syndrome, peritonitis
Systemic vasodilation, renal vasoconstriction	Sepsis, hepatorenal syndrome
Large-vessel renal vascular disease	Renal artery thrombosis or embolism, intraoperative arterial cross-clamping, renal artery stenosis, cholesterol emboli
Small-vessel renal vascular disease	Sepsis, vasculitis, atheroembolism, hemolytic-uremic syndrome, malignant hypertension, scleroderma, preeclampsia, sickle cell anemia, hypercalcemia, transplant rejection
Impaired renal blood flow	Cyclosporine, tacrolimus, ACEIs, ARBs, NSAIDs, radiocontrast agents

ACEIs = angiotensin-converting enzyme inhibitors; ARBs = angiotensin-receptor blockers; NSAIDs = nonsteroidal anti-inflammatory drugs.

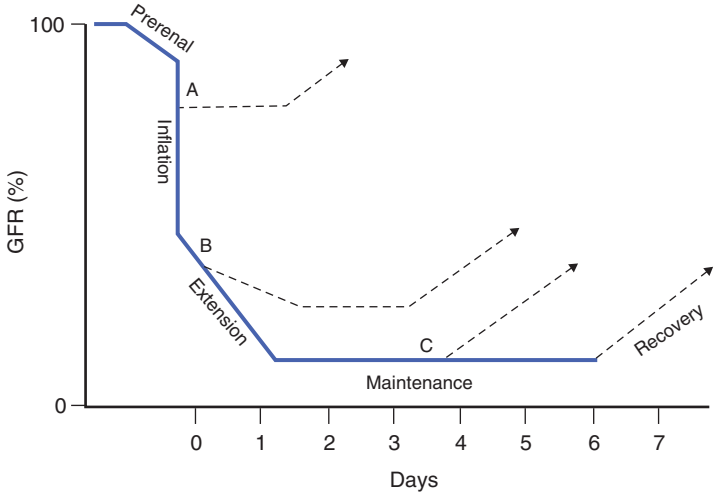

FIGURE 122-3. Phases of acute kidney injury. GFR = glomerular filtration rate. (From Sutton TA, Fisher CJ, Molitoris BA. Microvascular endothelial injury and dysfunction during ischemic acute renal failure. *Kidney Int.* 2002;62:1539-1549.)

result of glomerular capillary thrombosis and microvascular occlusion. Macrovascular disease such as atherosclerosis can cause AKI secondary to atheroembolization (Chapter 126), especially during or after an invasive or interventional vascular procedure in a patient with preexisting atherosclerotic disease.

A less common cause of AKI is glomerulonephritis (Chapter 123), which can be seen in systemic lupus nephritis (Chapter 274), Wegener's granulomatosis (Chapter 278), polyarteritis nodosa (Chapter 278), Goodpasture's syndrome (Chapter 123), Henoch-Schönlein purpura (Chapter 278), and hemolytic-uremic syndrome (Chapter 176). AKI in this setting is termed *rapidly progressive glomerulonephritis* and results from direct inflammatory glomerular or vascular injury.

Postrenal Acute Kidney Injury

Postrenal AKI is caused by obstruction to luminal flow of the glomerular filtrate. This obstruction results in a relatively complex pathophysiology that begins with transmission of backpressure to Bowman's space of the glomerulus. Intuitively, this backpressure would be expected to reduce the GFR. However, by dilation of the glomerular afferent arteriole, the GFR remains largely preserved. Unfortunately, such compensation is only transient, and the GFR will begin to attenuate if the obstruction is not rapidly relieved. With continued obstruction for more than 12 to 24 hours, renal blood flow and intratubular pressure decline, and large unperfused and underperfused areas of the renal cortex result in a reduction in GFR.

CLINICAL MANIFESTATIONS

AKI, even when advanced, frequently is first diagnosed by abnormalities observed in a patient's laboratory studies and not by any specific symptom or sign. The clinical manifestations associated with AKI are frequently protean, occur late in the course, and are often not apparent until the renal dysfunction has become severe. The clinical findings of AKI also depend on the stage at which it is diagnosed. Patients with AKI may report symptoms such as anorexia, fatigue, nausea and vomiting, and pruritus, as well as a decline in urine output or dark-colored urine. Furthermore, if the patient has become volume overloaded, shortness of breath and dyspnea on exertion may be noted.

A thorough physical examination with special emphasis on determination of volume status and effective arterial volume is essential. If volume overload is present, jugular venous distention, pulmonary crackles, and peripheral edema may be found (Chapter 58). Findings such as asterixis, myoclonus, or a pericardial rub may be seen in severe AKI.

DIAGNOSIS

A systematic approach that considers each of the three major categories in the pathogenesis of AKI will ensure that an accurate diagnosis and an appropriate therapeutic plan will be achieved. An appropriate diagnostic strategy is to exclude prerenal and postrenal causes first and then, if needed, begin an evaluation for possible intrinsic causes.

Laboratory analysis of blood and urine samples of patients with AKI reveals the level of dysfunction, will frequently suggest a cause, and may also direct the rapidity with which a specific therapy needs to be instituted. All patients with clinical findings of AKI should be evaluated with serum measurements of electrolytes, creatinine, calcium, and phosphorus; a blood urea nitrogen level; and complete blood count with differential. In addition, urine studies, including sodium, potassium, chloride, and creatinine (Cr) determinations for calculation of the fractional excretion of sodium (FE_{Na}), are important. The formula for calculating FE_{Na} is as follows:

$$FE_{Na} = \frac{\text{Urine Na} \times \text{Plasma Cr}}{\text{Plasma Na} \times \text{Urine Cr}} \times 100$$

The numerical value of FE_{Na} can be helpful in determining the potential cause of the AKI (Table 122-4). In some cases, it is better to use FE_{Cl} because urinary sodium can be elevated during systemic alkalosis when a high urinary bicarbonate level obligates the loss of sodium. Urine dipstick and microscopy (Table 122-5) should be performed on a fresh urine sample because important cellular elements that could indicate potential causes degrade rapidly with time. Finally, renal ultrasound to determine the presence or absence of outlet obstruction should also be included in the initial evaluation. Measurement of serum levels of structural biomarkers, such as kidney injury molecule 1 (KIM-1) and neutrophil gelatinase-associated lipocalin (NGAL), may aid in the diagnosis of AKI, although the data are not yet conclusive.

TABLE 122-4 FE_{Na} VALUES FOR THE VARIOUS CAUSES OF ACUTE KIDNEY INJURY

ETIOLOGY OF ACUTE KIDNEY INJURY	FE_{Na}	BUN–TO–SERUM CREATININE RATIO
Prerenal	<1%	>20
Intrarenal		<10-15
Tubular necrosis	≥1%	
Interstitial nephritis	≥1%	
Glomerulonephritis (early)	<1%	
Vascular disorders (early)	<1%	
Postrenal	≥1%	>20

TABLE 122-5 COMMON URINALYSIS FINDINGS IN ACUTE KIDNEY INJURY

CAUSE OF ACUTE KIDNEY INJURY	URINALYSIS
Prerenal	Normal or hyaline casts
Intrarenal	
Tubular cell injury	Muddy-brown, granular, epithelial casts
Interstitial nephritis	Pyuria, hematuria, mild proteinuria, granular and epithelial casts, eosinophils
Glomerulonephritis	Hematuria, marked proteinuria, red blood cell casts, granular casts
Vascular disorders	Normal or hematuria, mild proteinuria
Postrenal	Normal or hematuria, granular casts, pyuria

PRERENAL AZOTEMIA

Prerenal azotemia, which is the most common cause of renal dysfunction, can often be determined by the patient's history. Common historical features in patients with prerenal azotemia include vomiting, diarrhea, and poor oral intake. Heart failure can suggest a possible prerenal cause of reduced renal perfusion from overdiuresis or as exacerbation of the heart failure itself. Other medications that can attenuate renal perfusion, such as NSAIDs, ACE inhibitors, and ARBs, can cause prerenal azotemia. Common physical examination findings include tachycardia, systemic or orthostatic hypotension (or both), and dry mucous membranes.

Laboratory studies in patients with prerenal azotemia demonstrate elevated serum creatinine and blood urea nitrogen (BUN) levels. FE_{Na} is typically less than 1%. However, in a patient taking diuretics such as furosemide, FE_{Na} may be greater than 1% even though the patient has prerenal azotemia because of diuretic-induced natriuresis. For these clinical situations, the fractional excretion of urea can be used and is calculated in similar fashion:

$$FE_{urea} = \frac{\text{Urine urea} \times \text{Plasma Cr}}{\text{Plasma urea} \times \text{Urine Cr}} \times 100$$

FE_{urea} less than 35% suggests prerenal AKI. Other causes of an FE_{Na} greater than 1% include the presence of a non-reabsorbable solute such as bicarbonate, glucose, or mannitol. Chronic kidney disease, ATN, and late obstructive nephropathy are also associated with FE_{Na} greater than 1%. Therefore, in these disease states, FE_{Na} cannot provide reliable diagnostic information regarding AKI unless the FE_{Na} is less than 1%. Moreover, FE_{urea} has not been validated for these clinical entities.

Another laboratory parameter to assist in diagnosing prerenal AKI is the ratio of BUN to serum creatinine. Commonly, a patient with prerenal azotemia will have a BUN-to–serum creatinine ratio of greater than 20 : 1.

INTRARENAL ACUTE KIDNEY INJURY

A history of hypotension or exposure to a nephrotoxin or medication is a common finding in patients with intrarenal AKI. The nephrotoxin can be a specific tubular toxin that causes ATN or a medication that causes an allergic reaction as in acute interstitial nephritis (see Tables 122-1 and 122-2). Physical examination may reveal signs and symptoms of fluid overload. Rash may accompany acute interstitial nephritis. Cholesterol embolism in patients with severe atherosclerotic disease (Chapter 127) may manifest classically as cyanotic digits and AKI; this finding is frequently seen after invasive vascular surgery or an interventional study.

Laboratory studies will demonstrate elevated serum creatinine and BUN levels in intrarenal AKI. ATN and acute interstitial nephritis are frequently associated with FE_{Na} greater than 1, whereas FE_{Na} is typically less than 1 in glomerulonephritis and vascular disorders. Peripheral eosinophilia and urinary eosinophils may be present in acute interstitial nephritis, although the latter are neither sensitive nor specific for this type of AKI. Urinary eosinophils are also associated with cholesterol microembolic disease (Chapter 127). Intrarenal AKI has specific urinalysis findings that can be helpful in making diagnostic and therapeutic decisions (see Table 122-5).

POSTRENAL ACUTE KIDNEY INJURY

A history of prostatic hypertrophy (Chapter 131), prostate cancer (Chapter 207), lymphoma (Chapter 191), cervical cancer (Chapter 205), or retroperitoneal disease can often be found in patients with postrenal AKI. Postrenal AKI should always be in the differential diagnosis of patients with severe oliguria (urine output < 450 mL/day) or anuria (urine output < 100 mL/day). However, many patients with postrenal AKI are neither oliguric nor anuric. Beyond an elevation in a patient's serum creatinine and BUN levels, laboratory studies generally yield benign results. Bladder catheterization can be both diagnostic and therapeutic in postrenal AKI. However, renal ultrasound is the diagnostic test of choice, although it may be falsely negative early in postrenal AKI.

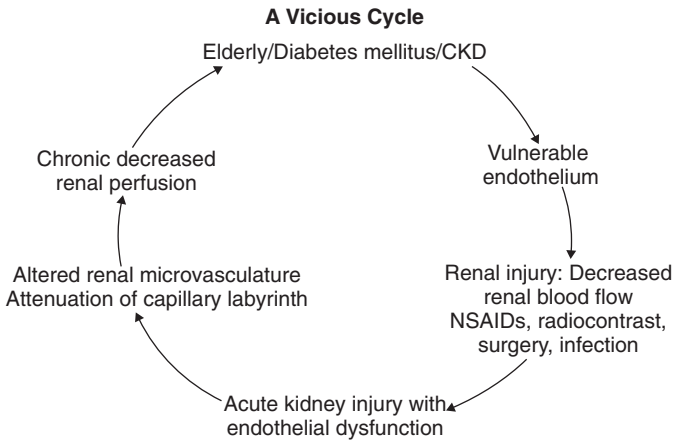

FIGURE 122-4. A vicious cycle exists between acute kidney injury (AKI) and chronic kidney disease (CKD), with CKD increasing the risk of developing AKI, and AKI accelerating progression of CKD.

TREATMENT

Rx

The cornerstones of therapy for AKI are rapid recognition and correction of reversible causes, avoidance of any further renal injury, and correction and maintenance of a normal electrolyte and fluid volume milieu. Preventive therapy or medical interventions performed during the initiation and extension phases of AKI provide the greatest chance for minimizing the extent of injury (see Fig. 122-3, lines A and B) and hastening renal recovery (see Fig. 122-3, line B); interventions provided during the maintenance phase of AKI have not proved beneficial (see Fig. 122-3, line C). If prerenal AKI is not addressed early in a patient's course or if the patient is seen late in the course, ATN may occur and markedly increase morbidity and mortality.

Prerenal azotemia in its early stages often can be rapidly corrected by aggressive normalization of effective arterial volume, although more care must be taken during volume resuscitation in patients with a history of heart failure. Key approaches include administering volume (e.g., normal saline) to achieve euvolemia, improving cardiac output by afterload reduction (Chapter 59), or normalizing systemic vascular resistance.

Postrenal AKI secondary to prostatic hypertrophy can frequently be corrected by placement of a bladder catheter. However, outlet obstruction from a neoplastic process will usually require urologic consultation for consideration of ureteral stenting or placement of a percutaneous nephrostomy tube.

Intrarenal AKI can be the most complex and difficult to treat. AKI caused by glomerulonephritis (Chapter 123) or vasculitis (Chapters 274 and 278) will frequently require immunosuppressive therapy. For suspected acute interstitial nephritis, the offending medication must be determined and discontinued; a 2-week tapering course of glucocorticoids, beginning with 1 mg/kg of prednisone for 3 days, is commonly recommended despite the absence of definitive data.

General supportive measures include avoiding any further nephrotoxins and paying careful attention to the patient's fluid balance by monitoring weight and daily input and output. In addition, serum electrolytes, creatinine, and BUN should be monitored at least daily, more frequently if the patient's renal function appears to be tenuous. Patients with AKI should also receive a low sodium, potassium, and protein diet, which can be liberalized as the patient's renal function improves. A phosphate binder (e.g., calcium acetate [1334 mg], lanthanum carbonate [500 mg], sevelamer [300 to 1000 mg], or aluminum hydroxide [300 to 600 mg] with each meal; see Table 121-4) is also usually helpful in controlling the serum phosphate level by minimizing the absorption of dietary phosphate.

Early nephrology consultation will ensure that the patient receives optimal care. Some patients will warrant urgent hemodialysis because of marked metabolic acidosis unresponsive to sodium bicarbonate infusions; electrolyte abnormalities, such as hyperkalemia that is unresponsive to medical management; pulmonary edema not responding to diuretic therapy; and uremic symptoms of encephalopathy, seizures, and pericarditis. In the absence of acute indications, however, when to initiate dialysis in AKI remains unresolved.

For AKI, intensive dialytic renal support therapy is no better than standard dialytic therapy,■ and intermittent hemodialysis and continuous renal replacement therapy lead to similar clinical outcomes in acute renal failure.■ Neither furosemide■ nor low-dose dopamine■ improve outcome, even though low-dose dopamine may temporarily improve metrics of renal physiology.

PREVENTION

Given the marked increase in morbidity and mortality associated with AKI, especially for critically ill patients, potential measures to prevent AKI are essential. The first step in prevention, however, is being aware of patients who are at highest risk for AKI because of known kidney disease or comorbid medical conditions, such as diabetes, hypertension, nephrotic syndrome, heart failure, and peripheral vascular disease.

Of all the risk factors for acquiring AKI, the presence of preexisting chronic kidney disease is the most predictive. Recent data document a vicious cycle involving AKI and CKD (Fig. 122-4). Appropriate hospital surveillance measures include avoiding nephrotoxic medications (e.g., NSAIDs and aminoglycosides); minimizing diagnostic procedures that require radiocontrast material, especially in the prerenal patient; and careful monitoring of urinary output with daily determination of serum electrolytes and creatinine levels after any procedures known to induce AKI. Additionally, educating the patient regarding common nonprescription nephrotoxins such as NSAIDs can reduce the risk for AKI in outpatients.

Before a potentially nephrotoxic exposure, early consultation with a nephrologist is warranted for this high-risk group to advise whether a specific medication or intervention may reduce the risk of AKI or whether an alternative medication or procedure, such as magnetic resonance imaging instead of computed tomography with intravenous radiocontrast agents, may be preferred. All potential nephrotoxins, such as NSAIDs, should be discontinued before a potentially nephrotoxic procedure and avoided after it. The patient's volume and hemodynamic status must be maximized.

In high-risk patients, a renal protective intervention is often instituted before exposure to the agent. Interventions that may be useful for preventing AKI associated with intravenous radiocontrast agents include sodium bicarbonate■ (e.g., 15 mEq/L infused at 3 mL/kg/hour for 1 hour before the procedure and at 1 mL/kg/hour for 6 hours after it) and N-acetylcysteine■ (usually 600 mg orally or intravenously 4 hours before the procedure), although the data for each individually or even the two together remain controversial.■

PROGNOSIS

Typically, AKI secondary to prerenal causes, if diagnosed and treated early, has the best prognosis for renal recovery. Patients with prerenal AKI commonly return to their baseline level of renal function and have a mortality rate of less than 10%. Similarly, patients with postrenal AKI also have a good prognosis for renal recovery if the outlet obstruction is promptly diagnosed and definitively treated.

In contrast, patients with intrarenal AKI have a less predictable renal outcome, and mortality in this group varies between 30 and 80%, depending on the severity of injury. Higher mortality rates occur in older patients with hospital-acquired AKI admitted to ICUs. Furthermore, mortality in patients with AKI is incremental, and seemingly modest increases in serum creatinine can result in marked increases in the mortality rate. Even a rise in serum creatinine of only 0.3 mg/dL results in a significantly increased risk of mortality.

The clinical course after recovery from ATN is subsequent tubular regeneration with recovery of renal function. However, this outcome is less ensured in patients with preexisting kidney disease. In addition, given the frequent systemic nature of their illness, patients with ATN, glomerulonephritis, and vasculitic causes of AKI may not fully recover to their baseline renal function. Patients who have a severe episode of AKI requiring hemodialysis may not recover their renal function and may need hemodialysis indefinitely (Chapter 133), especially if they have a preexisting history of chronic kidney disease. AKI hastens progression of chronic kidney disease to end-stage kidney disease and is often the major factor that causes such progression.

GLOMERULAR DISORDERS AND NEPHROTIC SYNDROMES

GERALD B. APPEL AND JAI RADHAKRISHNAN

GLOMERULAR DISORDERS

DEFINITION

Each *glomerulus,* the basic filtering unit of the kidney, consists of a tuft of anastomosing capillaries formed by the branching of the afferent arteriole. Approximately 1 million glomeruli comprise about 5% of the kidney weight and provide almost 2 m^2 of glomerular capillary filtering surface. The glomerular basement membrane provides both a size- and charge-selective barrier to the passage of circulating macromolecules. Renal pathology involving all glomeruli is called *diffuse* or *generalized;* if only some glomeruli are involved, the process is called *focal.* When dealing with the individual glomerulus, a process is *global* if the whole glomerular tuft is involved and *segmental* if only part of the glomerulus is involved. The modifying terms *proliferative, sclerosing,* and *necrotizing* are often used (e.g., focal and segmental glomerulosclerosis; diffuse global proliferative lupus nephritis). Extracapillary proliferation or crescent formation is caused by the accumulations of macrophages, fibroblasts, proliferating epithelial cells, and fibrin within Bowman's space. In general, crescent formation in any form of glomerular damage conveys a serious prognosis. Scarring of the tissue between the tubules and glomeruli, interstitial fibrosis, is also a poor prognostic sign in every glomerular disease.

EPIDEMIOLOGY

At present, about 17% of the U.S. population has proteinuria or renal dysfunction, and many, if not most, cases are caused by glomerular diseases. More than 500,000 Americans are in end-stage renal disease (ESRD) programs, and chronic kidney disease costs about $60 billion per year and accounts for about 28% of all Medicare spending, largely as a result of renal involvement by glomerular diseases. Diabetic renal damage alone affects many millions of persons and is the major cause of ESRD in the United States (Chapter 126). Worldwide, glomerular diseases associated with infectious agents such as malaria (Chapter 353) and schistosomiasis (Chapter 363) are still major health problems. The emergence of glomerular diseases linked to human immunodeficiency virus (HIV) and the hepatitis B and C viruses (Chapter 151) has focused new attention on the patterns and mechanisms of glomerular injury. Manifestations of glomerular injury range from asymptomatic microhematuria and albuminuria to rapidly progressive oliguric renal failure. Some patients develop massive fluid retention and edema at onset of their glomerular disease, whereas others present with only the slow insidious signs and symptoms of chronic renal failure (Chapter 132).

PATHOBIOLOGY

Common mechanisms such as breaks in the glomerular capillary wall and loss of the selective barrier to particles based on size and charge underlie the proteinuria and hematuria that are characteristic of glomerular diseases. Nevertheless, the nature of the initiating processes varies among different glomerular diseases. In some glomerular disorders, such as diabetes and amyloidosis, structural and biochemical alterations are present in the glomerular capillary wall. In others, immune-mediated renal injury is caused by deposition of circulating immune complexes, the localized effects of anti–glomerular basement membrane (anti-GBM) antibodies, or other mechanisms.

CLINICAL MANIFESTATIONS

Findings indicative of a glomerular origin of renal disease include erythrocyte casts and dysmorphic red blood cells (RBCs) in the urinary sediment as well as large amounts of albuminuria. Persistent urinary excretion of more than 500 to 1000 erythrocytes per milliliter (or greater than two RBCs per high-power field on microscopy) is abnormal. Dysmorphic RBCs, which are deformed as a result of their passage through the glomerular capillary wall and tubules, and red blood cell casts, which are formed when these erythrocytes become enmeshed in a proteinaceous matrix in the lumen of the tubules, are also indicative of glomerular disease.

In a normal person, the urinary excretion of albumin is less than 30 mg/day, and the total urinary excretion of protein is less than 150 mg/day. Although increases in urinary protein excretion may come from the filtration of abnormal circulating proteins (e.g., light chains in multiple myeloma) or from the deficient proximal tubular reabsorption of normal, filtered low-molecular-weight proteins (e.g., β_2-microglobulin), the most common cause of proteinuria, and specifically albuminuria, is glomerular injury. Proteinuria associated with glomerular disease may range from several hundred milligrams to more than 30 g daily. In some diseases, such as minimal change nephrotic syndrome, albumin is the predominant protein in the urine. In others, such as focal sclerosing glomerulonephritis and diabetes, the proteinuria, although still largely composed of albumin, is nonselective and contains many higher-molecular-weight proteins.

DIAGNOSIS

Some patients have asymptomatic microhematuria or proteinuria discovered by routine evaluations. Microscopic hematuria associated with deformed RBCs or RBC casts is likely to be glomerular in origin. Subnephrotic levels of proteinuria may arise from orthostatic proteinuria, hypertension, tubular disease, or glomerular damage.

In patients with asymptomatic urinary abnormalities of glomerular origin, the underlying glomerular lesion may represent the early phase of one of the progressive glomerular diseases or may be due to a benign, nonprogressive glomerular lesion. In general, if patients have less than 1 g of proteinuria daily or glomerular microhematuria but a normal glomerular filtration rate (GFR) and no evidence of systemic disease based on a careful history, physical examination, and serologic tests, it is not necessary to proceed to a renal biopsy to establish a diagnosis, because most of these patients need no immunosuppressive therapy. The patient can be followed closely, and biopsy need be performed only in patients with progressively increasing proteinuria or evidence of a decreasing GFR.

TABLE 123-1 TYPICAL FINDINGS OF NEPHROTIC SYNDROME VERSUS NEPHRITIS

NEPHROTIC SYNDROME	NEPHRITIS
RENAL INSUFFICIENCY	
Uncommon	Common at presentation

OTHER
Pregnancy related (includes preeclampsia) Transplant rejection Serum sickness Accelerated hypertensive nephrosclerosis Unilateral renal artery stenosis Massive obesity–sleep apnea Reflux nephropathy

THE NEPHROTIC SYNDROME

DEFINITION

The nephrotic syndrome (Table 123-1) is defined by albuminuria in amounts of more than 3 to 3.5 g/day accompanied by hypoalbuminemia, edema, and hyperlipidemia. In practice, many clinicians refer to "nephrotic range" proteinuria regardless of whether their patients have the other manifestations of the full syndrome, which is a consequence of the proteinuria.

EPIDEMIOLOGY

Many cases of the nephrotic syndrome are idiopathic (Table 123-2), but others are caused by known underlying conditions (Table 123-3). Although minimal change disease is the most common cause of nephrotic syndrome in children, idiopathic membranous nephropathy and focal segmental glomerular sclerosis are the most common causes in adults. In England, men account for about 58% of hospitalizations for nephrotic syndrome, and the mean hospital length of stay for nephrotic syndrome is about 6 days.

PATHOBIOLOGY

Hypoalbuminemia is largely a consequence of urinary protein loss. It also can be due to the catabolism of filtered albumin by the proximal tubule, the redistribution of albumin within the body, and the reduced hepatic synthesis of albumin. As a result, the relationship among urinary protein loss, the level of the serum albumin, and other secondary consequences of heavy albuminuria is inexact.

The salt and volume retention in the nephrotic syndrome may occur through at least two different major mechanisms. The classic teaching is that hypoalbuminemia reduces the oncotic pressure of plasma, the resulting intravascular volume depletion leads to activation of the renin-angiotensin-aldosterone axis, and this activation increases the retention of renal sodium and fluid. However, primary salt retention in the distal nephron also may occur independently of the renin-angiotensin-aldosterone axis.

CLINICAL MANIFESTATIONS

Patients may present with weight gain, peripheral edema, and periorbital edema. Hypertension is common. The urinalysis shows more than 3+ of proteinuria and varying degrees of hematuria, depending on the cause. A 24-hour urine usually shows 3 to 5 mg/kg/day of proteinuria.

Nephrotic patients often have a hypercoagulable state and are predisposed to deep vein thrombosis (Chapter 81), pulmonary emboli (Chapter 98), and renal vein thrombosis (Chapter 127). Patients with the nephrotic syndrome have increased risk of atherosclerotic complications. Most nephrotic patients have elevated levels of total and low-density lipoprotein (LDL) cholesterol with low or normal high-density lipoprotein (HDL) cholesterol. Lipoprotein(a) levels are elevated as well and return to normal with remission of the nephrotic syndrome.

DIAGNOSIS

Initial evaluation of the nephrotic patient includes laboratory tests to define whether the patient has primary idiopathic nephrotic syndrome (see Table 123-2) or a secondary cause related to a systemic disease, toxin, or medication (see Table 123-3). Common screening tests include the fasting blood sugar and glycosylated hemoglobin tests for diabetes, an antinuclear antibody test for collagen vascular disease, and a serum complement level, which screens for many immune complex–mediated diseases (Table 123-4). In selected patients, cryoglobulins, hepatitis B and C serologies, HIV testing, antineutrophil cytoplasmic antibodies (ANCAs), anti-GBM antibodies, serum protein electrophoresis, and other tests may be useful.

After exclusion of secondary causes, a renal biopsy is often required in the adult nephrotic patient. Biopsy results in patients with heavy proteinuria and the nephrotic syndrome are likely to provide a specific diagnosis, determine prognosis, and guide therapy.

TABLE 123-4 SERUM COMPLEMENT LEVELS IN GLOMERULAR DISEASES

DISEASES WITH A REDUCED COMPLEMENT LEVEL
Post-streptococcal glomerulonephritis
Subacute bacterial endocarditis, visceral abscess, shunt nephritis
Systemic lupus erythematosus
Cryoglobulinemia
Idiopathic membranoproliferative glomerulonephritis
DISEASES ASSOCIATED WITH A NORMAL SERUM COMPLEMENT
Minimal change nephrotic syndrome
Focal segmental glomerulosclerosis
Membranous nephropathy
Immunoglobulin A nephropathy
Henoch-Schönlein purpura
Anti–glomerular basement disease
Pauci-immune rapidly progressive glomerulonephritis
Polyarteritis nodosa
Wegener's granulomatosis

TREATMENT Rx

Treatment varies by the specific cause. Elevated lipid levels should be treated (Chapter 213). Anticoagulation is not recommended routinely but is needed if any thrombotic complications occur. Edema is treated with diuretics, and the combination of furosemide plus albumin is more effective than furosemide alone for patients with refractory edema.■

Idiopathic Nephrotic Syndrome

MINIMAL CHANGE DISEASE

Minimal change disease, which is the most common pattern of nephrotic syndrome in children, accounts for only about 5 to 10% of cases of idiopathic nephrotic syndrome in adults. A similar histologic pattern may be seen as an adverse reaction to certain medications (nonsteroidal anti-inflammatory drugs [NSAIDs], lithium) or in association with certain tumors (e.g., Hodgkin's disease).

CLINICAL MANIFESTATIONS

Patients typically present with weight gain and periorbital and peripheral edema related to the proteinuria, which is usually well into the nephrotic range. Additional findings in adults are hypertension and microscopic hematuria, each in about 30% of patients. However, active urinary sediment with RBC casts is not found. Many adult patients have mild to moderate azotemia, which may be related to hypoalbuminemia and intravascular volume depletion. Complement levels and serologic test results are normal.

DIAGNOSIS

In true minimal change disease, histopathology typically reveals no glomerular abnormalities on light microscopy (Fig. 123-1). The tubules may show lipid droplet accumulation from absorbed lipoproteins (hence the older term *lipoid nephrosis*). Immunofluorescence staining and electron microscopy (Fig. 123-2) show no immune-type deposits. By electron microscopy, the GBM is normal, and effacement or "fusion" of the visceral epithelial foot processes is noted along virtually the entire distribution of every capillary loop.

TREATMENT Rx

The course of minimal change nephrotic syndrome is often one of remissions, relapses, and responses to additional treatment. When treated with corticosteroids for 8 weeks, 85 to 95% of children experience a remission of proteinuria. In adults, the response rate is somewhat lower, with 75 to 85% of patients responding to regimens of daily (1 mg/kg, maximum 80 mg) or alternate-day (2 mg/kg, maximum 120 mg) prednisone therapy, tapered after 2 months of treatment for a total of 5 to 6 months of therapy. The time to clinical response is slower in adults, and they are not considered steroid resistant until they have failed to respond to 16 weeks of treatment. Tapering of the steroid dose after remission should be gradual over 1 to 2 months. Approximately 40% of adults relapse by 1 year and 50% by 5 years. Most clinicians treat the first relapse similarly to the initial episode. Patients who relapse a third time or who become corticosteroid dependent (unable to decrease the prednisone dose without proteinuria recurring) may be treated with a 2- to 3-month course of the alkylating agent cyclophosphamide at a dose of up to 2 mg/kg/day. Up to 50% of patients will have a remission of at least 5 years, but the response rate is lower in corticosteroid-dependent patients. Other alternative treatments for patients who frequently relapse or are steroid resistant include low-dose cyclosporine (3 to 5 mg/kg/day in divided doses for 4 months), tacrolimus (0.05 to 0.1 mg/kg/day in divided doses), and mycophenolate mofetil (750 to 1000 mg twice daily). All provide approximately equivalent remission and relapse rates, but cyclosporine and tacrolimus increase the risk of nephrotoxicity, so their blood levels must be carefully monitored.

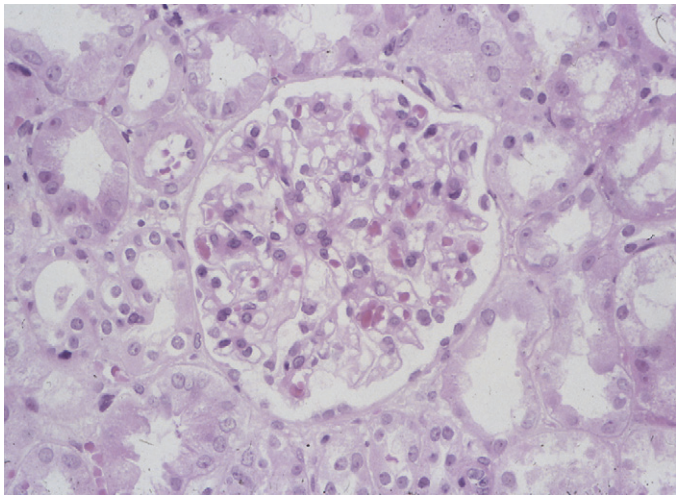

FIGURE 123-1. Unremarkable light microscopic appearance of minimal change disease glomerulopathy. Glomerular basement membranes are thin, and there is no glomerular hypercellularity.

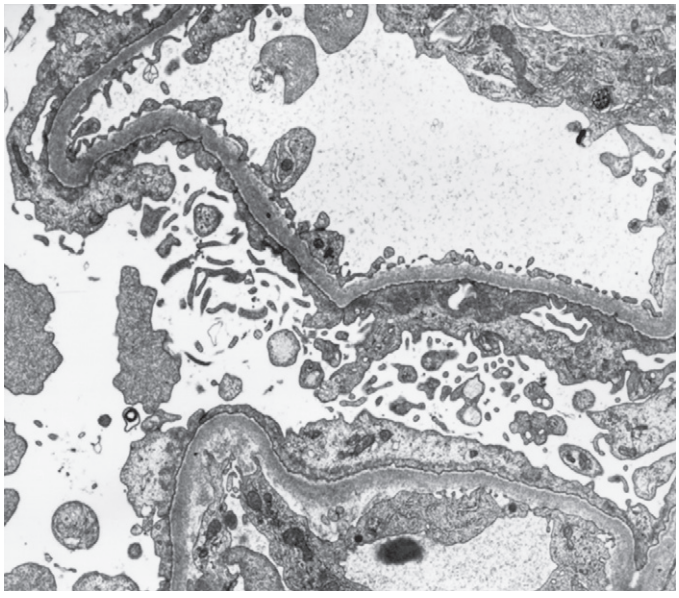

FIGURE 123-2. Minimal change disease. Electron micrograph shows widespread effacement of foot processes with microvillous transformation of the visceral epithelium. No electron-dense deposits are present (uranyl acetate, lead citrate stain; ×6000).

PROGNOSIS

The prognosis of minimal change disease is excellent in terms of kidney function, and most patients who have a decline in kidney function have focal segmental glomerulosclerosis on a subsequent kidney biopsy. However, more than 50% of patients have relapses, and 10 to 20% may become steroid dependent.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

About 20 to 25% of adults with idiopathic nephrotic syndrome are found on biopsy to have focal segmental glomerulosclerosis (FSGS). The incidence of FSGS is increasing in all races, but it is especially common in African Americans. FSGS may be either idiopathic or secondary to a number of different causes (e.g., heroin abuse, HIV infection, sickle cell disease, obesity, reflux of urine from the bladder to the kidneys, and lesions associated with single or remnant kidneys). FSGS can occur in multiple family members owing to genetic defects in components of the visceral epithelial cell: an autosomal recessive pattern caused by mutations in the structural protein podocin; and autosomal dominant forms, caused by mutations in the structural protein α-actinin 4, the TRPC6 glomerular slit diaphragm-associated channel, or INF2, which encodes a formin (actin-regulating protein). The predisposition of African Americans to FSGS is related to alleles in the genes for myosin heavy chain 9 (MYH9) and apolipoprotein L1.

CLINICAL MANIFESTATIONS

Patients with idiopathic FSGS typically present with either asymptomatic proteinuria or edema. Although criteria for the nephrotic syndrome are met in two thirds of patients at presentation, proteinuria may vary from less than 1 to more than 30 g/day. Hypertension is found in 30 to 50% of patients, and microscopic hematuria occurs in about one half of all patients. The GFR is decreased at presentation in 20 to 30% of patients. Complement levels and other serologic test results are normal.

DIAGNOSIS

By light microscopy, only some glomeruli initially have areas of segmental scarring (Fig. 123-3). As renal function declines, repeat biopsy specimens show more glomeruli with segmental sclerosing lesions and increased numbers of globally sclerotic glomeruli. By immunofluorescence staining, immunoglobulin M (IgM) and C3 commonly are trapped in the areas of glomerular sclerosis. Electron microscopy shows no deposits and only visceral epithelial cell foot process effacement. The histopathologic variants of FSGS are associated with epidemiologic, clinical, and prognostic differences. For example, the "tip lesion" variant has a relatively benign course, whereas the collapsing variant progresses more rapidly to renal failure.

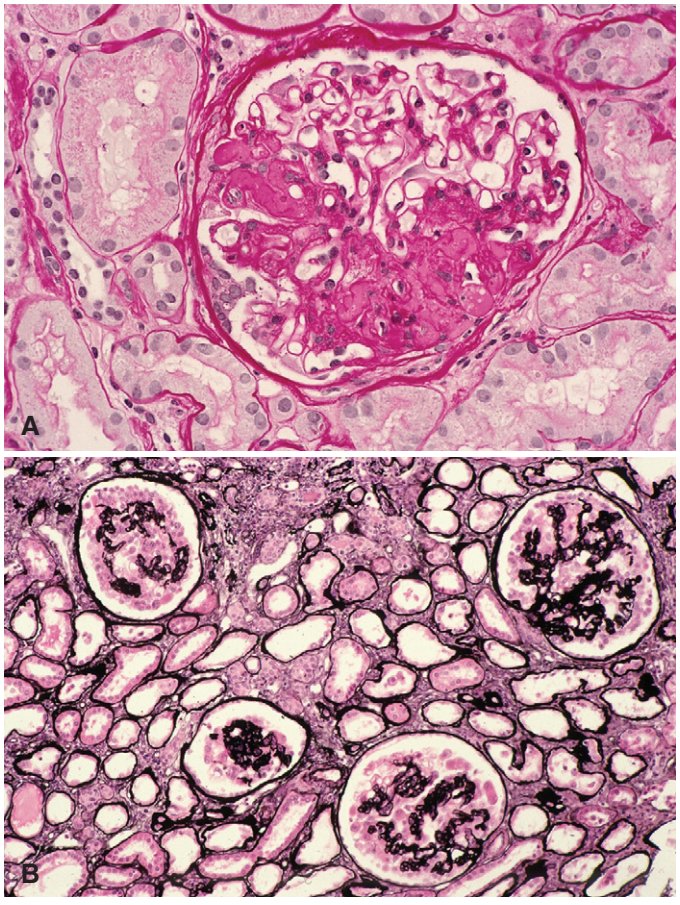

FIGURE 123-3. Focal segmental glomerulosclerosis. A, Light micrograph of classic focal segmental glomerulosclerosis. **B,** Silver stain of collapsing focal segmental glomerulosclerosis showing collapse of the glomerular tufts.

TREATMENT Rx

For primary (idiopathic) FSGS, corticosteroids are used as initial therapy (e.g., prednisone, 1 mg/kg/day, maximum 80 mg, or 2 mg/kg every other day, maximum 120 mg, as tolerated) for a minimum of 3 to 4 months and slowly tapered over the next 3 to 6 months if remission is achieved. A complete or partial remission may be seen in up to 40 to 60% of patients, with preservation of long-term renal function. In patients who relapse after initial therapy, oral cyclophosphamide (2 to 2.5 mg/kg/day for 12 weeks) or cyclosporine (4 mg/kg/day in divided doses) is used for 12 to 24 months, with slow tapering thereafter. With cyclosporine, careful monitoring of renal function and cyclosporine levels are necessary to avoid nephrotoxicity. In patients who are steroid resistant after 4 months of high-dose prednisone, the dose of prednisone should be tapered and patients should be treated with cyclosporine (3.5 mg/kg/day in divided doses adjusted to serum levels 125 to 225 µg/L) plus prednisone (0.15 mg/kg/day in divided doses, maximum 15 mg/day) for 6 months.

PROGNOSIS

The course of untreated FSGS is usually one of progressive proteinuria and declining GFR. Only a minority of patients experiences a spontaneous remission of proteinuria, and most untreated patients eventually develop ESRD within 5 to 20 years from presentation. Patients with a sustained remission of their nephrotic syndrome are unlikely to progress to ESRD, whereas those with unremitting nephrotic syndrome are likely to progress.

In general, patients with genetic forms of the disease are steroid resistant, have a progressive course, and do not experience recurrences of the FSGS when they receive a renal transplant. Overall, however, focal sclerosis recurs in the transplanted kidney in up to 30% of cases, often in association with elevated levels of a circulating permeability factor. Younger patients, those with a rapid course to renal failure, and those with a prior recurrence are more likely to have recurrence in the allograft.

MEMBRANOUS NEPHROPATHY

Membranous nephropathy is the most common pattern of idiopathic nephrotic syndrome in white patients. It may also be associated with infections (syphilis [Chapter 327] and hepatitis B and C [Chapter 151]), systemic lupus erythematosus (SLE; Chapter 274), medications (gold salts, NSAIDs), and certain tumors (solid tumors and lymphomas). In many cases of what was previously classified as idiopathic membranous nephropathy, the antigen is the M-type phospholipase A_2 receptor in the podocyte.

CLINICAL MANIFESTATIONS

Membranous nephropathy typically presents as proteinuria and edema. Hypertension and microhematuria are not infrequent findings, but renal function and GFR are usually normal at presentation. Despite the finding of complement in the glomerular immune deposits, serum complement levels are normal. Membranous nephropathy is the most common pattern of the nephrotic syndrome to be associated with a hypercoagulable state and renal vein thrombosis (Chapter 127). The presence of sudden flank pain, deterioration of renal function, or symptoms of pulmonary disease in a patient with membranous nephropathy should prompt an investigation for renal vein thrombosis and pulmonary emboli.

DIAGNOSIS

On light microscopy, the glomerular capillary loops often appear rigid or thickened (Fig. 123-4), but there is no cellular proliferation. Immunofluorescence staining and electron microscopy show subepithelial immune dense deposits all along the glomerular capillary loops (Fig. 123-5). The presence of circulating antibodies to the M-type phospholipase A_2 receptor are 75% sensitive and 100% specific for idiopathic membranous nephropathy.

TREATMENT Rx

Studies using corticosteroids to treat membranous nephropathy have given conflicting results, and proof of their benefit is lacking. By comparison, corticosteroid therapy (methylprednisolone, 1 g intravenously daily for 3 days, then oral prednisone, 0.5 mg/kg/day for 27 days, in months 1, 3, and 5) and oral cytotoxic therapy (chlorambucil, 0.2 mg/kg/day, or cyclophosphamide,

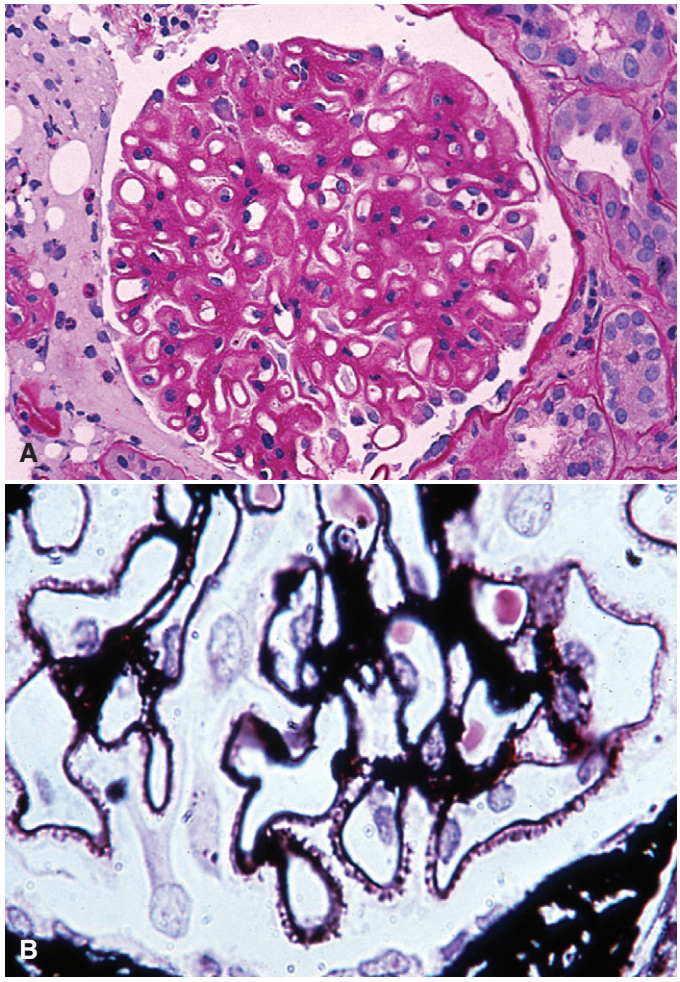

FIGURE 123-4. Membranous nephropathy. A, Light micrograph of membranous nephropathy demonstrating thickening of the glomerular capillary wall but no hypercellularity. **B,** Silver stain of idiopathic membranous nephropathy showing spike formation along the outer aspect of the glomerular basement membrane corresponding to projections of the basement membrane between the epimembranous deposits.

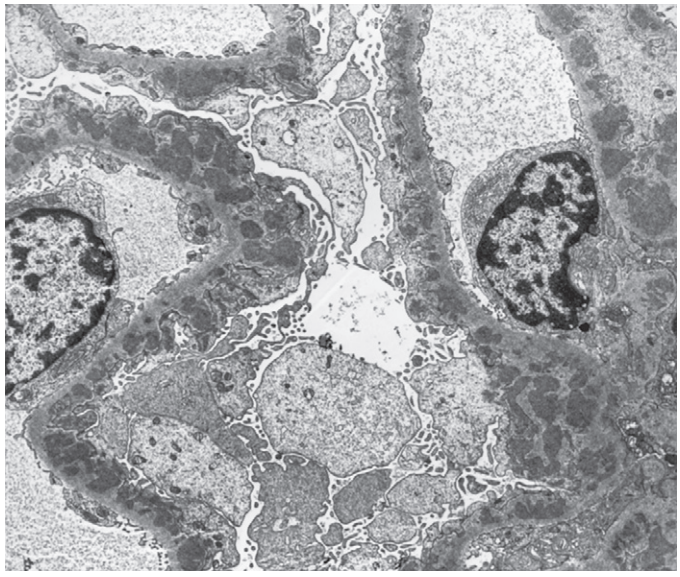

FIGURE 123-5. Membranous glomerulopathy. On ultrastructural examination, there are numerous, closely apposed epimembranous electron-dense deposits separated by basement membrane spikes (uranyl acetate, lead citrate stain; ×2500).

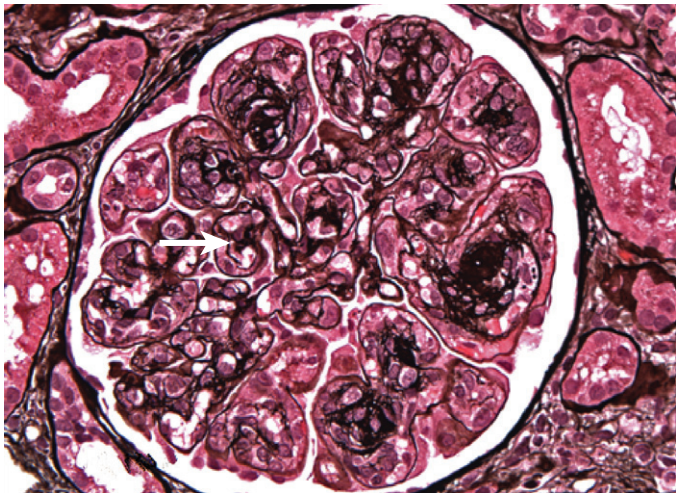

FIGURE 123-6. Membranoproliferative glomerulonephritis with lobulation of the glomerular tuft and splitting of the basement membrane as seen by silver stain.

2.5 mg/kg/day, for 30 days in months 2, 4, and 6) given in alternating months over 6 months results in more total remissions and better preservation of renal function compared with symptomatic therapy. The combination of cyclosporine (3.5 mg/kg/day adjusted to serum levels of 125 to 225 µg/L) plus prednisone (0.15 mg/kg/day up to a maximum of 15 mg/day) for 6 months also is more likely to induce remission of the nephrotic syndrome compared with placebo or prednisone alone. Other agents used successfully in uncontrolled or small controlled trials in membranous nephropathy include mycophenolate mofetil, adrenocorticotropic hormone, and the monoclonal anti-CD20 antibody, rituximab.

PROGNOSIS

In most large series, renal survival is more than 75% at 10 years, with a spontaneous remission rate of 20 to 30%. In general, older patients, males, and those with heavy persistent proteinuria are most likely to progress to renal failure and hence to benefit from therapy.

Membranoproliferative Glomerulonephritis

Idiopathic type I membranoproliferative or mesangiocapillary glomerulonephritis (MPGN) is an uncommon primary glomerular disease that represents only a small percentage of renal biopsy results. However, by light microscopy, similar patterns of glomerular damage commonly have been seen in association with hepatitis C (Chapter 151), SLE (Chapter 274), monoclonal gammopathies, and thrombotic microangiopathy associated with antiphospholipid antibodies (Chapter 179). All these stimuli have been proposed to incite the glomerular mesangial cells to grow out along the capillary wall and split the glomerular basement membrane.

Type II MPGN, or dense deposit disease, is an even less common disease that is associated with uncontrolled systemic activation of the alternative complement pathway. The cause may be C3 nephritic factor, which is an autoantibody directed against the C3 convertase of the alternate complement pathway, deficiencies of factor H or I or other inhibitors of the alternate complement cascade. Dense deposit disease may be associated with partial lipodystrophy. Because the histology of dense deposit disease may show patterns other than what are typical in MPGN (e.g., mesangial proliferation, sclerosis, crescents) and its pathogenesis is unique, many investigators feel it should be categorized independently of the other forms of MPGN.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most patients with idiopathic MPGN are children or young adults who present with proteinuria or the nephrotic syndrome. A low serum complement level is found intermittently in type I MPGN, whereas the C3 level is usually reduced in dense deposit disease. The diagnosis of type II MPGN requires a renal biopsy that shows complement C3 in a characteristic ribbon-like pattern around the capillary loop by light microscopy (Fig. 123-6).

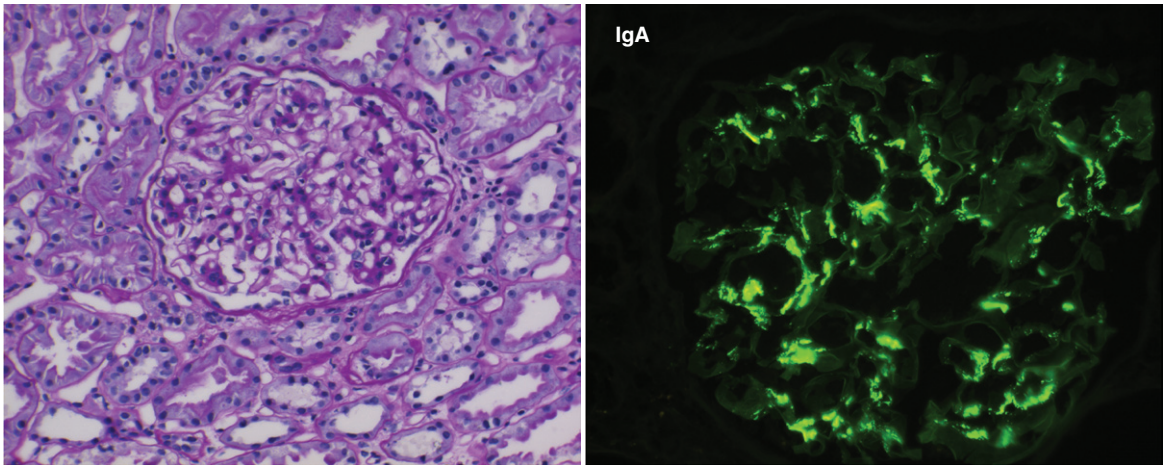

FIGURE 123-7. Immunoglobulin A (IgA) nephropathy with mesangial cell proliferation by light microscopy and IgA deposition on immunofluorescence.

TREATMENT AND PROGNOSIS

Rx

Attempts to treat idiopathic type I MPGN have included corticosteroids, other immunosuppressive medications, anticoagulants, and antiplatelet agents. No therapy has been proved effective in a randomized trial in adults, but corticosteroids have had some success in children at a dose of 40 mg/m^2 every other day for a mean period of 41 months. Most studies have found a similar course and prognosis for the various patterns of MPGN, with half of the patients progressing to ESRD within 10 years of diagnosis.

ACUTE GLOMERULONEPHRITIS AND THE NEPHRITIC SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

Known inciting causes of acute glomerulonephritis include infectious agents, such as type 12 and type 49 "nephritogenic" strains of group A streptococci and endocarditis caused by *Staphylococcus aureus* and *Streptococcus viridans*. Acute glomerulonephritis can also be caused by the deposition of immune complexes in autoimmune diseases such as SLE (Chapter 274), and the damaging effect of circulating antibodies directed against the GBM, as in Goodpasture's syndrome.

Invading neutrophils and monocytes, as well as resident glomerular cells, can damage the glomerulus through a number of mediators, including oxidants, chemoattractant agents, proteases, cytokines, and growth factors. Some factors, such as transforming growth factor-β, have been related to eventual glomerulosclerosis and chronic glomerular damage.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with acute glomerulonephritis often present with a nephritic picture characterized by a decreased GFR, azotemia, oliguria, hypertension, and an active urinary sediment (see Table 123-1). Hypertension is common and is caused by intravascular volume expansion, although renin levels may not be appropriately suppressed for the degree of volume expansion. Patients may note dark, smoky, or cola-colored urine in association with an active urinary sediment, which is composed of erythrocytes, leukocytes, and a variety of casts, including RBC casts. Although many patients with acute glomerulonephritis have proteinuria, sometimes even in the nephrotic range, most patients have lesser degrees of albumin leakage into the urine, especially when the GFR is markedly reduced. Regardless of the inciting cause, acute glomerulonephritis is characterized on light microscopy by hypercellularity of the glomerulus, which may be composed of infiltrating inflammatory cells, proliferation of resident glomerular cells, or both.

Immunoglobulin A Nephropathy

EPIDEMIOLOGY AND PATHOBIOLOGY

IgA nephropathy, which is now recognized as the most frequent form of idiopathic glomerulonephritis worldwide, represents 15 to 40% of primary glomerulonephritides in parts of Europe and Asia. In geographic areas where renal biopsies are commonly performed for milder urinary findings, a higher incidence of IgA has been noted. In the United States, some centers report this diagnosis in up to 20% of all primary glomerulopathies. Affected males outnumber females, and the peak occurrence is in the second to third decades of life.

In IgA nephropathy, the predominant antibody is composed of polymeric IgA1, but the antigen—whether infectious, dietary, or other—to which it is directed is unknown in most cases. The pathogenesis may involve abnormal O-linked galactosylation of the IgA molecule at the hinge region, with resultant abnormal binding of IgA complexes to the glomerular mesangial cells.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

IgA nephropathy often presents either as asymptomatic microscopic hematuria with or without proteinuria (the most common presentation in adults) or as episodic gross hematuria following an upper respiratory tract infection or exercise (the most common presentation in children and young adults). Hypertension is present in 20 to 50% of all patients. Increased serum IgA levels, noted in one third to one half of cases, do not correlate with the course of the disease. Serum complement levels are normal. The diagnosis of IgA nephropathy is established by finding glomerular IgA deposits as either the dominant or the codominant immunoglobulin on immunofluorescence microscopy (Fig. 123-7). Deposits of C3 and IgG also are often found. The light microscopy picture varies from the most common picture of mild mesangial proliferation to severe crescentic glomerulonephritis. By electron microscopy, immune-type dense deposits are typically found in the mesangial and paramesangial areas.

TREATMENT

Rx

Because the pathogenesis of IgA nephropathy is thought to involve abnormal antigenic stimulation of mucosal IgA production and subsequent immune complex deposition in the glomeruli, treatment has been directed at these sites. Efforts to treat the disease by preventing antigenic stimulation, including broad-spectrum antibiotics (e.g., doxycycline), tonsillectomy, and dietary manipulations (e.g., gluten elimination), generally have been controversial or unsuccessful. Most physicians choose to treat only patients at high risk for progression to renal failure. Trials using fish oils to decrease proteinuria and slow progressive disease have given conflicting results. Controlled studies suggest that glucocorticoids (e.g., pulse methylprednisolone, 1 g daily for three doses in months 0, 2, and 4, followed by prednisone, 0.5 mg/kg every other day for 6 months) may decrease proteinuria and progressive renal failure in some patients. The benefit of immunosuppressive agents (e.g., cyclophosphamide, azathioprine, mycophenolate mofetil) is far from clear. For the few patients with crescentic IgA nephropathy, cytotoxic agents have been used. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) have reduced proteinuria and the progression of renal disease in small randomized studies and appear to have incremental benefit when added to glucocorticoid therapy.

PROGNOSIS

The course is variable, with some patients showing no decline in GFR over decades and others developing the nephrotic syndrome, hypertension, and

renal failure. Factors predictive of a poor outcome in IgA nephropathy include older age at onset, absence of gross hematuria, hypertension, persistent proteinuria greater than 1 g/day, male gender, an elevated serum creatinine level, and the histologic features of severe proliferation and sclerosis or tubulointerstitial damage and crescent formation. Renal survival rates are estimated at 75 to 85% at 10 years and 70 to 75% at 20 years. A significant percentage of transplant recipients have a morphologic recurrence in the allograft, but graft loss owing to the disease is uncommon.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP; Chapter 278) is characterized by a small-vessel vasculitis with arthralgias, skin purpura, and abdominal symptoms as well as a proliferative acute glomerulonephritis. HSP is predominantly a disease of childhood, although cases occur in adults. Despite the finding of circulating IgA-containing immune complexes, no infectious agent or allergen has been defined as causative, and serum complement levels are normal.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of HSP (Chapter 278) include dermatologic, gastrointestinal, rheumatologic, and renal findings. Skin involvement typically starts with a macular rash that coalesces into purpuric lesions (see Fig. 278-2 in Chapter 278) on the ankles, legs, and occasionally arms and buttocks. Gastrointestinal symptoms include cramps, diarrhea, nausea, and vomiting, with melena and bloody diarrhea in the most severely involved cases. Although arthralgias of the knees, wrists, and ankles are common, true arthritis is uncommon. Symptoms of different organ system involvement may occur concurrently or separately, and recurrent episodes during the first year are not uncommon. The renal histopathology of HSP is similar to that of IgA nephropathy. In the skin, there is a small-vessel leukocytoclastic angiitis with immune deposition of IgA.

TREATMENT AND PROGNOSIS

Rx

Like IgA nephropathy, HSP has no proven therapy. Episodes of rash, arthralgias, and abdominal symptoms usually resolve spontaneously. Some patients with severe abdominal findings have been treated with short courses of high doses of corticosteroids. Patients with severe glomerular involvement may benefit by modalities used to treat patients with severe IgA nephropathy. Although most patients with HSP recover fully, patients with a more severe nephritic or nephrotic presentation and more severe glomerular damage on renal biopsy have an unfavorable long-term prognosis.

Post-streptococcal Glomerulonephritis

Acute post-streptococcal glomerulonephritis may occur in either an epidemic form or as sporadic cases after infection with nephritogenic strains of group A β-hemolytic streptococci (Chapter 298). Post-streptococcal glomerulonephritis is largely a disease of childhood, but severe disease in adults has been well documented. The disease is most common after episodes of pharyngitis, but it can follow streptococcal infections at any site, and subclinical cases greatly outnumber clinical cases. Post-streptococcal glomerulonephritis is an acute immune complex disease characterized by the formation of antibodies against streptococci with the localization of immune complexes with complement in the kidney.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most cases are diagnosed by detecting hematuria, proteinuria, hypertension, and the nephritic syndrome (see Table 123-1) 10 days to several weeks after a streptococcal infection. Throat cultures and skin cultures of suspected sites of streptococcal involvement often may not be positive for group A β-hemolytic streptococci. A variety of antibodies (e.g., antistreptolysin O [ASLO], antihyaluronidase [AHT]) and a streptozyme panel of antibodies against streptococcal antigens (which includes ASLO, AHT, antistreptokinase, and anti-DNase) often show high titers, but a change in titer over time is more indicative of a recent streptococcal infection. More than 95% of patients with post-streptococcal glomerulonephritis secondary to pharyngitis and 85% of patients with streptococcal skin infections have positive antibody titers. The serum total hemolytic complement levels and C3 levels are decreased in more than 90% of patients during the episode of acute glomerulonephritis.

In a patient with a classic acute nephritic episode after a documented streptococcal infection, a change in streptococcal antibody titer, and a depressed serum complement level, a renal biopsy adds little to the diagnosis. In other cases, a biopsy may be necessary to confirm or refute the diagnosis. On light microscopy (Fig. 123-8), glomeruli are markedly enlarged and often fill Bowman's space. Glomeruli exhibit hypercellularity owing to an infiltration of monocytes and polymorphonuclear cells and a proliferation of the glomerular cellular elements. The capillary lumens often are compressed by the glomerular hypercellularity. Some cases demonstrate extracapillary proliferation with crescent formation. On immunofluorescence microscopy, there is coarse granular deposition of IgG, IgM, and complement, especially C3, along the capillary wall. Electron microscopy shows large dome-shaped, electron-dense subepithelial deposits resembling the humps of a camel at isolated intervals along the GBM.

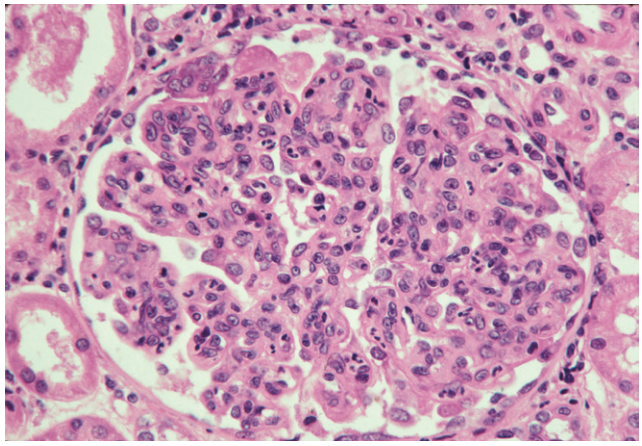

FIGURE 123-8. Post-streptococcal glomerulonephritis with hypercellular glomerulus filling Bowman's space and infiltrated by polymorphonuclear and other cells.

TREATMENT AND PROGNOSIS

Rx

Therapy is symptomatic and directed at controlling the hypertension and fluid retention with antihypertensive agents (see Tables 67-5 and 67-7 in Chapter 67) and diuretics. In most patients, post-streptococcal glomerulonephritis is a self-limited disease, with recovery of renal function and disappearance of hypertension in several weeks. However, the presence of underlying renal disease, especially diabetic nephropathy, is associated with a worse prognosis. Proteinuria and hematuria may resolve more slowly over months.

Glomerulonephritis with Endocarditis and Visceral Abscesses

Various glomerular lesions are found in patients with acute and chronic bacterial endocarditis (Chapter 76). Although embolic phenomena can lead to glomerular ischemia and infarcts, a common finding is an immune complex glomerulonephritis. With *S. viridans* endocarditis, both focal and diffuse proliferative glomerulonephritides are common. With the increased incidence of *S. aureus* endocarditis, 40 to 80% of patients with endocarditis have clinical evidence of an immune complex proliferative glomerulonephritis. Glomerulonephritis is now more common with acute than subacute bacterial endocarditis, and the duration of illness is not an important determinant of the renal disease.

Patients often have hematuria and RBC casts in their urinary sediment, proteinuria ranging from less than 1 g/day to nephrotic levels, and progressive renal failure. Serum total complement and C3 levels are usually reduced. Renal insufficiency may be mild and reversible with appropriate antibiotic therapy, or it may be progressive and lead to dialysis and irreversible renal failure.

A proliferative immune complex glomerulonephritis can occur in patients with deep visceral bacterial abscesses and infections, such as empyema of the lung (Chapter 99) and osteomyelitis (Chapter 296). Immune complex forms of acute glomerulonephritis also have been noted in patients with bacterial pneumonias, including *Mycoplasma* (Chapter 325), and patients with chronically infected cerebral ventriculoatrial shunts for hydrocephalus. Many patients have nephrotic-range proteinuria and only mild renal dysfunction. With appropriate antibiotic therapy, most patients' glomerular lesions heal, and renal function recovers.

TABLE 123-5 CLASSIFICATION OF RAPIDLY PROGRESSIVE ("CRESCENTIC") GLOMERULONEPHRITIS

PRIMARY
Type I: Anti–glomerular basement membrane antibody disease, Goodpasture's syndrome (with pulmonary disease)
Type II: Immune complex mediated
Type III: Pauci-immune (usually antineutrophil cytoplasmic antibody-positive)
SECONDARY
Membranoproliferative glomerulonephritis
Immunoglobulin A nephropathy, Henoch-Schönlein purpura
Post-streptococcal glomerulonephritis
Systemic lupus erythematosus
Polyarteritis nodosa, hypersensitivity angiitis

TABLE 123-6 COMMON RENAL DISEASES WITH ASSOCIATED PULMONARY DISEASES

DISEASE	MARKER
Goodpasture's syndrome	+Anti–glomerular basement membrane antibodies
Wegener's granulomatosis, polyarteritis	+Antineutrophil cytoplasmic antibodies
Systemic lupus erythematosus	+Anti-DNA antibodies, low complement
Nephrotic syndrome, renal vein thrombosis, pulmonary embolus	+Lung scan or +CT angiography
Pneumonia with immune complex glomerulonephritis	Low complement, circulating immune complexes
Uremic lung	Elevated creatinine level

CT = computed tomography.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) represents a variety of glomerular diseases that are notable for progression to renal failure in a matter of weeks to months (Table 123-5). Patients with primary RPGN can be divided into three patterns as defined by immunologic pathogenesis: type I, with anti-GBM disease (e.g., Goodpasture's syndrome); type II, with immune complex deposition (e.g., SLE, Henoch-Schönlein purpura, post-streptococcal); and type III, without immune deposits or anti-GBM antibodies (so-called pauci-immune, usually ANCA-positive RPGN). The renal biopsy in all RPGN shows extensive extracapillary proliferation, that is, crescent formation.

ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

The disease has two peaks of occurrence: in the third decade of life in men and in women after 60 years of age. Anti-GBM disease (Table 123-6) is caused by circulating antibodies that are directed against the noncollagenous domain of the α_3 chain of type IV collagen and that damage the GBM. The result is an inflammatory response, breaks in the GBM, and the formation of a proliferative and often crescentic glomerulonephritis. If the anti-GBM antibodies cross-react with and damage the basement membrane of pulmonary capillaries, the patient develops pulmonary hemorrhage and hemoptysis, an association called *Goodpasture's syndrome*.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients present with a nephritic picture (see Table 123-1). Renal function may deteriorate from normal to dialysis-requiring levels in a matter of days to weeks. Patients with pulmonary involvement may have life-threatening hemoptysis with dyspnea and with diffuse alveolar infiltrates on chest radiograph.

The pathology of anti-GBM disease shows a proliferative glomerulonephritis, often with severe crescentic proliferation in Bowman's space. There is linear deposition of immunoglobulin (usually IgG) along the GBM by immunofluorescence (Fig. 123-9), but electron microscopy does not show any electron-dense deposits.

Although the treatment of this rare disease has not been studied in large controlled trials, intensive immunosuppressive therapy with cyclophosphamide (e.g., 2 mg/kg/day as tolerated) and corticosteroids (e.g., pulse methylprednisolone, 15 to 30 mg/kg to a maximum of dose of 1000 mg intravenously daily for three doses, followed by oral prednisone, 1 mg/kg per day to a maximum of 60 to 80 mg/day and slowly tapered after achieving clinical remission) to reduce the production of anti-GBM antibodies, combined with daily plasmapheresis to remove circulating anti-GBM antibodies, has been successful in many patients. Rapid treatment is recommended to prevent irreversible renal damage and is necessary in patients with pulmonary hemorrhage. The optimal duration of therapy is uncertain, but daily plasmapheresis should be performed, preferably until anti-GBM antibody is undetectable, and corticosteroids and cyclophosphamide should be continued until clinical remission is achieved, typically between 3 and 6 months. Patients who already require dialysis at the time of treatment generally do not regain renal function despite aggressive therapy.

IMMUNE COMPLEX RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Type II RPGN, which is associated with immune complex–mediated damage to the glomeruli, may occur with idiopathic glomerulopathies, such as IgA nephropathy and MPGN, or with postinfectious glomerulonephritis and SLE. The therapy for IgA nephropathy and MPGN was discussed earlier.

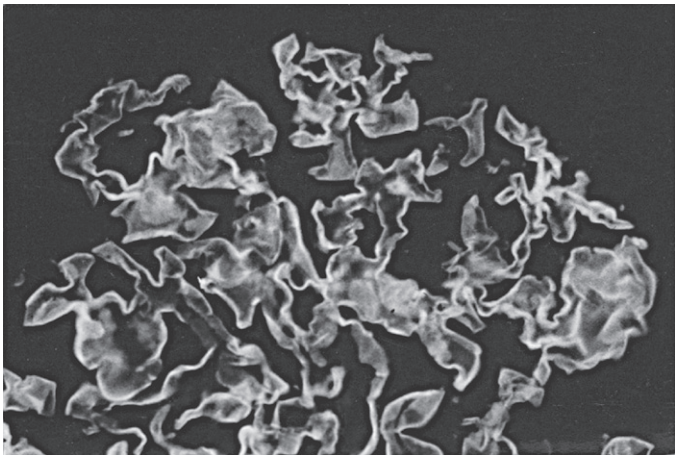

FIGURE 123-9. Anti–glomerular basement membrane (GBM) glomerulonephritis. An immunofluorescence micrograph of a portion of a glomerulus with anti-GBM glomerulonephritis shows linear staining of GBM for immunoglobulin G (IgG) (fluorescein isothiocyanate anti-IgG stain, ×600). (From Falk RJ, Jennette JC, Nachman PH. Primary glomerular disease. In: Brenner BM, ed. Brenner and Rector's The Kidney. 7th ed. Philadelphia: Elsevier; 2004.)

Many cases of crescentic postinfectious glomerulonephritis resolve with successful treatment of the underlying infection. For the treatment of severe SLE, see later.

PAUCI-IMMUNE AND VASCULITIS-ASSOCIATED RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Pauci-immune type III RPGN includes patients with and without evidence of systemic vasculitis. Most patients have circulating ANCAs that are directed against components of neutrophil primary granules.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients often present with progressive renal failure and a nephritic picture (see Table 123-1). Patients who are perinuclear ANCA positive (antibodies usually directed against granulocyte myeloperoxidase) more often have a clinical picture akin to that of microscopic polyangiitis (Chapter 278) with arthritis, leukocytoclastic angiitis, and constitutional and systemic signs. Patients who are cytoplasmic ANCA positive (antibodies usually directed against a granulocyte serine proteinase, anti-PR3) more often have Wegener's granulomatosis (Chapter 278) associated with their glomerulonephritis. However, there is considerable overlap among these groups, and some patients have both ANCA and anti-GBM antibodies (Fig. 123-10). Although there is no direct correlation between ANCA titers and disease activity, patients with high titers (especially high anti-PR3 titers) and those with a four-fold increase in titers are more likely to have flares of their disease.

TREATMENT AND PROGNOSIS

Rx

For induction therapy, combination therapy with corticosteroids (e.g., pulse methylprednisolone, 10-15 mg/kg/day up to a maximum of 500-1000 mg intravenously daily, for 3 days, followed by oral prednisolone, 1 mg/kg/day)

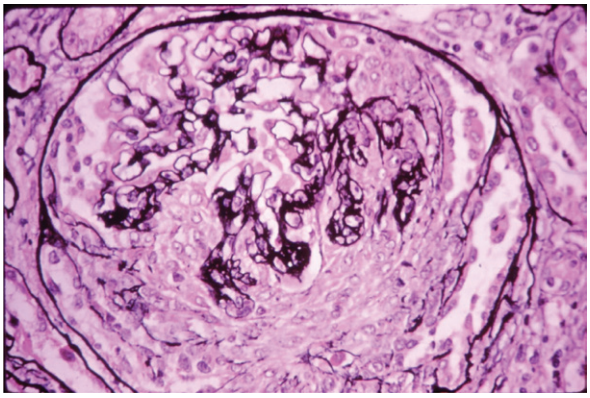

FIGURE 123-10. Crescentic glomerulonephritis typical of both anti–glomerular basement membrane disease and antineutrophil cytoplasmic antibody–positive pauci-immune glomerulonephritis.

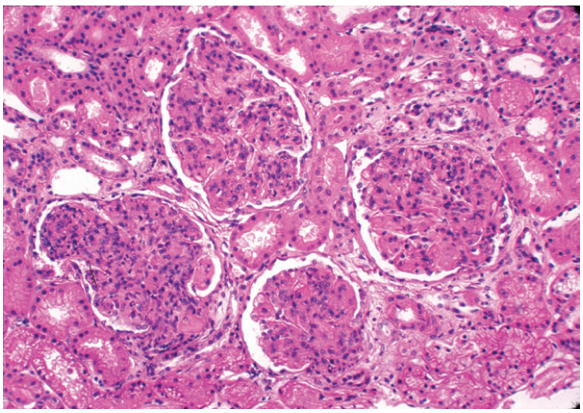

FIGURE 123-11. Diffuse proliferative lupus nephritis with involvement of all glomeruli.

and cyclophosphamide (e.g., 15 mg/kg intravenously every 2 to 3 weeks or 1.5 to 2 mg/kg/day orally), with or without plasmapheresis, has markedly improved renal and patient survival rates in patients with Wegener's granulomatosis (Chapter 278) and microscopic polyangiitis (Chapter 278). Methotrexate (20 to 25 mg per week orally for 12 months) is as effective as cyclophosphamide in achieving remission but leads to a higher relapse rate, so it should be limited to non-organ- or non-life-threatening disease, in which it is a less toxic alternative to cyclophosphamide. In severe renal vasculitis, renal survival, but not patient survival, is improved with the addition of plasmapheresis.[6] Rituximab (375 mg/m^2 weekly for 4 weeks) is as effective as cyclophosphamide at 6-month follow-up.[7] Maintenance regimens using azathioprine (1.5 mg/kg/day) or methotrexate (20 to 25 mg/week) should be administered for 12 to 18 months after achieving remission.[8] Corticosteroids should be slowly tapered off, as determined by the presence of clinical symptoms. Ongoing trials include the comparison of mycophenolate mofetil to azathioprine for maintenance therapy of ANCA-positive vasculitis.

As in all forms of RPGN, renal function may deteriorate rapidly. In pauci-immune RPGN, high-risk patients include older patients, patients with severe pulmonary involvement, and patients with severe renal failure. Analyses have found no difference in prognosis in patients with or without documented true arterial vasculitis or with crescentic or focal segmental necrotizing glomerulonephritis.

GLOMERULAR DISEASES ASSOCIATED WITH GENETIC DEFECTS

Some patients, often with a history of similar findings in siblings and other relatives, have a hereditary nephritis.

Alport syndrome is a hereditary form of glomerulonephritis that often presents with asymptomatic urinary findings. In approximately 85% of cases, it is an X-linked condition with hematuria and proteinuria, often in association with high-pitched hearing loss and abnormalities of the lens of the eye (lenticonus). The defect in most of these cases is localized to a mutation in the α_5 chain of type IV collagen (COL4A5). Other families have different patterns of inheritance, more often with mutations in the α_3 and α_4 chains of type IV collagen (COL4A3, COL4A4). Although the light microscopy findings vary from mild mesangial proliferative to advanced sclerosing lesions depending on the stage of biopsy, electron microscopy typically shows areas of GBM thinning and areas of basement membrane splitting with lamellations. Some patients with mutations in the collagen IV gene have microhematuria and proteinuria with areas of extreme basement membrane thinning on electron microscopy. In males, Alport's syndrome often leads to progressive glomerulosclerosis and ESRD.

Fabry's disease (Chapter 215), which is caused by an X-linked recessive genetic defect of α-galactosidase, leads to the deposition of ceramide trihexose in the kidneys and other organs. It may cause progressive proteinuria and renal insufficiency in males and in some female carriers. It also is associated with telangiectasias of the skin, typically in the bathing suit area; acroparesthesias; cardiac abnormalities; and eye changes.

Nail-patella syndrome, associated with skeletal and nail deformities, is a rare cause of the nephrotic syndrome in children. It is due to an autosomal dominant mutation in the LMX1B transcription factor that regulates collagen, nephrin, and podocin gene expression.

TABLE 123-7 CLASSIFICATION OF LUPUS NEPHRITIS

CLASS	CLINICAL FEATURES
I. Minimal mesangial LN	No renal findings
II. Mesangial proliferative LN	Mild clinical renal disease; minimally active urinary sediment; mild to moderate proteinuria (never nephrotic) but may have active serology
III. Focal proliferative LN < 50% glomeruli involved A. Active A/C. Active and chronic C. Chronic	More active sediment changes; often active serology; increased proteinuria (about 25% nephrotic); hypertension may be present; some evolve into class IV pattern; active lesions require treatment, chronic do not
IV. Diffuse proliferative LN (>50% glomeruli involved); all may be with segmental or global involvement (S or G) A. Active A/C. Active and chronic C. Chronic	Most severe renal involvement with active sediment, hypertension, heavy proteinuria (frequent nephrotic syndrome), often reduced glomerular filtration rate; serology very active. Active lesions require treatment
V. Membranous LN glomerulonephritis	Significant proteinuria (often nephrotic) with less active lupus serology
VI. Advanced sclerosing LN	More than 90% glomerulosclerosis; no treatment prevents renal failure

LN = lupus nephritis.

Systemic Lupus Erythematosus

Renal involvement may greatly influence the course and therapy of SLE (Chapter 274). Although the incidence of clinical renal disease in SLE varies from 15% to 75%, histologic evidence of renal involvement is found in most biopsy specimens.

The International Society of Nephrology classification of lupus nephritis uses light microscopy, immunofluorescence, and electron microscopy to classify each biopsy in order to separate milder mesangial lesions and bland membranous lupus nephritis from true proliferative lupus nephritis (Table 123-7). In general, class I and II patients have mild lesions that require no therapy directed at the kidney. All patients with class IV lesions on biopsy deserve some form of vigorous therapy for their lupus nephritis. Many class III patients, especially those with active necrotizing lesions and large amounts of subendothelial deposits (Fig. 123-11), also benefit from therapy. For class V patients, the optimal therapy is less clear, and recommendations vary from vigorous treatment of all patients with membranous lupus nephritis to reserving such therapy for those with serologic activity or more severe nephrotic syndrome. Vigorous therapy of lupus nephritis now emphasizes monthly high-dose intravenous cyclophosphamide therapy (0.5 to 1 g/m^2) for 6 months combined with intravenous methylprednisolone (1000 mg/m^2) as the best regimen for preventing flares of disease or progression to renal failure. Daily oral mycophenolate mofetil (target dose, 1500 mg twice daily) appears to be equally effective in inducing remissions of severe lupus nephritis.[9] Maintenance therapy with mycophenolate mofetil (500 to 1000 mg twice daily) or azathioprine (1 to 3 mg/kg/day) is more effective and less

toxic than continued intravenous cyclophosphamide therapy after the 6-month induction period. Rituximab, an anti-CD20 monoclonal antibody, has not proved beneficial when added to full doses of other immunosuppressive agents in controlled trials of patients with SLE renal disease. Other agents under investigation include blockers of T- and B-cell costimulatory molecules, and anti-B LyS therapy.

Many patients with lupus nephritis (40 to 50%) produce autoantibodies against certain phospholipids, including anticardiolipin antibodies. If these patients experience clotting in the glomeruli and arterioles, they require anticoagulation or antiplatelet agents, or both, as well as immunosuppressive medications.

Diabetes Mellitus

Diabetic nephropathy, which is the most common form of glomerular damage seen in developed countries, is discussed in detail in Chapter 126.

Amyloidosis

Renal amyloid deposits, whether due to AL or to AA amyloid, are predominantly found within the glomeruli, where they often appear as amorphous eosinophilic extracellular nodules (Chapter 194) that stain positively with Congo red and display apple-green birefringence under polarized light. By electron microscopy, amyloid appears as nonbranching rigid fibrils 8 to 10 nm in diameter.

Although almost 80% of patients with AL amyloid have renal disease, amyloidosis is a disease with multisystem involvement. Renal manifestations include albuminuria and renal insufficiency. Approximately 25% of patients with AL amyloid present with the nephrotic syndrome, which eventually is diagnosed in up to one half of patients. Patients may present with symptoms referable to cardiac involvement (Chapter 60) or neuropathy (Chapter 428), as well as with renal symptoms. Diagnosis may be made from organ biopsy other than the kidney (e.g., gingival biopsy, rectal biopsy, or fat pad biopsy). Treatment strategies for renal AL amyloidosis are similar to those for multiple myeloma and other plasma cell dyscrasias (Chapter 193).

AA amyloid is usually associated with chronic inflammatory conditions such as rheumatoid arthritis (Chapter 272), familial Mediterranean fever (Chapter 269), inflammatory bowel disease (Chapter 143), osteomyelitis (Chapter 296), and other chronic infections. Treatment is directed at the underlying inflammatory process. Specific therapy against the primary inflammatory disease (e.g., anti–tumor necrosis factor therapy in rheumatoid arthritis and colchicine in familial Mediterranean fever) can prevent fibrillogenesis in AA amyloid patients. Eprodisate, a compound that inhibits polymerization and deposition of amyloid fibrils (800 to 2400 mg/day based on renal function), can slow the progression of renal disease in patients with AA amyloidosis.[10]

Light Chain Deposition Disease

Light chain deposition disease, like AL amyloidosis, is a systemic disease caused by the overproduction and extracellular deposition of a monoclonal immunoglobulin light chain (Chapter 193). However, the deposits do not form β-pleated sheets, do not stain with Congo red, and are granular rather than fibrillar. Most patients with light chain deposition disease have a lymphoplasmacytic B-cell disease similar to multiple myeloma (Chapter 193).

Albuminuria is common, and the nephrotic syndrome is found in one half of patients at presentation, often accompanied by hypertension and renal insufficiency. On light microscopy, most glomeruli contain eosinophilic mesangial glomerular nodules. Some biopsies show associated light chain cast nephropathy with eosinophilic laminated casts obstructing the tubules, as seen in myeloma. By immunofluorescence, a single class of immunoglobulin light chain (κ in 80% of cases) stains in a diffuse linear pattern along the GBM, in the nodules, and along the tubular basement membranes. The treatment for most patients with light chain deposition disease is chemotherapy similar to that for myeloma (Chapter 193).

Fibrillary Glomerulopathy-Immunotactoid Glomerulopathy

Some patients with renal disease have glomerular lesions with deposits of nonamyloid fibrillar proteins ranging in size from 12 to more than 50 nm. Patients with these lesions have been divided into two groups: those with fibrillary glomerulonephritis with fibrils of 20 nm in diameter, and those with immunotactoid glomerulonephritis, a much rarer disease often associated with lymphoproliferative disorders, in which the fibrils are much larger (30 to 50 nm). Proteinuria is found in almost all patients, and hematuria, the nephrotic syndrome, and renal insufficiency eventually develop in most. There is no proven therapy for fibrillary glomerulopathy at this time.

Human Immunodeficiency Virus–Associated Nephropathy

Infection with human immunodeficiency virus (HIV) (Chapter 394) is associated with a number of patterns of renal disease, including acute renal failure and a unique form of glomerulopathy now called HIV-associated nephropathy. HIV-associated nephropathy is characterized by heavy proteinuria and rapid progression to renal failure. On light microscopy, findings on renal biopsy include diffuse global collapse of the glomerular tufts, severe tubulointerstitial changes with interstitial inflammation, edema, microcystic dilation of tubules, and severe tubular degenerative changes. On electron microscopy, tubuloreticular inclusions can be seen in the glomerular endothelium. The use of ACE inhibitors, in doses needed to achieve a target systolic blood pressure of 120 mm Hg or lower as tolerated (see Table 67-5 in Chapter 67), and highly active antiretroviral therapy (HAART) may slow the progression to renal failure and decrease proteinuria. Corticosteroids (e.g., prednisone, 1 mg/kg for 1 month followed by a taper over several months) may be beneficial in selected patients with HIV-associated nephropathy.

Mixed Cryoglobulinemia

Cryoglobulinemia (Chapter 193) is caused by the production of circulating immunoglobulins that precipitate on cooling and resolubilize on warming. Cryoglobulinemia may be found in association with many types of diseases, including infections, collagen-vascular disease, and lymphoproliferative diseases such as multiple myeloma and Waldenström's macroglobulinemia. Many patients with what was originally described as glomerulonephritis due to essential mixed cryoglobulinemia have been found to have hepatitis C–associated renal disease. Some patients develop an acute nephritic picture with acute renal insufficiency. Most patients have proteinuria, and about 20% present with the nephrotic syndrome. Most patients with renal disease have a slow, indolent course characterized by proteinuria, hypertension, hematuria, and renal insufficiency. Hypocomplementemia, especially of the early components C1q to C4, is a characteristic finding in cryoglobulinemic glomerulonephritis whether hepatitis C–related or idiopathic. Treatment of hepatitis C–associated cryoglobulinemia includes antiviral therapy (Chapter 151). When significant renal disease is present, various combinations of corticosteroids with or without rituximab or cyclophosphamide or plasmapheresis can be tried.

Thrombotic Microangiopathies

A number of systemic diseases, including hemolytic-uremic syndrome (Chapters 127 and 175), thrombotic thrombocytopenic purpura (TTP; Chapter 175), and the antiphospholipid syndrome (Chapter 179), as well as microangiopathy associated with drugs such as mitomycin and cyclosporine, are characterized by microthromboses of the glomerular capillaries and small arterioles. The renal findings may be dominant or only part of a more generalized picture of microangiopathy.

Renal manifestations of the thrombotic microangiopathies may include gross or microscopic hematuria, proteinuria that is typically less than 2 g/day but may reach nephrotic levels, and renal insufficiency. Patients may have oliguric or nonoliguric acute renal failure. The histologic findings in all of the microangiopathies resemble each other and include glomerular capillary thromboses, areas of ischemic damage, and intimal proliferation with luminal narrowing by thrombi of arterioles and small arteries. In all thrombotic microangiopathies, treatment includes correcting hypovolemia, controlling hypertension, and the use of dialytic support for those with severe renal failure. In TTP associated with an acquired or hereditary deficiency of the von Willebrand's convertase ADAMTS-13 and in some other cases, plasmapheresis with fresh-frozen plasma is beneficial (Chapter 175). In the antiphospholipid syndrome, anticoagulation with heparin and then warfarin is useful (Chapter 37).

124 TUBULOINTERSTITIAL DISEASES

ERIC G. NEILSON

TUBULOINTERSTITIAL NEPHRITIS

DEFINITION

Interstitial nephritis can be primary and begin in the tubulointerstitium or appear as a secondary event and spread from blood vessels, including the glomerular capillaries. Although injury to the tubulointerstitial compartment can be the result of autoimmunity, a toxic insult, an infection, or exposure to a drug, the inflammatory process always has an immunologic component that leads to the release of tissue cytokines, which eventually convert tubular epithelia into fibroblasts to produce fibrosis.

Tubulointerstitial nephritis can be arbitrarily divided into acute and chronic types. The acute form of interstitial nephritis often begins abruptly. When inciting events subside, so does the nephritis, and the glomerular filtration rate tends to normalize, with little residual damage except in patients with preexisting disease. Chronic interstitial nephritis is persistent and over time reduces the number of functioning nephrons by encasing and dismantling them, with irreversible fibrosis. So-called toxic nephropathy is similar to this form of nephritis. Sometimes acute and chronic injury are difficult to distinguish because global destruction of the tubulointerstitium can occur within a matter of weeks.

EPIDEMIOLOGY

Acute interstitial nephritis appears unexpectedly in otherwise healthy individuals from a variety of causes. About 1% of patients with hematuria and proteinuria have acute interstitial nephritis, and it is seen in 1 to 15% of autopsy series.

The development of acute interstitial nephritis is largely due to the use of pharmaceuticals. Other important causes include infection and idiopathic autoimmune diseases (Table 124-1). Penicillin moieties (less so nafcillin and piperacillin), cephalosporins, sulfa-like drugs, and nonsteroidal anti-inflammatory drugs (NSAIDs) top the list. NSAIDs cause both acute interstitial nephritis and chronic analgesic nephropathy. Diphtheria in children (Chapter 300), legionellosis (Chapter 322), leptospirosis (Chapter 331), histoplasmosis (Chapter 340), tuberculosis (Chapter 332), and DNA viruses such as cytomegalovirus (Chapter 384) and Epstein-Barr virus (Chapter 385) are well-recognized agents of acute interstitial nephritis. Anti–tubular basement membrane disease is a rare cause of autoimmune interstitial nephritis. Although sarcoidosis or the tubulointerstitial nephritis and uveitis (TINU) syndrome can manifest as acute interstitial nephritis on biopsy, they often quickly evolve into chronic disease.

All forms of injury to the kidney, regardless of origin, progress to end-stage renal disease through a terminal phase of chronic interstitial nephritis. In addition to glomerulonephritides (Chapter 123), cystic diseases (Chapter 129), and diabetes (Chapters 236 and 237), a wide variety of renal conditions start slowly in the tubulointerstitium and often go unrecognized until late in the course, when biopsy shows chronic interstitial nephritis.

Stones
Outlet obstruction
Vesicoureteral reflux
MISCELLANEOUS
Age-related vascular disease
Hypertension
Ischemia
Balkan (endemic) nephropathy
Radiation nephritis

Primary chronic interstitial nephritis can be caused by a variety of toxic, metabolic, hematologic, obstructive, and infectious processes. Ingestion of six or more tablets per day of acetaminophen, aspirin, or NSAIDs, alone or together, for at least 3 years puts patients at risk for analgesic nephropathy. A careful history of drug or toxin exposure, previous renal images, and a family history often point to a probable diagnosis (Table 124-2).

PATHOBIOLOGY

Pathophysiology

Regardless of the origin of renal inflammation, the kidneys do not fail until interstitial nephritis, fibrosis, and tubular atrophy develop. Interstitial nephritis is the pathologic equivalent of clinical progression because it is the final common pathway to permanent tissue damage. The degree of reduction in the glomerular filtration rate correlates with the degree of interstitial injury. Urinary flow is impeded by tubular obstruction. Increased vascular resistance causes progressive tubular injury and fibrosis. A net reduction in the cross-sectional area of peritubular vessels increases postglomerular resistance to the extent that the compensatory increase in glomerular hydrostatic pressure cannot fully restore filtration to normal levels. Tubuloglomerular feedback assumes increasing importance in the transition from acute to chronic glomerulonephritis when autoregulation of renal blood flow is disrupted by tubulointerstitial fibrosis. Loss of autoregulation by tubuloglomerular feedback results from the absence or insensitivity of the afferent arteriole. Perhaps more significant is the effect of interstitial pressure on the sensitivity of the feedback mechanism. Tubular atrophy may disrupt the normal renal osmotic gradient by decreasing sodium chloride transport along the proximal tubule or thick ascending loop of Henle. The result is poor abstraction of water from the filtrate, with hyposthenuria and polyuria. Such an increase in solute and water within the tubular fluid results in adaptive downregulation of the glomerular filtration process.

The antigen targets for the immune system in interstitial nephritis are poorly understood. Drugs act as haptens, mimic endogenous structures in the interstitium, alter regulation of the immune system, or function in some combination of the foregoing. Bacteria, fungi, and viruses can infect the kidney and cause mononuclear cell infiltration or activate Toll-like receptors on tubular epithelia, which subsequently educate the adaptive immune response to events in the interstitium. Autoimmune diseases such as anti–tubular basement membrane disease or spontaneous interstitial nephritis remain confined to the kidney, whereas systemic diseases spread to the kidney where they cause persistent, chronic interstitial nephritis.

Although the adaptive immune response is similar to that of other tissues, T-cell activation figures prominently in interstitial nephritis. Antibodies (anti–tubular basement membrane disease) and immune complex deposition along the tubular basement membrane (systemic lupus erythematosus) are rarely seen. Antigens presented by class II major histocompatibility complex molecules on macrophages, dendritic cells, and adjacent tubular epithelia, in conjunction with associative recognition molecules, engage the CD4/CD8 T-cell repertoires. The resultant cytokine and protease activity injures tubular nephrons and basement membranes and causes fibroblasts to form locally by epithelial-mesenchymal transition. Transforming growth factor-β (TGF-β), fibroblast growth factor 2, and platelet-derived growth factor are particularly active in this transition. If the nephritis persists, fibrogenesis dismantles nephrons and causes tubular atrophy; in late stages, the inflammatory reaction outgrows its survival factors, and lymphocytes and fibroblasts disappear by apoptosis and leave an acellular fibrotic scar.

Viruses, including Epstein-Barr virus, have long been suspected of contributing to idiopathic, chronic interstitial nephritis. Malacoplakia and xanthogranulomatous pyelonephritis are probably not defects in nephrogenesis but rather are destructive responses to bacterial inflammation in the interstitium. Focal abnormalities in kidney structure can be a nidus for infections associated with perinephric, psoas, or peritoneal abscesses. Children with vesicoureteral reflux can have chronic or repeating episodes of pyelonephritis, but whether the reflux or the infection is more important to progression to renal failure is unclear. There is also no agreement on whether recurrent pyelonephritis by itself produces chronic interstitial nephritis in adults.

Pathology

Both kidneys are typically involved, except in cases of unilateral infection, obstruction, or trauma. The inflammatory reaction in acute interstitial nephritis consists mainly of T lymphocytes and monocytes, but neutrophils, plasma cells, and eosinophils can be present. The T cells are of a mixed phenotype with a distinct preference for $CD4^+$ lymphocytes. The infiltrative process is associated with interstitial edema, which displaces tubules away from one another and causes the kidneys to swell. The tubular basement membrane may be disrupted in more severe cases, but immune deposits are rarely found by immunofluorescence.

In chronic interstitial nephritis, the kidney assumes an irregular or contracted appearance. The tubular epithelia sit on thickened or disrupted tubular basement membranes and are often effaced against dilated lumens, and the tubules eventually dismantle and atrophy. *Chronic* is a relative term, because fibrotic changes can be seen within 7 to 10 days of continuing inflammation. Normal glomeruli in primary interstitial nephritis are eventually surrounded by periglomerular fibrosis and subsequently undergo segmental or global sclerosis. Chronic vascular thickening and glomerular changes are present in advanced stages of disease, so pathologic determination of the primary cause may be difficult in some biopsy samples. Progressive glomerular sclerosis also occurs with aging and must be factored in when interpreting the biopsy findings.

A third pathologic category, granuloma formation, can be seen in either acute or chronic interstitial nephritis. In acute granulomatous interstitial nephritis, granulomas are sparse and non-necrotic, and giant cells are rare. The granulomas in chronic interstitial nephritis contain an abundance of giant cells, and those caused by tuberculosis may become necrotic. Drugs are

a common cause of this lesion in the acute setting, and most of the drugs associated with acute interstitial nephritis have been reported to cause granuloma formation. In the absence of drug exposure, sarcoidosis (Chapter 95), Wegener's granulomatosis (Chapter 278), histoplasmosis (Chapter 340), or tuberculosis (Chapter 332) should be considered, depending on the context, when numerous granulomas are present. The renal granulomas seen in Wegener's granulomatosis are almost always accompanied by glomerular and vascular pathology.

ACUTE INTERSTITIAL NEPHRITIS

CLINICAL MANIFESTATIONS

Most patients present with an asymptomatic rise in the serum creatinine level or an abnormal urinalysis, and it is important to consider acute interstitial nephritis in any patient with an unexplained precipitous diminution in renal function. Because injury is often asymptomatic, patients may already have substantial renal failure on initial presentation. Patients may also present with nonspecific symptoms such as lethargy or weakness, and many patients have fever and oliguria owing to severe acute kidney injury (Chapter 122).

Several features can distinguish acute interstitial nephritis from acute tubular necrosis (Chapter 122) or glomerulonephritis (Chapter 123) (Table 124-3). Fever and occasional flank pain over the kidneys occur in infection or with drug-induced acute interstitial nephritis. Lumbar pain, sometimes unilateral, is due to distention of the renal capsule. Allergic reactions are associated with maculopapular rash, fever, and eosinophilia, but the entire triad is seen in less than 33% of patients, and such signs are uncommon when NSAIDs cause acute interstitial nephritis.

The course of renal failure in acute interstitial nephritis takes several days to weeks and follows the kinetics of the primary immune response. However, renal failure can be precipitous, especially in patients re-exposed to a previous agent. Rarely, the course can be protracted, with the glomerular filtration rate declining over a period of months if the diagnosis is not recognized. This protracted course is more common with diuretic-induced interstitial nephritis. The onset of drug-induced nephritis ranges from days to weeks after the initiation of therapy, and a previous allergic history is rare. The classic setting for a drug reaction is a febrile patient with an infectious process and who defervesces while taking antibiotics but then develops recurrent fever several days later.

DIAGNOSIS

Urinalysis is particularly helpful. Mild to moderate proteinuria and hematuria are seen in most cases, and gross hematuria is observed occasionally. The sediment typically shows red and white blood cells, and white blood cell casts are commonly seen. Conversely, red blood cell casts suggest a glomerular diagnosis. The finding of eosinophils in the urine supports the diagnosis of allergic interstitial nephritis, but the absence of eosinophiluria does not exclude the diagnosis of acute interstitial nephritis.

An elevated serum creatinine level is usually the first abnormal laboratory result in renal injury. The normal serum creatinine of 0.6 to 1.3 mg/dL varies with muscle mass, age, and gender. Early recognition of acute interstitial nephritis requires a high degree of clinical suspicion because the serum creatinine level may be only mildly elevated even after the kidneys lose half their function.

The magnitude of proteinuria in acute interstitial nephritis is nearly always less than 3 g/24 hours and is typically less than 1 g/24 hours. Nephrotic-range proteinuria is not seen unless there is a coexisting glomerular lesion, such as a concurrent minimal-change lesion, or after exposure to NSAIDs. Many patients with acute interstitial nephritis also have a fractional excretion of sodium (FE_{Na}) greater than 1, but occasionally they are oliguric.

TABLE 124-3 TYPICAL CLINICAL MANIFESTATION OF ACUTE INTERSTITIAL NEPHRITIS

History of drug hypersensitivity or recent infection and taking antibiotics
Sudden onset of fever lasting several days to weeks
Variable degrees of hypertension
Rise in creatinine with FE_{Na} >1.0; no expected acute tubular necrosis or glomerulonephritis
Kidney size normal or increased
Hematuria with mild proteinuria (<1.0 g)
Presence of WBC casts and WBCs on urinalysis; rarely eosinophils

FE_{Na} = fractional excretion of sodium; WBC = white blood cell.

Imaging is of little diagnostic value. The kidney in acute interstitial nephritis is usually normal or slightly increased in size on echographic or tomographic images. Increased cortical echogenicity may correlate with diffuse interstitial infiltrates on renal biopsy. Gallium scanning is not particularly useful because a variety of other renal processes can cause gallium uptake, including minimal change glomerulonephritis, cortical necrosis, and acute tubular necrosis; in addition, acute interstitial nephritis can be found on biopsy in those with a normal scan.

Differential Diagnosis

It is sometimes difficult to distinguish among nonoliguric acute tubular necrosis, acute interstitial nephritis, and glomerulonephritis without a biopsy. Selective tubular defects and tubular syndromes such as proximal acquired Fanconi's syndrome (bicarbonaturia with a plasma carbon dioxide [CO_2] content <20 mEq/L, aminoaciduria, phosphate wasting, uricosuria, and glycosuria) or distal renal tubular acidosis type 1 (urine pH >5.6, plasma CO_2 content <20 mEq/L, with low or high potassium) can be seen in subacute or chronic interstitial nephritis but argue against acute interstitial nephritis.

Biopsy

Ultimately, the diagnosis can be established with certainty only by renal biopsy, which confirms and assesses the extent of acute interstitial inflammation. A biopsy should be performed in patients with acute renal failure who have suggestive signs or symptoms of an interstitial process and in whom prerenal azotemia and obvious acute tubular necrosis cannot be excluded on clinical grounds (Table 124-4). In primary acute interstitial nephritis, the biopsy demonstrates inflammatory cells that typically spare the glomeruli until late in the course (Fig. 124-1A). Lesions that reduce renal function are usually diffuse, but drug-induced interstitial injury is often patchy, beginning deep in the cortex before spreading.

TREATMENT

Rx

Biopsy is important to confirm acute interstitial nephritis, because chronic interstitial fibrosis rarely responds to aggressive treatment. The principal intervention for acute interstitial nephritis is to remove the inciting drug or treat the infection. Switching to different derivatives of a suspected drug is unwise. Concomitantly, or if the serum creatinine concentration does not fall after a few days, steroids (prednisone 0.75 to 1.0 mg/kg orally) can be given daily for approximately 1 week. If no further improvement occurs, oral cyclophosphamide (1 to 2 mg/kg/day) can be added for several more weeks. In patients who respond, cyclophosphamide can be steroid sparing, particularly in those with persistent sarcoidosis. It is important not to continue high-dose immunosuppression without some evidence of benefit because immunosuppressive drugs in patients with azotemia can lead to serious infection and even death. It is better to reserve these drugs for use with kidney transplantation if the primary disease does not respond.

PROGNOSIS

The prognosis for acute interstitial nephritis is good if it is recognized early. Early removal of offending agents or prompt treatment with antibiotics or immunosuppressive drugs can be renoprotective.

CHRONIC INTERSTITIAL NEPHRITIS

CLINICAL MANIFESTATIONS

Patients with primary chronic interstitial nephritis typically have elevated levels of serum creatinine and signs and symptoms of renal failure, including

TABLE 124-4 WHEN TO CONSIDER A RENAL BIOPSY TO DIAGNOSE NEPHRITIS

The setting, history, or clinical findings do not support a diagnosis of acute tubular necrosis or volume depletion
The clinical setting warrants a tissue diagnosis to determine the type of lesion, the extent of involvement, or the degree of fibrosis
The patient is stable enough to undergo biopsy and receive immunosuppressive drugs
The physician believes that the choice of therapy or the length of treatment is partially determined by the type of tissue injury

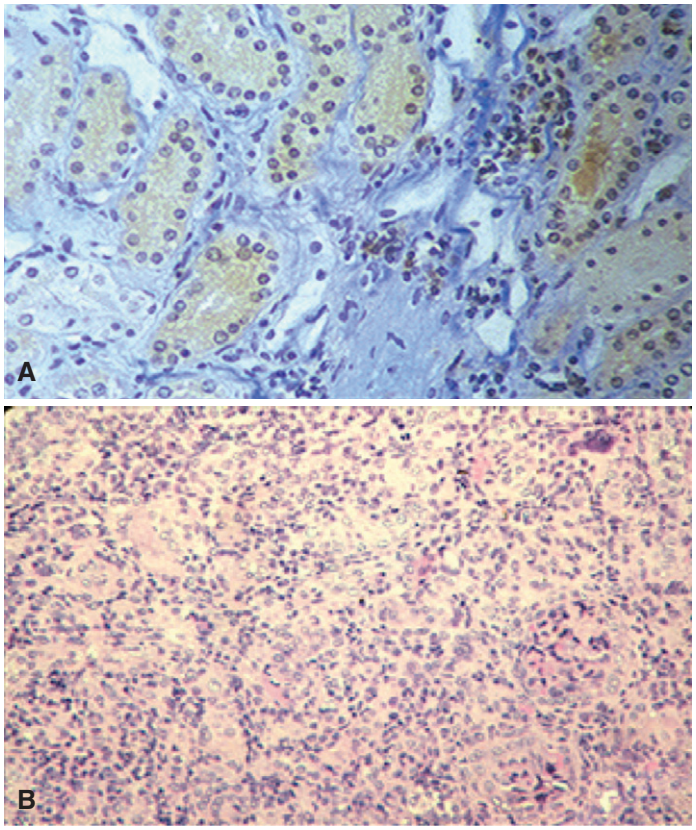

FIGURE 124-1. Tubulointerstitial nephritis on biopsy. A, Acute interstitial nephritis can be most aggressive when the interstitium is crowded with mononuclear cells and giant cells that destroy nearly all tubular nephrons (hematoxylin-eosin). **B,** Chronic interstitial nephritis is a slower process, with substantial collagen deposition (blue color; trichrome), tubular dropout, and fibroblasts in the interstitial spaces widened by fibrosis.

hematuria, hyposthenuria, nocturia, fatigue, and nausea. Urinalysis shows a fixed specific gravity of about 1.010, occasional glycosuria, and nonnephrotic–range proteinuria (often <1 g/L), with red and white blood cells and granular casts. Pyuria and positive urine cultures for bacteria are seen occasionally, and varying degrees of metabolic acidosis and hyperphosphatemia may be present. Before the glomerular filtration rate falls below 25 to 30 mL/minute, tubular acidosis is common. Anemia is often out of proportion to the degree of renal failure, and many patients have hypertension but only minimal edema until advanced stages of renal failure. Acquired Fanconi's syndrome can be seen in patients with a serum creatinine level less than 2.5 mg/dL in the setting of drug exposure, myeloma, human immunodeficiency virus (HIV) infection, lead exposure, and herbal nephropathy.

DIAGNOSIS

A careful dietary history is critical. As for any patient with evidence of renal failure, the evaluation includes laboratory tests to determine possible causes and severity. These tests include measures of renal function(serum creatinine level and blood urea nitrogen level), as well as levels of serum electrolytes, calcium, phosphate, uric acid, and albumin. Urinalysis shows a fixed specific gravity of about 1.010, occasional glycosuria, proteinuria (often <1 g/L), and red cells, white cells, and granular casts. Depending on the clinical situation, the search for specific causes may include serum and urine protein electrophoresis, blood cultures, and serologic tests for autoimmune diseases (e.g., cryoglobulin level, antinuclear antibodies [see Table 265-1 in Chapter 265], anti–neutrophil cytoplasmic antibody, and anti–glomerular basement membrane antibody levels).

Classic images of analgesic nephropathy on tomography are quite specific (Fig. 124-2) and show a decrease in overall kidney size, with atrophic scars and an irregular cortical contour, sometimes accompanied by papillary necrosis.

On biopsy (see Table 124-4), chronic interstitial nephritis is manifest by a cellular infiltrate that is eventually replaced by tubulointerstitial fibrosis (Fig. 124-1B). Infiltrates of lymphocytes and rare neutrophils are scattered and less abundant than in acute interstitial nephritis.

Specific Causes

Analgesics

Aspirin, acetaminophen, and NSAIDs alone or together are a source of toxic metabolites and can induce medullary ischemia and papillary necrosis, sometimes with papillary calcification. The likelihood of analgesic nephropathy from taking acetaminophen alone is much less than with the others. Uroepithelial malignancies also occur with increased frequency in this group of patients.

Aristolochic Acid Nephropathy

Aristolochic acid has been implicated as a cause of Balkan nephropathy and so-called Chinese herbal nephropathy. A growing number of people are taking vitamins and herbal preparations purchased from health food stores (Chapter 38). Some of these remedies contain botanicals that produce chronic interstitial nephritis. Patients who are dieting often use these remedies and are first seen when they already have late-stage disease, which increases the risk for uroepithelial malignancies.

Vascular Disease

Chronic renal ischemia from vascular injury can lead to interstitial nephritis, nephrosclerosis, and fibrosis. This is the classic renal lesion of untreated essential hypertension (Chapter 67). Similar injury is seen with aging, diabetes (Chapter 126), sickle cell disease (Chapter 166), and radiation nephritis (Chapter 19). This tubulointerstitial injury from the vascular diseases just mentioned is quite different from the aggressive necrosis seen with acute vasculitis. In patients taking calcineurin inhibitors such as cyclosporine or tacrolimus, renal ischemia from vasoconstriction can cause interstitial fibrosis that is sometimes difficult to distinguish from chronic allograft rejection.

Obstruction

Significant urinary obstruction (Chapter 125) owing to occlusion of both ureters by bladder tumors, cervical carcinoma, ureteral valve disease, or bladder outlet obstruction is an important cause of chronic interstitial nephritis. Complete or partial urinary tract obstruction is accompanied by a decline in glomerular filtration and classic tubular abnormalities, including diminished reabsorption of solutes, impaired excretion of H^+ and K^+, and a vasopressin-resistant concentrating defect in the medulla. Obstruction is associated with a fall in the glomerular filtration rate because of reduced plasma flow and hydraulic pressure associated with the release of angiotensin II, leukotrienes, and nitric oxide, a process leading to mononuclear cell infiltration. Growth factors such as TGF-β, released by infiltrating cells, may contribute to the interstitial and glomerular fibrosis. Obstruction is more common in men than in women and is part of the routine assessment of renal failure by renal ultrasound (Chapters 122 and 125). Almost all obstructed kidneys eventually become infected if the obstruction is not relieved.

Hypercalcemia

Hypercalcemia can decrease glomerular filtration through renal vasoconstriction, a decrease in the glomerular ultrafiltration coefficient, and volume depletion as a result of a vasopressin-resistant concentrating defect associated with nephrocalcinosis and calcium deposition around the basement membranes of the distal tubules and collecting ducts. Such deposition secondarily leads to mononuclear cell infiltration and tubular death. Nephrocalcinosis also occurs in normocalcemic disorders of augmented calcium absorption through the gut (sarcoidosis [Chapter 95], vitamin D intoxication [Chapter 253]), skeletal breakdown (neoplasms or multiple myeloma [Chapter 193]), or classic distal renal tubular acidosis.

Myeloma

The chronic renal failure of multiple myeloma (Chapter 193) is caused by several mechanisms, including cast nephropathy ("myeloma kidney"), coexistent volume depletion, hypercalcemia (Chapter 253), nephrocalcinosis (Chapter 253), and uric acid nephropathy. Proteinaceous casts form in dilated, atrophic distal nephron segments that are surrounded by multinucleated giant cells in interstitial infiltrates. The casts typically contain both Tamm-Horsfall protein and a pathologic light chain. Interstitial plasma cells and mononuclear infiltrates, calcifications in the interstitium, and amyloid deposits in the vessels and glomeruli are often present. Light chains are nephrotoxic by direct injury to tubular cells or through intrarenal obstruction from cast formation. In the setting of excess light chain production, the proximal tubule reabsorptive capacity is overwhelmed, leading to their urinary excretion as Bence Jones

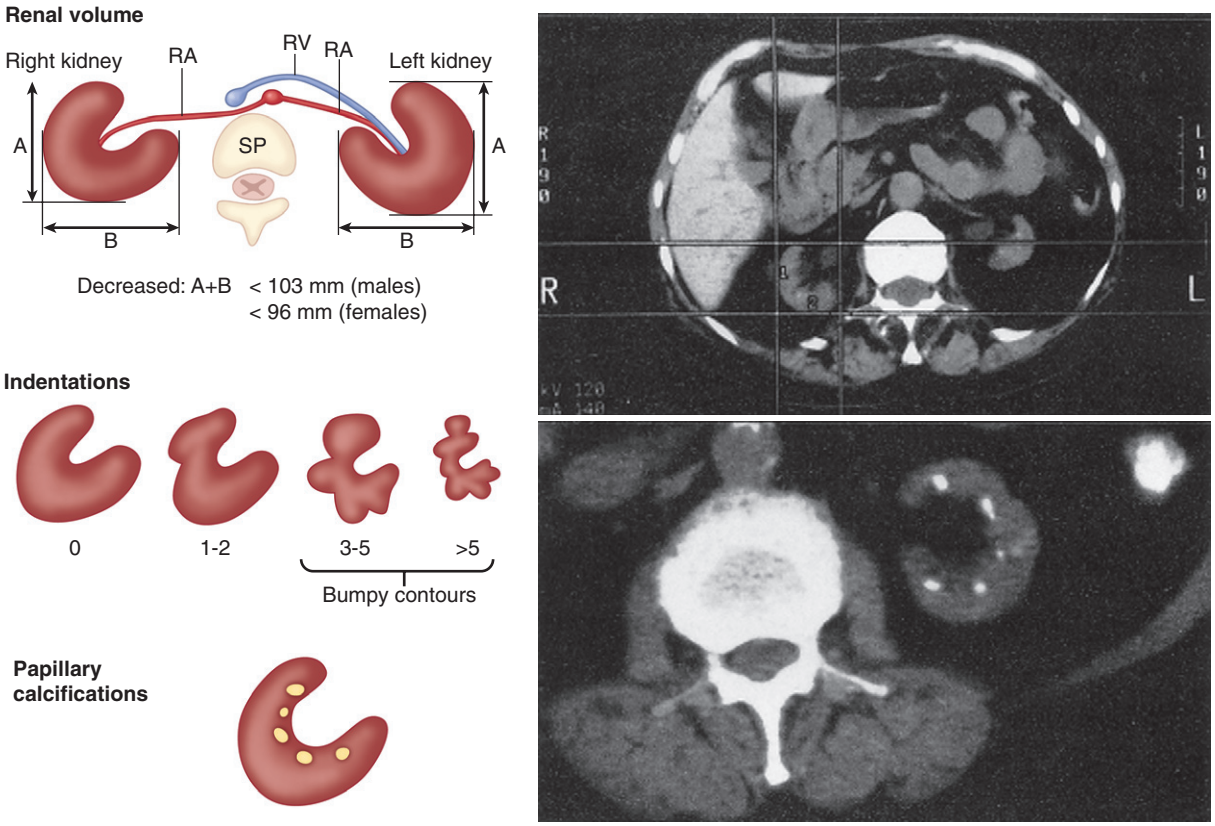

FIGURE 124-2. Renal changes in analgesic nephropathy seen by tomographic imaging. Structural changes, including reduced volume, nodularity, and calcifications, are seen on computed tomography. RA = right artery; RV = right vein; SP = spinal vertebra. (From Elseviers MM, De Schepper A, Corthouts R, et al. High diagnostic performance of CT scan for analgesic nephropathy in patients with incipient to severe renal failure. *Kidney Int.* 1995;48:1316.)

proteins. An elevated intratubular pressure partly accounts for the decline in glomerular filtration in experimental cast nephropathy.

Lead Toxicity

Epidemiologic analyses support the association between excess lead burden (Chapter 21) and chronic renal failure. Blood lead levels reflect only recent, not chronic, exposure and can be normal in patients with a significant lead burden. Lead preferentially deposits in the proximal tubule, and nuclear inclusions within proximal tubular cells are characteristic of lead nephropathy.

Ingestion of moonshine liquor, with its high lead content, can be an important historical clue to the diagnosis. In adults, lead nephropathy produces chronic interstitial nephritis, fibrosis, and nephrosclerosis. Proximal tubular dysfunction may produce isolated tubule defects or a full Fanconi's syndrome. Patients often have recurrent gout, and hyperuricemia and hypertension may be present. Some laboratories can measure δ-aminolevulinic acid dehydratase, which is inhibited by lead. Although chelation studies may document lead burden, this test is difficult to perform in patients with renal failure. X-ray fluorescent measurements of in vivo skeletal lead stores correlate well with ethylenediaminetetraacetic acid (EDTA) chelation tests and have the advantage of being rapid and noninvasive.

Cadmium Toxicity

Cadmium nephropathy (Chapter 21) is seen in regions with contamination from smelters that result in prolonged low-level exposure. Cadmium is bound to metallothionein, and proximal tubular cells take up these complexes. The liver and kidney are the two major organs in which cadmium accumulates. Its half-life in the body is longer than 10 years. Like blood levels of lead, blood levels of cadmium fall after acute exposure because of extensive tissue deposition. Once a threshold of renal deposition is exceeded, excess cadmium is excreted in urine. Cadmium intoxication produces irreversible proximal tubular dysfunction, hypercalciuria, nephrolithiasis, and metabolic bone disease with pain (called "ouch-ouch" disease in Japan).

Hyperuricemia

Hyperuricemia, especially in acutely treated myeloproliferative disease, can cause acute renal failure. Many patients with chronic renal failure have serum uric acid levels higher than 10 mg/dL, attributable to diminished glomerular filtration and the effects of diuretics. However, most studies have not demonstrated an independent association of hyperuricemia with chronic interstitial disease that could not otherwise be attributed to hypertension, vascular disease, calculi, or aging.

TREATMENT

Chronic interstitial nephritis tends to progress slowly. Inciting factors such as obstruction, infection, drugs, or toxins should be removed whenever possible. Angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers (see Table 67-5 in Chapter 67) are used early to slow disease progression, with a systolic blood pressure goal of 130 mm Hg or less (Chapters 67 and 132), except when hyperkalemia limits their use. Early treatment of acidosis with oral sodium bicarbonate, starting at 600 mg three times daily. Anemia with erythropoietin (e.g., darbepoetin alfa 0.45 µg/kg weekly to keep the hemoglobin concentration between 10 and 12 g/L), hyperphosphatemia with oral phosphate binders (see Table 121-4 in Chapter 121), and hyperparathyroidism with calcitriol (starting at 0.25 µg/day) can improve performance status and protect against bone loss (Chapters 132 and 133). There is no clear role for immunosuppressive drugs in the treatment of chronic interstitial nephritis, except perhaps in early sarcoidosis (Chapter 95).

For certain specific causes of chronic interstitial nephritis, specific therapeutic approaches are warranted. For analgesic nephropathy, stopping analgesic use can help reduce progression. For hypercalcemia (Chapter 253), therapy is directed toward the primary disease: reduction of the serum calcium concentration, when appropriate, and correction of acid-base disturbances.

Appropriate therapy for presumed cast nephropathy in multiple myeloma includes chemotherapy to ameliorate excess light chain production (Chapter 193); treatment of hypercalcemia (Chapter 253); alkalinization of the urine with the addition of bicarbonate to hypotonic fluids; and avoidance of radiocontrast agents, which may enhance the nephrotoxicity of light chains. Loop diuretics should be used with caution, particularly in the setting of volume depletion.

EDTA is advocated as chelation therapy for lead toxicity (Chapter 21). The goal of chelation is to normalize the EDTA mobilization test. In occasional patients, this may arrest or reverse the progression of the renal failure.

PROGNOSIS

The prognosis for chronic interstitial nephritis is highly variable and depends on the underlying condition and on comorbid conditions, including cardiovascular disease and diabetes mellitus, which become increasingly common in these patients over time.

125 OBSTRUCTIVE UROPATHY

MARK L. ZEIDEL

DEFINITION

Each day in the average adult, 1.5 to 2 L of urine flows from the kidneys to the end of the urethra, a process that requires proper functioning of each renal pelvis, the ureters, bladder, and urethra. *Obstructive uropathy* occurs when a defect (structural or functional) in the urinary tract blocks or reduces urine flow. When obstructive uropathy impairs renal function, *obstructive nephropathy* ensues. Increased hydrostatic pressure from obstruction downstream may cause dilation of upstream elements of the urinary tract, or *hydronephrosis*. Because recovery of renal function is inversely related to the duration and severity of the obstruction, prompt recognition and treatment of obstructive uropathy can preserve renal function in this condition.

EPIDEMIOLOGY

Although there are few studies of unselected populations, autopsy series reveal a 3.1% frequency of hydronephrosis in all subjects (2.9% in females, 3.3% in males). Autopsy series of children younger than 16 years reveal hydronephrosis in 2.2% of boys and 1.5% of girls; 80% of hydronephrosis occurs in children younger than 12 months. In adults, hydronephrosis occurs with equal frequency in both sexes in those younger than 20 years, but owing to pregnancy and uterine cancer, it is more common in women than in men between the ages of 20 and 60 years. In those older than 60 years, obstructive uropathy is more common in men because of prostate disease. The annual frequency of hospitalization for obstructive uropathy in the United States is 166 per 100,000. Each year, about 2000 patients with a presumed diagnosis of obstructive nephropathy begin treatment for end-stage renal disease (ESRD), representing 2% of ESRD patients. Among these patients, 4% are younger than 20 years, 44% are aged 20 to 64 years, and the balance are older than 64 years.

PATHOBIOLOGY

Normal urine flow from the renal papilla requires the orderly contraction of the renal pelvis, which "milks" the urine into the proximal end of the ureter. The ureter drives the urine to the bladder by rhythmic peristalsis coupled with periodic opening of the ureterovesical junction. As the bladder fills, stretch is detected in the wall and possibly the urothelium, thereby activating relaxation reflexes that suppress contraction of the bladder wall musculature and tighten the urethral sphincter to allow the bladder to expand without large increases in intravesicular pressure (Fig. 125-1; Chapter 25). When filling reaches a critical level, the voiding reflex is initiated. Suppression of detrusor muscle contraction ends, and stimulation begins, while the urethral sphincter is relaxed, leading to the buildup of pressure needed for voiding. Obstructive uropathy may occur as a result of functional or mechanical defects. Functional failures include an inability to open the ureteropelvic or ureterovesical junction, failure to open the urethrovesical junction, or failure of bladder reflexes. Partial or complete mechanical blockade of the urinary tract at any level can lead to obstruction.

Obstruction can occur at any point along the urinary tract from the renal pelvis and proximal urethra to the end of the urethra (phimosis). Because diagnosis and treatment depend heavily on the location of the obstruction, disorders are classified by anatomic location and whether the obstruction is due to factors within the urinary tract (intrinsic obstruction) or factors outside the tract (extrinsic obstruction) (Table 125-1). Intrinsic obstruction

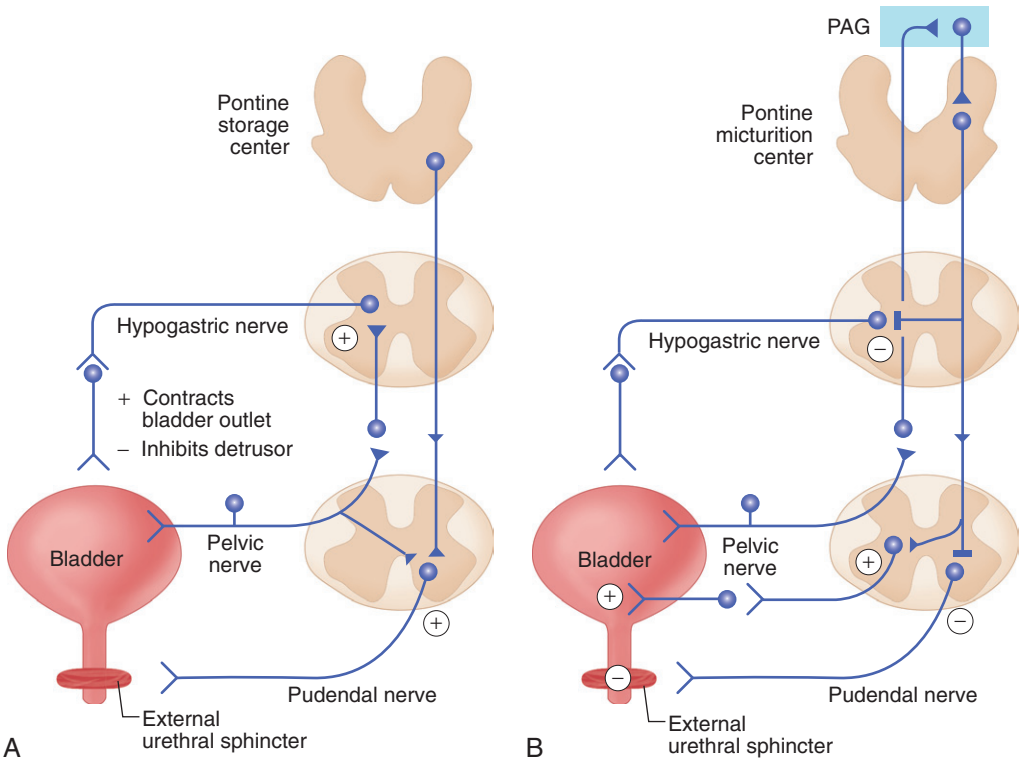

FIGURE 125-1. Neural circuits controlling continence and micturition. A, Reflexes mediating urine storage and continence. As the bladder fills, distention stimulates low-level firing of vesical afferents (pelvic nerve), which in turn stimulate sympathetic outflow to the bladder outlet (hypogastric nerve to contract the internal sphincter and inhibit detrusor activity) and pudendal outflow to the external urethral sphincter. These responses occur by spinal reflex pathways that promote continence. The pontine storage center in the rostral pons augments pudendal nerve firing to enhance external urethral sphincter activity. **B,** Voiding reflexes. As the bladder becomes fuller, afferents fire more intensely and activate spinobulbospinal reflex pathways passing through the pontine micturition center. These reflexes stimulate parasympathetic outflow to the bladder and urethral smooth muscle (hypogastric nerve) and inhibit sympathetic and pudendal outflow to the urethral outlet. Ascending afferent input from the spinal cord may pass through the periaqueductal gray (PAG) matter before reaching the cortex, leading to the sensation of urgency. (Modified from DeGroat WC. Integrative control of the lower urinary tract: a preclinical perspective. *Br J Pharmacol.* 2006;147[Suppl 2]:S25-S40.)

may be due to intraluminal or intramural causes. Intraluminal causes include stones or sludging of material, such as sloughed papillae or clots in papillary necrosis. Intramural causes may be anatomic (e.g., tumors or strictures) or functional (e.g., uncoordinated ureteral peristalsis or failure to open the ureteropelvic or ureterovesical junction). Extrinsic causes of obstruction are grouped according to the organ system causing the obstruction.

PATHOLOGY AND PATHOPHYSIOLOGY

Acute obstruction of urine flow out of the nephron reversibly alters renal blood flow, glomerular filtration, and tubular function. Acute unilateral obstruction may cause minimal clinical disturbance because, in the absence of other disease, the contralateral kidney compensates for the loss of function in the affected kidney. Obstructive uropathy is most often partial and of prolonged duration; this chronic obstruction leads to fibrosis and permanent damage.

In acute complete obstruction, glomerular filtration ceases and tubular transport is markedly reduced. Immediately after the onset of complete ureteral obstruction, blockage of urine flow markedly increases tubular intraluminal pressure, which is transmitted back to the glomerulus. Initial dilation of the afferent arteriole maintains glomerular filtration. However, local production of the potent vasoconstrictors angiotensin II and thromboxane A_2 soon decreases the renal blood flow, glomerular filtration pressure, and glomerular filtration rate. Angiotensin and thromboxane also contract glomerular mesangial cells, reducing the glomerular capillary bed surface area available for filtration. At the same time, prostaglandin E_2 and I_2 levels rise and attenuate the level of vasoconstriction.

Obstruction also disrupts the ability of renal tubules (including the proximal tubule, the medullary thick ascending limb of Henle, and the cortical and medullary collecting ducts) to absorb sodium, secrete potassium and acid, and concentrate and dilute the urine. Reduced tubular transport results from the local release of mediators, such as prostaglandin E_2, that inhibit transport, the local accumulation of macrophages, and the release of inflammatory mediators, as well as mechanisms intrinsic to tubular epithelial cells. When urine flow is halted or markedly slowed, reduced delivery of solutes to tubular cells slows the rate of apical sodium entry, resulting in reduced synthesis and deployment to the plasma membrane of crucial transporter proteins, such as Na^+, K^+-ATPase, and apical sodium entry pathways, such as the epithelial sodium channel and Na/K/Cl cotransporter. As obstruction becomes more prolonged, renal fibrosis and permanent damage ensue. In addition to attenuation of salt reabsorption, reduced solute reabsorption in the thick ascending limb leads to loss of high solute concentrations in the medullary interstitium. Obstruction also markedly reduces the synthesis and membrane trafficking of aquaporins, especially aquaporin 2. The combined impact of the absence of medullary solute accumulation and reduced aquaporin activity leads to an inability to concentrate and dilute the urine.

With bilateral complete obstruction, the loss of function of both kidneys leads to the accumulation of salt, water, and uremic toxins; acidosis; and hyperkalemia. Accumulation of salt and water leads to elevated levels of salt-wasting hormones, such as atrial natriuretic peptide, kinins, and prostaglandins, and reduced levels of salt-retaining hormones, such as angiotensin II, catecholamines, and aldosterone. These hormonal changes act synergistically with the postobstructive state of the kidneys to enhance glomerular filtration and reduce tubular salt reabsorption.

Obstructive nephropathy markedly attenuates the ability of distal nephron segments to secrete potassium and acid, leading to hyperkalemia and a non–anion gap metabolic acidosis. With acidemia, failure to acidify the urine may be revealed by a high urine pH (>5.5) and a positive urine anion gap (urine sodium and potassium higher than urine chloride), which indicates distal nephron failure to excrete ammonium in urine. In elderly patients, especially those with azotemia, chronic partial obstruction is associated with hyporeninemic hypoaldosteronism. In this condition, hyperkalemia and non–anion gap metabolic acidosis result from a combination of inadequate aldosterone production for the level of potassium and blood pH and an inadequate tubular response to aldosterone secondary to tubular dysfunction.

Chronic partial urethral obstruction, such as that caused by prostatic hypertrophy in men, can lead to dilation and remodeling of the bladder. Under normal circumstances, as the bladder fills, stretch receptors in the bladder wall and possibly in the epithelium sense the filling. Signaling via afferents to brain stem centers transmits efferent impulses to inhibit bladder wall contraction, permitting the bladder to fill with a modest increase in hydrostatic pressure (see Fig. 125-1). These bladder-filling reflexes also tighten the internal urethral sphincter and allow the maintenance of continence without the need for voluntary contraction of the external sphincter. However, bladder filling to volumes of 200 to 300 mL in women and 300 to 400 mL in men activates additional stretch receptors, stimulating brain stem micturition centers (see Fig. 125-1). Efferents from these centers augment reflex contraction of the bladder detrusor musculature, relax the internal sphincter, and alert the cortex of the need to void. As the bladder fills further, the micturition reflex becomes stronger, the urge to void becomes uncomfortable and urgent, and the bladder begins to contract against the voluntary, external sphincter, rendering it difficult to maintain continence.

With chronic urethral obstruction, micturition requires higher contractile pressure, resulting in detrusor muscle hypertrophy. The bladder empties less completely, and residual volumes increase. Initially, retained urine owing to incomplete emptying diminishes the volume capacity of the bladder between micturitions, thereby resulting in frequency and nocturia. Over time, with bladder remodeling and changes in autonomic reflexes, the transition from bladder accommodation to the micturition reflex may be delayed and occur at increasingly higher bladder-filling volumes. When the micturition reflex is suddenly activated in patients whose bladders are dilated, urgency, dribbling, and frank incontinence ensue. Some of these same features occur in women with pelvic floor disturbances that impede normal bladder function. Bladder wall remodeling and elevated pressures on voiding may increase back pressure up the ureters and result in the physiologic changes of chronic obstruction, including diminished ability to acidify and concentrate the urine, as well as reduced glomerular filtration.

The renal response to the release of obstruction depends on several factors, including whether the obstruction is unilateral or bilateral and the extent and duration of the obstruction. Release of acute unilateral obstruction leads to gradual reversal of renal vasoconstriction and rapid recovery of the glomerular filtration rate. Because tubular transport mechanisms may still be inhibited, postobstructive salt wasting, inability to secrete potassium and acid, and inability to concentrate and dilute the urine persist and lead to the production of a high quantity of isosthenuric urine (urine with a tonicity similar to that of plasma) from the affected kidney. However, the normal contralateral kidney compensates for these abnormalities in tubular transport. Release of an acute bilateral obstruction can lead to high volumes of urine output and striking salt wasting.

CLINICAL MANIFESTATIONS

The clinical appearance of obstructive uropathy depends on the extent (partial or complete), duration (acute or chronic), and location of the obstruction, as well as on whether one or both kidneys are affected (Table 125-2). Patients may be asymptomatic even with severe obstruction, especially when the obstruction has developed gradually.

Symptoms

In patients with acute obstruction, bladder distention caused by the inability to relax the urethral sphincter (e.g., postoperatively) gives rise to sharp pain. By contrast, significant bladder stretching may occur without pain in the setting of gradual urethral obstruction from prostatic enlargement.

Renal colic from the abrupt distention of the ureter is a common manifestation of the passage of a renal calculus (Chapter 128), with or without acute ureteral obstruction. Renal colic is a severe, stabbing pain localized to the flank (when the stone is in the upper third of the ureter) or radiating to the groin or pelvic structures (when the stone is located in the lower two thirds of the ureter).

Patients with chronic partial obstruction may have no symptoms or may have intermittent pain. Chronic partial ureteral obstruction may cause intermittent flank pain. Abdominal pain that radiates to the flank during voiding may indicate vesicoureteral reflux. Increasing the urine volume with the administration of fluid loads or diuretics may elicit pain in patients with partial obstruction by stretching the ureteral wall.

Symptoms such as reduced force and caliber of the urine stream, urinary frequency, hesitancy, incontinence, nocturia, postvoid dribbling, and urgency often arise with urethral obstruction. A neurogenic bladder may alter micturition and result in frequency, urgency, and incontinence. Incontinence may occur because an inadequate sensation of bladder fullness or an inability to void properly leads to overfilling of the bladder and reflex emptying (overflow incontinence).

In patients with complete bilateral ureteral obstruction, complete obstruction of a solitary functioning kidney, or complete obstruction to urine flow beyond the bladder, anuric acute renal failure occurs. Patients with partial obstruction may have normal urine volumes or polyuria. In some cases, partial obstruction prevents urinary concentration, leading to polyuria, increased thirst, and sometimes hypernatremia. Although unusual, a history of oligoanuria alternating with polyuria or the sudden onset of anuria strongly suggests obstructive uropathy.

Bilateral complete obstruction or complete obstruction of a single functioning kidney may cause signs, symptoms, and laboratory evidence of acute renal failure (Chapter 122), with volume overload, hypertension, and metabolic disturbances. By contrast, unilateral obstruction with a functioning contralateral kidney usually does not lead to manifestations of renal failure because the functioning kidney may compensate in large part for the failure of filtration and tubular transport in the obstructed kidney. If the obstruction affects both kidneys, patients may have symptoms of impaired renal function, including nocturia and polyuria from failure to concentrate the urine and increased levels of potassium, phosphate, creatinine, and blood urea nitrogen (Chapter 122).

TABLE 125-2 CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS IN URINARY TRACT OBSTRUCTION

- No symptoms (chronic hydronephrosis)
- Intermittent pain (chronic hydronephrosis)
- Elevated levels of blood urea nitrogen and serum creatinine with no other symptoms (chronic hydronephrosis)
- Renal colic (usually caused by ureteral stones or papillary necrosis)
- Changes in urinary output
  - Anuria or oliguria (acute renal failure)
  - Polyuria (incomplete or partial obstruction)
  - Fluctuating urinary output
- Hematuria
- Palpable masses
  - Flank (hydronephrotic kidney, usually in infants)
  - Suprapubic (distended bladder)
- Hypertension
  - Volume dependent (usually caused by chronic bilateral obstruction)
  - Renin dependent (usually caused by acute unilateral obstruction)
- Repeated urinary tract infections or infection refractory to treatment
- Hyperkalemic, hyperchloremic acidosis (usually caused by defective tubular secretion of hydrogen and potassium)
- Hypernatremia (seen in infants with partial obstruction and polyuria)
- Polycythemia (increased renal production of erythropoietin)
- Lower urinary tract symptoms: hesitancy, urgency, incontinence, postvoid dribbling, decreased force and caliber of the urinary stream, nocturia

Physical Examination

In patients with acute ureteral obstruction, the physical examination may be normal or it may reveal flank tenderness. Flank tenderness can denote obstruction or pyelonephritis. Renal colic may cause abdominal distention and evidence of reduced peristalsis with diminished bowel sounds. Kidneys enlarged by chronic hydronephrosis may be palpable on the abdominal examination or may cause costovertebral angle tenderness and flank rigidity. In patients with acute obstruction below the bladder, acute bladder distention may be detectable as a suprapubic mass, and the bladder may be tender. In the setting of bladder distention, the rectal examination in men may reveal prostatic enlargement, whereas the pelvic examination in women may reveal pelvic masses. Obstructive uropathy may cause hypertension owing to salt and water retention. Examination of the sensory and reflex pathways of the sacral nerves may reveal neurologic causes of urinary retention.

Hematuria

Laboratory Findings

Patients with obstruction may exhibit gross hematuria, especially in the setting of ureteral stones, which may cause bleeding by abrading the ureteral epithelium (urothelium) as they pass. Microscopic examination of the urine reveals round, regular red cells; this is different from hematuria from glomerular disease, in which red cells (because they cross the glomerulus and remain for prolonged periods in the tubules) appear dysmorphic. Gross hematuria from any cause may lead to clots, which themselves can cause obstruction.

A urinary tract infection in a younger man or repeated urinary tract infections without apparent cause suggest a structural lesion in the urinary tract and are often associated with partial or complete obstruction. Infection occurs more commonly in patients with obstruction involving the bladder or urethra, likely due to disruption of normal defenses against bacterial access and adherence to the bladder urothelium. The finding of unusual organisms (e.g., *Pseudomonas* or *Proteus* species) in noninstrumented patients suggests the disruption of normal defense mechanisms and possible obstruction.

Depending on the extent and duration of obstruction, obstructive uropathy impairs renal function. Hyperkalemia and a nonanion acidosis, owing to distal renal tubular acidosis (Chapter 130), commonly develop. Chronic and

more complete obstruction causes permanent renal damage and can lead to ESRD. Any patient with no previous history of kidney disease who has significant renal impairment should be evaluated for obstructive uropathy, especially if the urinary sediment is bland (Chapter 122). In addition, obstruction should be considered as a potential cause of accelerating deterioration of renal function in patients with underlying disease. In some obstructed kidneys, vasoconstriction may reduce cortical blood flow and oxygen tension, leading to increased erythropoietin production and polycythemia, which reverses with relief of the obstruction.

DIAGNOSIS

Because obstructive uropathy may be asymptomatic or may manifest in many different ways, the diagnosis may not be apparent. However, early diagnosis (Table 125-3) and prompt treatment reduce the extent of long-term renal damage.

Age, gender, and concomitant conditions often help identify the cause of obstruction. In children, congenital sources of obstruction at the ureteropelvic or ureterovesical junction are a major cause of ESRD. In adult women, complications of pregnancy or reproductive malignancies such as cervical or uterine cancer may cause obstruction due to compression of the ureters or ureterovesical junction. In older men, prostatic hypertrophy or cancer often causes urethral obstruction.

In outpatients, a history of renal colic, flank pain, or hematuria may suggest stone disease leading to ureteral obstruction. Changes in the volume or frequency of urination, including anuria, polyuria, or swings from oligoanuria to polyuria, may suggest obstruction. Bladder dysfunction is suggested by symptoms of frequency, urgency, and nocturia. In addition, a history of conditions that predispose to obstructive uropathy, such as sickle cell disease, chronic ingestion of high levels of pain relievers (papillary necrosis), previous stone disease, or abdominal cancer (which may lead to ureteral obstruction), should raise the suspicion of obstruction. Finally, the presence of a single functioning kidney should raise the possibility that unilateral obstruction may be causing azotemia. In the inpatient setting, monitoring the pattern of urine output may reveal oligoanuria or polyuria.

Laboratory Studies

Initial laboratory evaluation includes a careful urinalysis and standard chemistry panel. The urine may reveal hematuria in the case of stones, bacteriuria, numerous granulocytes in the setting of obstruction and infection, or a urine pH greater than 7.5 in the case of chronic infection with urea-splitting organisms. Serum chemistries may reveal hyperkalemia, non–anion gap acidosis, and, more rarely, hypernatremia. Corresponding urine chemistry evaluation may reveal a pH higher than 5.5, lack of a negative anion gap (see earlier), and isosthenuria. The urine sediment may also reveal evidence of crystals

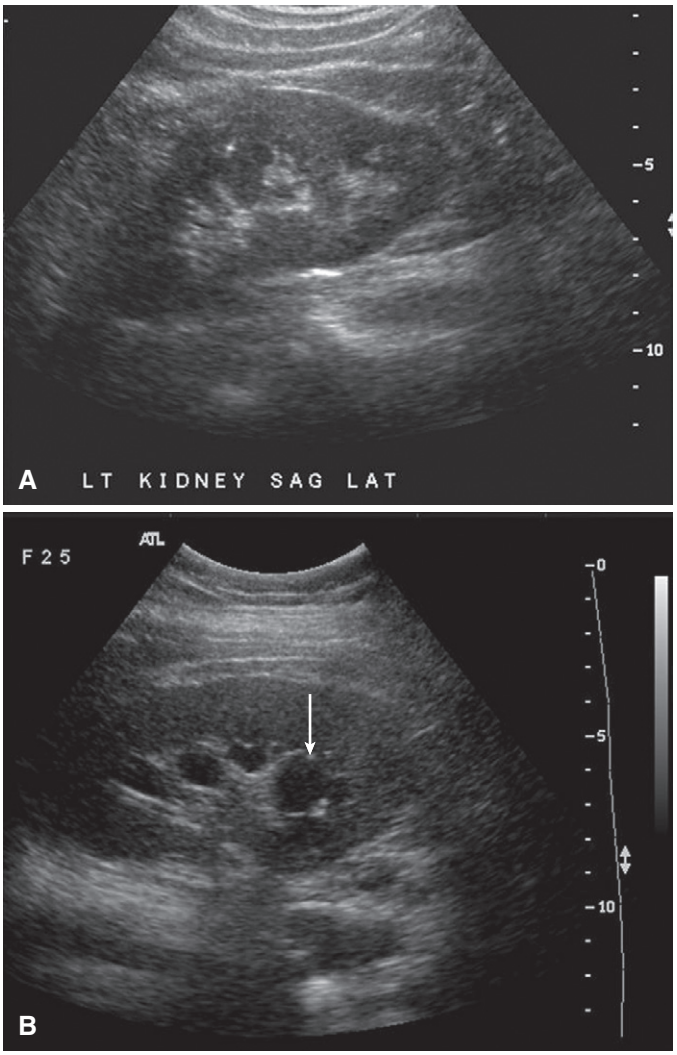

FIGURE 125-2. **A,** Renal ultrasound of a normal kidney. The outline of the kidney is clearly seen, and the calyces (darker areas) are small and somewhat indistinct. **B,** Renal ultrasound of an obstructed kidney. The arrow points directly at a dilated renal calyx. Other dilated calyces are seen as large, round, dark areas adjacent to the calyx pointed out by the arrow. For orientation, the tail end of the arrow overlies the margin of the renal cortex. (Courtesy Jonathan Kruskal, MD.)

(uric acid or calcium oxalate), suggestive of stone disease. In addition, laboratory measurements should include blood urea nitrogen and creatinine to assess the adequacy of glomerular filtration.

Diagnostic Testing

When obstructive uropathy is suspected, ultrasonography is the best screening modality because it is highly sensitive, safe, and inexpensive and does not expose the patient to contrast material or ionizing radiation. Because of its safety and low cost, ultrasonography is often used in patients with acute renal failure to rule out obstruction. Ultrasound may reveal dilation of the calyces, renal pelvis, and, on occasion, proximal ureter (Fig. 125-2). It is also the preferred test to diagnose a renal calculus (Chapter 128; see Fig. 125-2). False-positive findings (dilation in the absence of obstruction) occur in patients with congenital anomalies, during diuresis, and in many patients with ileal conduits. False-negative findings may occur because the pelvis and calyces fail to dilate despite obstruction, as may occur with retroperitoneal fibrosis or volume depletion. Because of the possibility of false-negative ultrasound results, computed tomography (CT) is warranted when the clinical setting strongly suggests obstruction and the ultrasound findings are negative. CT scanning may define the anatomic location of obstruction in patients found to have hydronephrosis on ultrasound, or it may identify obstruction in patients with negative ultrasound studies. In the setting of cancer or other structural lesions obstructing the ureters or invading the bladder, CT may help identify the cause of obstruction.

Diffusion-weighted magnetic resonance imaging (MRI) can noninvasively detect changes in renal perfusion and in tissue density that occur during acute ureteral obstruction, but the role of MRI in patients with suspected obstructive uropathy remains unclear. MRI is limited by the risk of nephrogenic systemic fibrosis in azotemic patients, especially if the glomerular filtration rate is below 30 mL/minute. Definitive diagnosis of the location of obstruction can be obtained by retrograde pyelography, in which contrast material is injected directly into the ureters via catheters inserted into the urethra and bladder, or by antegrade pyelography, in which the contrast material is injected into the renal pelvis via a percutaneous catheter. Retrograde pyelography is performed when obstruction has been diagnosed or is strongly suggested. This procedure precisely localizes the site of obstruction and guides the urologist in the placement of stents to clear the obstruction.

When bladder dysfunction or lesions in the bladder have been identified, retrograde cystograms may define bladder anatomy. In addition, cystometrography with urodynamic testing can define the force of detrusor function, determine whether the detrusor and sphincter act in a coordinated fashion (lack of coordination is referred to as *dyssynergy*), and define the extent to which pressure within the bladder is elevated and is causing obstruction to urine flow (Chapter 25).

Differential Diagnosis

Because obstructive uropathy may have subtle manifestations that mimic many other conditions, the differential diagnosis depends on the initial clinical symptoms and signs. Though suggestive of obstructive uropathy, anuria and acute renal failure (Chapter 133) may result from intrarenal diseases such as glomerulonephritis or acute tubular necrosis. Patients with polyuria, hypernatremia, and dilute urine may have nephrogenic or central diabetes insipidus (Chapters 236 and 237). Obstructive uropathy is a rare cause of nephrogenic diabetes insipidus. Patients with hyperkalemic hyperchloremic metabolic acidosis may have hyporeninemic hypoaldosteronism, which is associated with chronic mild obstruction or other tubular disorders (Chapter 124). Renal colic may resemble abdominal pain secondary to diseases of the gastrointestinal or reproductive tract, such as appendicitis (Chapter 144) or an ovarian cyst (Chapter 243), especially when the colic is associated with nausea, vomiting, and diaphoresis.

TREATMENT

Rx

Once obstructive nephropathy has been identified, therapy focuses on the rapid restoration of normal urine flow, treatment of any accompanying infection, and management of postobstructive complications. The degree to which renal function recovers depends on several factors, including the extent and duration of the obstruction and the extent of previous renal dysfunction.

Acute Obstruction

Complete obstruction causes acute renal failure. Because the extent and rate of recovery of renal function depend on the speed of relief, prompt resolution of obstruction obviates the complications of uremia and the need for acute dialysis in patients with bilateral obstruction or obstruction of a single functioning kidney. In the setting of antecedent renal disease, partial obstruction may lead to permanent renal damage, so prompt relief can salvage significant renal function. In all cases of obstruction, the urine should be examined and cultured to identify and treat infections (Chapter 292). In patients with urinary sepsis and obstruction, the sepsis cannot be treated successfully until the obstruction is relieved; in such patients, it is also crucial to look for perinephric abscesses and drain them if present.

The site of the obstruction and its cause determine the therapeutic approach. Obstruction in the urethra or owing to bladder dysfunction may be relieved by placement of a urethral catheter. If catheters cannot be passed through the urethra, urgent suprapubic cystotomy is needed, followed by a more permanent approach, such as surgical diversion or ileal conduits, to prevent recurrent obstruction. If the obstruction is in the upper urinary tract, retrograde ureteral catheters with stents or nephrostomy tubes may be needed to relieve the obstruction. Retrograde catheters have the advantage that internal stents can be left in place to restore normal voiding, avoiding the need to maintain percutaneous drainage tubes.

Acute Obstruction Caused by Calculi

Calculi (Chapter 128) are the most common cause of ureteral obstruction. The cornerstones of therapy include analgesia, relief of the obstruction, and treatment of concomitant infections (Chapter 292). Stones smaller than 6 mm often pass without procedural intervention, but larger (7 to 15 mm) stones are more likely to cause complete obstruction and are unlikely to pass without intervention. If the stone is above the pelvic brim and is less than 15 mm, extracorporeal shock wave or ultrasonic lithotripsy is 90% effective, with passage of the fragments within 3 months. It is important to increase the volume of urine flow after these approaches to help the patient pass the fragments. For stones located below the pelvic brim or for larger stones, endoureteroscopy with direct removal may be performed via catheters passed through the urethra. In all patients with stone disease, it is crucial to identify the cause and initiate appropriate measures to prevent further stones (Chapter 128). The common practice of routinely placing a ureteral stent after ureteroscopy increases irritative lower urinary symptoms without any demonstrable clinical benefit.■

Chronic Partial Obstruction

Although patients with chronic partial obstruction may do well for prolonged periods, the obstructive process should be relieved because it poses a long-term threat to renal function. Prompt relief is mandatory when partial obstruction progresses to frank urinary retention, the obstruction is accompanied by urinary sepsis or repeated urinary tract infections, the obstruction is causing renal damage, or the patient has symptoms such as voiding dysfunction, flank pain, or dysuria. Most often, chronic partial obstruction results from lesions in the lower urinary tract, including urethral blockage from prostate enlargement (Chapter 131). In men, benign prostatic hypertrophy, which may remain stable for long periods, usually responds to medications, but therapeutic decisions, including surgery, depend on symptoms, the presence of infection, and the risk for permanent bladder or renal dysfunction (Chapter 131). The possibility of prostate cancer also must be assessed (Chapter 207).

Chronic obstruction at the bladder neck or urethra can lead to bladder dilation and remodeling, with attendant persistence of dysfunction and symptoms even after relief of the obstruction. On this basis, it may be appropriate to relieve the obstruction before infection, major symptoms, or renal dysfunction occurs. Urethral strictures can be treated by dilation or urethrotomy.

Postobstructive Diuresis

Though usually self-limited, postobstructive diuresis can last several days to a week and may result in clinically important depletion of sodium, potassium, and chloride. Because postobstructive diuresis is prolonged and promoted by excessive fluid replacement, administration of volume is justified only when excessive losses result in clear volume depletion. Proper replacement is guided by measurement of urine chemistries and osmolality. Because the urine is generally isosthenuric, with relatively high sodium levels as a result of residual tubular dysfunction, appropriate replacement fluid is often 0.45% saline given at a rate somewhat slower than that of urine output. By careful monitoring of vital signs, volume status, urine output, and serum and urine chemistry and osmolality, coupled with judicious fluid replacement, the diuresis can be limited and will not cause serious volume or electrolyte abnormalities.

PROGNOSIS

The recovery of renal function depends on the duration and completeness of the obstruction. If the obstruction involves only one kidney and the other kidney has relatively normal function, the preserved kidney will compensate for the loss of function in the obstructed kidney. If obstruction is of relatively short duration and is partial, renal function will likely improve, leaving the patient with no symptoms of renal failure. However, if obstruction is bilateral, complete, or near-complete and persists for a week or more, significant permanent renal damage ensues, particularly if renal function was impaired before the onset of obstruction. Following restoration of urine flow, it may take weeks for renal function to recover, and recovery may be partial or negligible. In these cases, patients may need chronic renal replacement therapy (Chapter 133).

DIABETES AND THE KIDNEY

RAYMOND C. HARRIS

EPIDEMIOLOGY

In the industrialized world, diabetes mellitus is the single leading cause of end-stage renal disease (ESRD). Both the incidence and the prevalence of ESRD secondary to diabetes continue to rise. In the United States, more than 30% of patients undergoing either dialysis or renal transplantation have ESRD as a result of diabetic nephropathy, and 40% of the new (incident) cases of ESRD are attributable to diabetes.

In the United States, Europe, and Japan, more than 90% of patients with diabetes have type 2 (Chapter 237) rather than type 1 (Chapter 236) (insulinopenic) diabetes. Correspondingly, more than 80% of the ESRD secondary to diabetes is also seen in patients with type 2 diabetes. Although it was previously supposed that ESRD was less common in type 2 diabetes than in type 1 diabetes, when cohorts of patients with both types are monitored for an extended period, the incidence of renal disease is equivalent. The demographics of ESRD secondary to type 2 diabetes mirror the prevalence of type 2 diabetes in the U.S. population, with a higher incidence in females and in African Americans, Hispanic Americans, Native Americans, and Asian Americans and a peak incidence in the fifth to seventh decades of life. Given the global epidemic of obesity in developed countries, an increasing incidence of diabetic nephropathy is being widely appreciated.

PATHOBIOLOGY

Hyperglycemia

Increasing evidence implicates the metabolic sequelae of hyperglycemia as the most important causative factor in the development of diabetic nephropathy. Nearly 20 years ago, randomized clinical trials first demonstrated that aggressive control of blood sugar decreases the development of nephropathy, as well as other microvascular complications, in type 1 diabetes. Furthermore, repeat renal biopsies have documented that the renal lesions of diabetic nephropathy may reverse after long-term (10 years) functioning pancreas transplantation. Hyperglycemia leads to increased generation of reactive oxygen species; depletion of the reduced form of nicotinamide dinucleotide (phosphate); activation of the polyol pathway, which can lead to de novo synthesis of diacylglycerol and increased protein kinase C activity; alterations in the hexosamine pathway; and nonenzymatic protein glycation (advanced glycosylation end products), all of which have been implicated in development of diabetic nephropathy as well as other diabetic microvasculopathies.

Hemodynamics

Patients with type 1 and, to a lesser extent, type 2 diabetes exhibit an increased glomerular filtration rate (GFR)—so-called hyperfiltration—that is mediated by proportionately greater relaxation of the afferent arteriole than the efferent arteriole; such hyperfiltration leads to increased glomerular blood flow and elevated glomerular capillary pressure. With poorly controlled diabetes, patients develop glomerular hypertrophy, with an increased glomerular capillary surface area. These intraglomerular hemodynamic and structural alterations may contribute to the beginning or progression (or both) of diabetic renal injury. Because angiotensin-converting enzyme (ACE) inhibitors and decreased dietary protein reduce intraglomerular capillary pressure in experimental animals, the hyperfiltration hypothesis provides one rationale for the success of these interventions in resisting the progression of diabetic nephropathy (see later).

Hormones and Cytokines

Studies in experimental animals have implicated a number of cytokines, hormones, and intracellular signaling pathways in either the development or the progression of diabetic nephropathy, notably transforming growth factor-β (TGF-β), connective tissue growth factor, angiotensin II, vascular endothelial growth factor (VEGF), endothelin, prostaglandins, and nitric oxide. Because these factors have also been implicated in a variety of nondiabetic kidney diseases, it is likely that they are not specific for diabetic nephropathy. However, agents that interrupt angiotensin II production and signaling are very effective in slowing the progression of diabetic nephropathy. Furthermore, agents that interrupt intracellular pathways activated by these factors or by other consequences of hyperglycemia may provide future therapeutic opportunities.

Genetics

At present, it is impossible to predict in which patients diabetic nephropathy will develop. Although poor glycemic and blood pressure control undoubtedly contributes, nephropathy may or may not develop in an individual patient even after many years of hypertension and hyperglycemia. Type 1 diabetics with siblings who have diabetic nephropathy have a greater than 70% lifetime risk of developing diabetic nephropathy. There also appears to be a hereditary predisposition for the development of diabetic nephropathy in patients with type 2 diabetes.

Diabetic nephropathy is likely to be a polygenic disease. Various genetic linkage analyses have provided conflicting results, likely owing to genetic heterogeneity and the relatively small number of cases examined in individual studies. For example, in some (but not all) studies, an ACE insertion (I)/deletion (D) polymorphism has been associated with an increased incidence of the D allele, which predisposes to increased levels of ACE and the development or greater severity of a variety of nondiabetic renal diseases. Similarly, some but not all linkage studies have suggested the involvement of angiotensinogen polymorphisms and angiotensin II type 1 (AT1) receptor polymorphisms in the development of diabetic nephropathy.

Endothelial dysfunction in diabetes is associated with impaired vascular nitric oxide synthesis. Linkage studies have suggested that polymorphisms in endothelial nitric oxide synthase (eNOS) are associated with nephropathy in Pima Indians with type 2 diabetes, and some but not all linkage studies in other populations with diabetic nephropathy have identified eNOS polymorphisms. Polymorphisms in apolipoprotein E have also been linked to a predisposition to develop diabetic nephropathy in some studies. A variety of other genes, including those for the receptor for advanced glycosylation end products (RAGE), the glucose transporter Glut1, plasminogen activator inhibitor 1 (PAI-1), TGF-β, the B2 bradykinin receptor paroxonase, the homocysteine metabolism-related enzyme methylenetetrahydrofolate reductase, atrial natriuretic peptide, RANTES (regulated on activation, T-cell expressed and secreted), superoxide dismutase, lipoprotein lipase, decorin, VEGF, and peroxisome proliferator-activated receptor-γ (PPAR-γ), have also been linked in some but not all studies.

CLINICAL MANIFESTATIONS

Natural History

Although a minority of patients with diabetic nephropathy have type 1 diabetes, the natural history of the disease is best exemplified in this population. This is true because the onset of diabetes is more clearly definable, and initially, patients with type 1 diabetes usually do not have the comorbid conditions often associated with type 2 diabetes, including essential hypertension, atherosclerotic cardiovascular disease, and obesity, which may independently produce chronic renal injury. Furthermore, the relatively advanced age of onset of type 2 diabetes and the increased cardiovascular mortality in this population may preclude the development of all manifestations of diabetic nephropathy. In type 1 diabetes, diabetic nephropathy progresses in four relatively distinct stages (Fig. 126-1).

Stage I

In stage I, which commences soon after the overt manifestations of diabetes, the kidney undergoes hypertrophy of both the glomeruli and the tubules in comparison with age- and weight-matched normal control subjects. Despite up to a 50% increase in renal blood flow and GFR, macroalbuminuria is not yet detectable, but transient microalbuminuria (measurable by radioimmunoassay, enzyme-linked immunosorbent assay, or special dipsticks) is occasionally evident, especially when induced by stress, physical exertion, concurrent illness, or poor glycemic control. Hypertension is usually absent in the early stages of type 1 diabetes but is often present in type 2 diabetes at its initial detection.

Stage II

Approximately 30% of type 1 diabetic patients progress to clinically silent stage II, characterized by fixed microalbuminuria of at least 30 mg/24 hours, after having diabetes for a median of 10 years. Although the GFR remains elevated or is within the normal range, abnormal renal histology manifests as glomerular and tubular basement membrane thickening and expansion of the

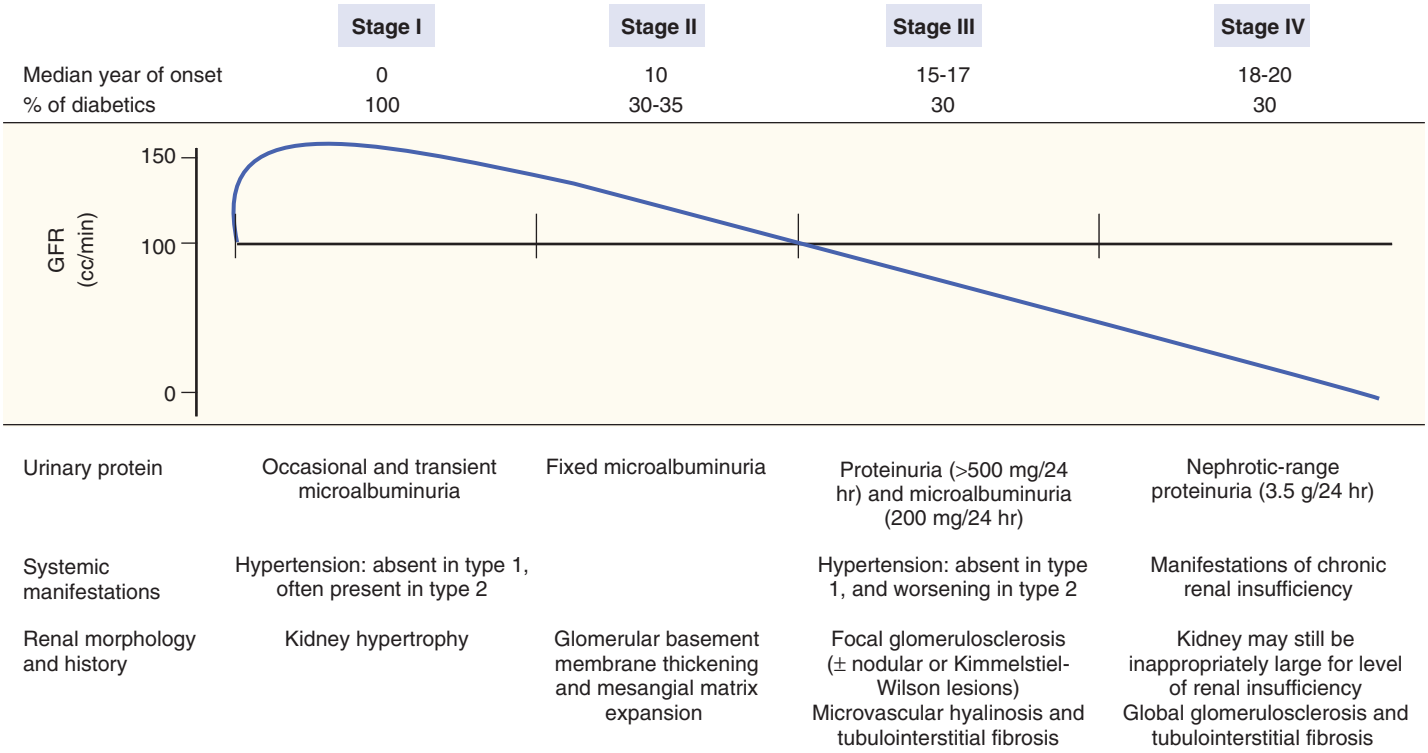

FIGURE 126-1. Stages of diabetic nephropathy. GFR = glomerular filtration rate.

mesangial matrix. Microalbuminuria is more likely to develop in patients with other microvascular insults, especially proliferative retinopathy. Microalbuminuria is more likely to be caused by diabetic nephropathy in type 1 than in type 2 diabetes, in which hypertension itself may lead to microalbuminuria.

Stage III

The great majority of patients who initially have fixed microalbuminuria progress within 5 to 7 years to overt nephropathy (stage III), with proteinuria (>500 mg of total protein per 24 hours) and macroalbuminuria (>200 mg/24 hours) detectable on a routine urinary protein dipstick. Blood pressure begins to rise in type 1 patients and becomes more problematic in type 2 patients.

Renal biopsy reveals diffuse or nodular (Kimmelstiel-Wilson) glomerulosclerosis. Although the Kimmelstiel-Wilson lesion is considered pathognomonic of advanced diabetic nephropathy, only about 25% of patients manifest this lesion. A nodular pattern of glomerulopathy mimicking Kimmelstiel-Wilson lesions may also be seen in light chain nephropathy (Chapter 193), amyloidosis (Chapter 194), and membranoproliferative glomerulonephritis type II (Chapter 123). Also pathognomonic of diabetic nephropathy is the finding of both afferent and efferent arteriolar hyalinosis; this differs from the arteriolar lesion of essential hypertension, which is restricted to the afferent arteriole. In overt diabetic nephropathy, progressive tubulointerstitial fibrosis correlates most closely with the decline in renal function. The GFR begins to fall from the normal range, but the serum creatinine level may remain in the normal range.

Stage IV

Stage IV, or advanced diabetic nephropathy, is characterized by a relentless decline in renal function to end-stage disease. Patients manifest nephrotic-range proteinuria (>3.5 g/24 hours) and systemic hypertension but have no evidence of inflammatory glomerular (red blood cell casts) or tubulointerstitial (white blood cells, white blood cell casts) lesions. The kidneys may be inappropriately large for the observed degree of renal insufficiency.

Other Renal Complications

Type IV (hyporeninemic, hypoaldosteronemic) renal tubular acidosis (Chapter 124) with hyperkalemia is commonly encountered in patients with diabetes and mild to moderate renal insufficiency. These patients should be carefully monitored for the development of severe hyperkalemia (Chapter 119) in response to volume depletion or after the initiation of drugs that interfere with the renin-angiotensin system, such as ACE inhibitors, angiotensin receptor blockers (ARBs), β-adrenergic blockers, both nonselective and selective cyclooxygenase 2 nonsteroidal anti-inflammatory agents, and heparin, as well as potassium-sparing diuretics.

Patients with diabetes have an increased incidence of bacterial and fungal infections of the genitourinary tract (Chapter 292), as well as an increased risk for developing intrarenal and perinephric abscesses. Unilateral or bilateral renal artery stenosis (Chapter 127) is more frequent in type 2 diabetes and should be considered if a diabetic patient has intractable hypertension or a rapidly rising serum creatinine level immediately after initiation of therapy with an ACE inhibitor or AT1 receptor blocker. Other causes of acute deterioration in renal function include papillary necrosis with ureteral obstruction owing to sloughing of a papilla, obstructive uropathy (Chapter 125) caused by bladder dysfunction as a result of autonomic neuropathy, and contrast media–induced acute tubular necrosis (Chapter 124). In addition, prerenal azotemia or acute tubular necrosis may develop in diabetic patients as a result of heart failure or volume depletion owing to vomiting induced by gastroparesis (Chapter 236) or diarrhea from autonomic neuropathy.

PREVENTION

Tight glycemic control (Chapter 236) significantly lessens but does not completely eliminate the incidence of diabetic nephropathy.[3] Elevated blood pressure is an important risk factor for the progression of diabetic nephropathy, and blood pressure targets for patients with diabetes are lower (130/80 mm Hg) than those for those without diabetes. However, blood pressure control does not prevent the development of microalbuminuria.[4]

TREATMENT

Latent (Stage II) and Overt (Stage III) Diabetic Nephropathy

Tight glycemic control in type 1 diabetes may not prevent progression to macroalbuminuria, but it prevents other microvascular complications such as retinopathy and peripheral neuropathy (Fig. 126-2). It also slows the progression of nephropathy in type 2 as well as type 1 diabetic patients (Chapter 236).[3,4]

Optimal blood pressure control does not retard the progression of renal disease in patients without macroalbuminuria,[4] but it does retard the progression of frank diabetic nephropathy. In addition to lowering systemic blood pressure, both ACE inhibitors and ARBs have the additional benefit of delaying

Stage I	Tight glucose control BP control—consider use of ACEI or ARB
Stage II	Tight glucose control ACEI or ARB BP control Smoking cessation Weight reduction Exercise Annual eye examination
Stage III	ACEI or ARB BP control Restriction of dietary protein (to 0.8g/kg of ideal body weight/day) Antihyperlipidemic medications
Stage IV	Treat manifestations of nephrotic syndrome and chronic renal insufficiency Prepare for renal replacement therapy, including prevention of abnormalities in calcium/phosphorus metabolism and prevention of anemia by early use of erythropoietin

FIGURE 126-2. Treatment of diabetic nephropathy. ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocker; BP = blood pressure.

the progression of nephropathy in both type 1 and type 2 patients.[6,7] The combination of a direct renin inhibitor and an ARB may further decrease proteinuria in patients with diabetic nephropathy.[8]

When administering ACE inhibitors or ARBs to patients with diabetic nephropathy, serum potassium and creatinine levels should be monitored closely for the first week because of the possibility of associated type IV renal tubular acidosis or renal artery stenosis. If blood pressure control is not achieved with these agents, diuretics and other antihypertensive agents, including cardioselective β-blockers, α-blockers, and nondihydropyridine calcium-channel blockers (CCBs), can be added (Chapter 67). Although dihydropyridine CCBs may increase intraglomerular capillary pressure, control of systemic blood pressure is essential, and both dihydropyridine and nondihydropyridine CCBs can effectively treat hypertension in these patients without accelerating renal injury.

Judicial restriction of dietary protein (to 0.8 g/kg of ideal body weight per day) is recommended. Although further dietary protein restriction may retard the progression of diabetic nephropathy, an individual's nutritional requirements must be considered. Smoking cessation (Chapter 31) and the use of antihyperlipidemic medications in patients with documented lipid abnormalities (Chapter 213) should be encouraged.

The efficacy of treatment can be determined by monitoring albuminuria and/or total proteinuria. For patients with deteriorating renal function, GFR determined by creatinine clearance and plots of the reciprocal of serum creatinine versus time (1/sCr) are effective indicators of whether interventions are slowing the progression of nephropathy.

Renal Replacement Therapy

In general, management of a diabetic patient nearing ESRD is similar to that of a nondiabetic patient. The patient should be under the care of a nephrologist, and planning for dialysis should be initiated. Although dialysis is generally started when the GFR declines to approximately 10 to 15 mL/minute, early initiation of dialysis is sometimes necessary in diabetic patients when either volume-dependent hypertension or hyperkalemia is not manageable by nondialytic therapy or when uremia, combined with gastroparesis, leads to anorexia, malnutrition, or uncontrollable emesis. Ultimately, more than 80% of patients with end-stage diabetic nephropathy require dialysis (Chapter 133), with about six times as many undergoing hemodialysis as peritoneal dialysis. Approximately 25% of the renal transplant recipients (Chapter 133) in the United States are diabetic patients. The vast majority (>90%) are type 1 diabetics, given their younger age and less severe macrovascular comorbidities in comparison with type 2 patients. Pancreas or combined kidney-pancreas transplantation has a significant effect on quality of life among patients with diabetic nephropathy by improving autonomic neuropathy, either retarding or possibly correcting retinopathy, and avoiding the potential complications of insulin administration. However, all transplantation options remain limited by organ availability.

PROGNOSIS

Because of the associated macrovascular complications (cardiovascular, cerebrovascular, peripheral vascular) and the increased risk for infection, the mortality of diabetic patients who receive either type of dialysis is 1.5 to 2.0 times that of nondiabetic patients, with a 5-year survival rate of less than 20%. The survival of diabetic patients is slightly worse with peritoneal dialysis than with hemodialysis, although it is not clear whether this is related to the type of dialysis or reflects the severity of illness among patients treated with peritoneal dialysis.

Long-term survival and quality of life are generally superior in patients undergoing transplantation compared with those receiving only dialysis. However, the other microvascular complications (retinopathy, neuropathy) are not improved by renal transplantation alone.

VASCULAR DISORDERS OF THE KIDNEY

THOMAS D. DUBOSE JR. AND RENATO M. SANTOS

Vascular disorders that significantly alter renal perfusion can impact the glomerular filtration rate (GFR), tubular function, and, ultimately, kidney function. Stenosis, thrombosis, emboli, atherosclerosis, inflammation, or hypertension may involve the renal arteries, arterioles, microvasculature, and renal veins.

ARTERIES

Renal Artery Stenosis

DEFINITION

Renal artery stenosis, which is a narrowing of the renal arteries, leads to hypoperfusion of one or both of the kidneys. The two most common forms of renal artery stenosis are atherosclerotic disease and fibromuscular dysplasia. The two differ in prevalence, pathophysiology, clinical presentation, prognosis, and management.

EPIDEMIOLOGY

Atherosclerotic disease, which is much more common than fibromuscular dysplasia, accounts for 90% of renal artery stenosis. The prevalence of renal

artery stenosis in the Medicare population is only 0.5%, but it is 2 to 4% in patients with hypertension (Chapter 67) and about 5.5% in patients with chronic kidney disease. Atherosclerotic disease is also more common in the elderly and in patients with typical cardiovascular risk factors such as coronary artery disease, heart failure, carotid or peripheral vascular disease, and dyslipidemia. In patients with established coronary artery disease or peripheral vascular disease and hypertension, the prevalence of some degree of renal artery stenosis may be as high as 20 to 40%.

Fibromuscular dysplasia is 2 to 10 times more common in women than in men. It is an important cause of treatable hypertension in young patients without cardiovascular risk factors, and it is pathologically and angiographically distinct from atherosclerotic disease. Although the cause is unknown, there appears to be a genetic predisposition to fibromuscular dysplasia. Other possible pathogenetic factors include hormonal influences (most patients are women of childbearing age), mechanical factors, and ischemia of the vessel wall.

PATHOBIOLOGY

The pathobiology of atherosclerotic renal artery stenosis is identical to that of atherosclerotic disease in other arterial beds (Chapter 70). Fibromuscular dysplasia includes four distinct histopathologic types: medial fibroplasia, which is the most common type and accounts for 75 to 80% of cases; perimedial fibroplasia, with irregular thickening of the media; medial hyperplasia, with smooth muscle hyperplasia without fibrosis; and intimal fibroplasia. Unlike atherosclerotic disease, which localizes at the ostial and proximal segments of the renal arteries, fibromuscular dysplasia more commonly involves the middle and distal arterial segments.

Models of renovascular hypertension using renal artery clips in animals have elegantly demonstrated that activation of the renin-angiotensin-aldosterone system by renal hypoperfusion causes an increase in systemic blood pressure. This mechanism is further supported by the ability of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) to control the resulting hypertension in animals and in patients with fibromuscular dysplasia. The mechanism for the development of hypertension with renal artery stenosis, however, appears to be more complex. Although atherosclerotic renal activation of the renin-angiotensin-aldosterone system by renal hypoperfusion is essential for initiating the pressor response, it is transient. Over time, the pathobiology transitions to pressor mechanisms independent of angiotensin II, including vasoconstriction owing to oxidative stress, endothelial dysfunction, endothelin release, and sympathetic activation. Confounding risks including smoking, advanced age, dyslipidemia, diabetes, and hypertension itself, which can contribute to vascular injury. The uncertain cause-and-effect relationship of these confounding risks may explain the inconsistent blood pressure response to renal revascularization for atherosclerotic renal artery stenosis compared with fibromuscular dysplasia.

Renal artery stenosis leads to ischemic nephropathy, defined as an impairment of renal function beyond the occlusive disease in the main renal arteries. However, the pathophysiologic basis of renal injury is likely multifactorial. Unlike cardiac or cerebral tissue, perfusion of the kidneys is determined by glomerular ultrafiltration and the autoregulation of the GFR and renal blood flow rather than metabolic needs. Less than 10% of renal blood flow is required to meet the oxygen demands of the kidneys. Therefore, a severe reduction in perfusion to the entire renal parenchyma is necessary to affect kidney function materially. This relationship is supported by the observation that hemodynamically significant lesions of fibromuscular dysplasia are rarely associated with renal dysfunction. Conversely, a decline in kidney function is common in atherosclerotic renal artery stenosis. Atherogenic stimuli such as hypercholesterolemia can magnify oxidative stress and activate pro-inflammatory and pro-fibrogenic pathways. Repetitive bouts of hypoperfusion in atherosclerotic disease may lead to renal tubular injury and, over time, can lead to tubulointerstitial fibrosis. Thus, a combination of repetitive perfusion insults superimposed on atherogenic risk factors contributes to renal dysfunction.

CLINICAL MANIFESTATIONS

The clinical features of renal artery stenosis are related primarily to renovascular hypertension and ischemic nephropathy (Table 127-1). A significant percentage of patients has resistant hypertension that is unresponsive to high doses of multiple antihypertensive agents. Malignant phase hypertension, though rarely seen with contemporary antihypertensive drugs, still occurs.

Hemodynamically significant renal artery stenosis can also lead to end-organ manifestations remote from the kidneys. A common association is "flash" pulmonary edema (Chapter 58) that cannot be explained by other cardiac problems, particularly if left ventricular function is preserved. Severe hypertension can also precipitate the acute coronary syndrome (Chapter 72), stroke (Chapter 414), transient ischemic attack (Chapter 414), intracranial hemorrhage (Chapter 415), encephalopathy, or papilledema.

TABLE 127-1 CLINICAL FEATURES OF RENAL ARTERY STENOSIS

Onset of hypertension before 30 or after 50 years of age
Absence of a family history of hypertension
Short duration or recent worsening of hypertension
Severe hypertension or retinopathy
Resistance to antihypertensive therapy
Signs of other cardiovascular disease
Deterioration of renal function with angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy
Abdominal bruit
Unexplained hypokalemia with or without metabolic alkalosis
Unexplained progression of kidney disease or failure
Neurofibromatosis

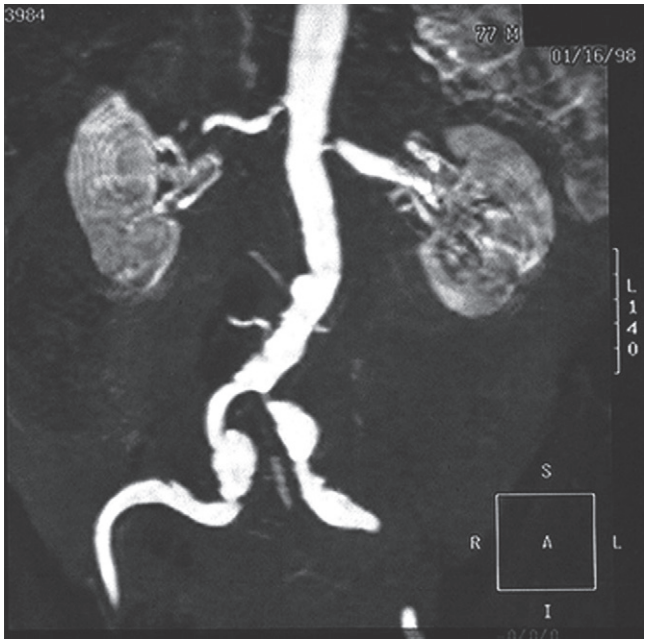

FIGURE 127-1. Magnetic resonance angiogram of the abdominal aorta showing bilateral renal artery stenosis. Significant iliac stenosis is also demonstrated.

DIAGNOSIS

There are no universally accepted guidelines for routine screening for renal artery stenosis (see Table 67-4 in Chapter 67), but the decision to perform diagnostic imaging studies depends on the likelihood that revascularization would be beneficial. Incidental renal artery stenosis is a common finding on noninvasive imaging tests obtained for unrelated reasons.

Preferred imaging modalities include renal duplex ultrasonography, computed tomography (CT) angiography, and magnetic resonance angiography (MRA) (Fig. 127-1). Captopril renal scintigraphy is no longer recommended owing to its poor sensitivity and specificity in the presence of renal insufficiency, bilateral disease, or disease in a solitary functioning kidney.

Renal Doppler ultrasonography is an excellent noninvasive screen for either type of renal artery stenosis and is the preferred initial test for fibromuscular dysplasia. However, it is not available in all centers, is highly operator dependent, and is affected by body habitus and bowel gas; therefore, multiple views, such as oblique and flank approaches, may be required to visualize the cortical branches.

In patients with suspected atherosclerotic renal artery stenosis, the choice among ultrasonography, CT angiography, and MRA depends in part on the availability of the technology, the experience of the vascular imaging department, and the preferences and expertise of the institution. CT angiography is rapid and has good spatial resolution but has the distinct disadvantage of requiring a large contrast load. MRA avoids the need for iodinated contrast

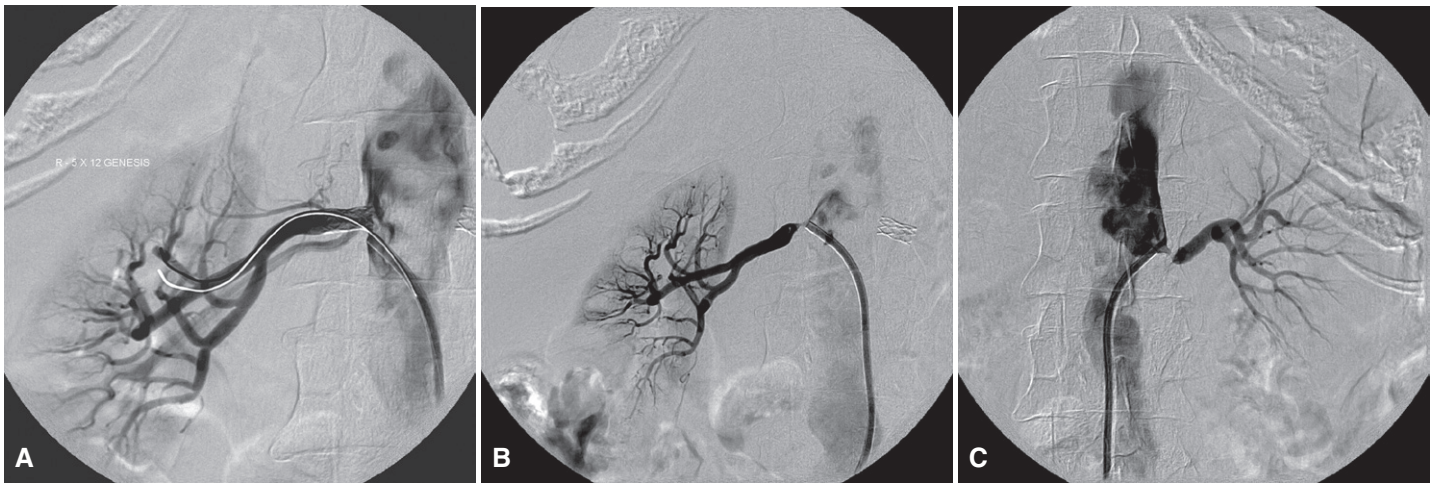

FIGURE 127-2. Renal angiograms from an elderly patient with heart failure. Cardiac catheterization revealed normal coronary arteries, but after initiation of therapy with an angiotensin-converting enzyme inhibitor and spironolactone, progressive kidney disease with hyperkalemia and poor blood pressure control ensued. Renal Doppler ultrasonography suggested bilateral renal artery stenosis, as confirmed by angiography (**A** and **B**). The patient underwent successful percutaneous revascularization in stages, leading to a return to normal left ventricular function and improved blood pressure control (**C**).

and can accurately visualize the proximal segment of the renal artery, although motion artifact and spatial resolution limit the ability to image the middle and distal segments. MRA requires gadolinium enhancement, which may precipitate a rare but severe condition called nephrogenic systemic fibrosis (Chapter 275), especially when the linear gadolinium chelate gadodiamide is used in patients with advanced chronic kidney disease or acute kidney injury. Clearly, the risk of nephrogenic systemic fibrosis limits the applicability of enhanced MRA for patients with advanced renal dysfunction. When the diagnosis remains unclear or when renal artery revascularization is being considered, invasive digital subtraction renal angiography (Fig. 127-2), the "gold standard" test, may be required. In addition to providing anatomic information, the translesion gradient can be measured. Although the complication rates are low, the usual risks of catheterization should be considered, including access site trauma, contrast reactions, and contrast nephropathy.

TREATMENT

Rx

The goals of therapy are to control blood pressure, stabilize renal function, and reduce cardiovascular complications.

Atherosclerotic renal artery stenosis reflects a high atherosclerotic burden and is a strong predictor of subsequent cardiovascular events and cardiac mortality. Efforts to optimize medical therapy for secondary prevention include aspirin (81 mg/day), statins to treat dyslipidemia (Chapter 213), management of diabetes (Chapter 236), and control of blood pressure (Chapter 67). Medical therapy for blood pressure control should include ACE inhibitors or ARBs because of their proven benefit in renal protection (see Table 67-6 in Chapter 67). The serum creatinine and GFR should be monitored for the first weeks after initiating ACE inhibitor or ARB therapy, particularly in the elderly. An increase in creatinine of 1.0 mg/dL or greater is an indication to discontinue ACE inhibitor or ARB therapy; it suggests bilateral renal artery stenosis, renal artery stenosis in a unilateral functional kidney, or, in a kidney transplant recipient, renal artery stenosis in the allograft. Smoking cessation, weight control, and increased exercise should be universally recommended.

Renal artery revascularization for atherosclerotic renal artery stenosis remains controversial. In a large trial that randomized more than 800 patients with atherosclerotic renal artery stenosis to medical therapy or renal stenting, no difference was found in blood pressure control or recovery of renal function. Similarly, smaller randomized trials of balloon angioplasty or stenting versus medical therapy showed no benefit of revascularization. The potential utility of renal revascularization for atherosclerotic renal artery stenosis remains poorly defined, and the challenge is to identify patients with ischemic nephropathy and viable renal parenchyma who might improve from revascularization—perhaps those with a recent deterioration in blood pressure control, a sudden decline in renal function, a resistive index of less than 0.8, resistant hypertension, or episodes of malignant hypertension.

In patients with fibromuscular dysplasia, medical treatment alone is usually ill-advised because the stenosis can progress to renal artery occlusion despite adequate blood pressure control. Fibromuscular dysplasia responds well to balloon angioplasty; stenting is rarely needed, and restenosis rates are generally low. Close follow-up with serial blood pressure measurements and evaluation of renal function should be performed every 3 to 4 months.

PROGNOSIS

When adjusted for baseline variables, atherosclerotic renal artery stenosis remains an independent predictor of cardiovascular mortality, with a 4-year adjusted mortality rate of 25 to 40%. Factors associated with higher mortality include an elevated baseline creatinine level, more severe renal artery stenosis, worsening renal function, age, diabetes, other cardiovascular disease, and heart failure. Improvement of blood pressure control or renal function after revascularization is associated with improved survival, even though revascularization does not affect overall survival.

For fibromuscular dysplasia, angioplasty cures hypertension in about 45% of patients. Younger age, milder hypertension, and shorter duration of hypertension are associated with successful outcomes. An atrophic kidney (<8 cm), however, is unlikely to recover with revascularization.

Thromboembolic Occlusion of the Renal Arteries

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute occlusion of the renal arteries and segmental branches may arise as a result of intrinsic pathology of the renal arteries, abdominal trauma, or embolization of thrombi arising in the heart or proximal aorta (Table 127-2). Thrombosis can occur as a complication of progressive atherosclerosis, in which case it may be an important cause of progressive renal insufficiency. In other patients, thrombosis may be associated with thrombophilic states (Chapter 179), such as the antiphospholipid antibody syndrome. Thrombosis also may occur as a consequence of inflammatory disorders, including Takayasu's arteritis (Chapter 78), syphilis (Chapter 327), thromboangiitis obliterans (Chapter 80), and systemic vasculitides, especially Wegener's granulomatosis (Chapter 278). In situ thrombosis has been observed in structural lesions of the renal arteries, such as fibromuscular dysplasia or renal artery aneurysms. In patients younger than 60 years, traumatic thrombosis is the most common cause. Blunt trauma and deceleration injuries can cause acute thrombosis as a result of intimal tears, contusion against the vertebral column, or compression from a retroperitoneal hematoma. Iatrogenic causes include diagnostic angiography or arterial intervention in the renal arteries or vessels proximal to the kidneys.

Embolization, which is a more common cause of renal artery occlusion than in situ thrombosis, is generally unilateral but is bilateral in 15 to 30% of cases. Total infarction of the kidney is much less common than segmental infarction or ischemia. Approximately 90% of thromboemboli to the renal arteries originate in the heart. Atrial fibrillation with embolization of atrial thrombus is the most common cause, but left ventricular thrombus, valvular heart disease (Chapter 75), bacterial endocarditis (Chapter 76), nonbacterial (aseptic) endocarditis (Chapter 76), and atrial myxoma (Chapter 60) are other causes. Noncardiac sources include aortic atheroma and mural thrombus, as well as paradoxical emboli through an atrial septal defect or patent foramen ovale (Chapter 69).

Excessive anticoagulation

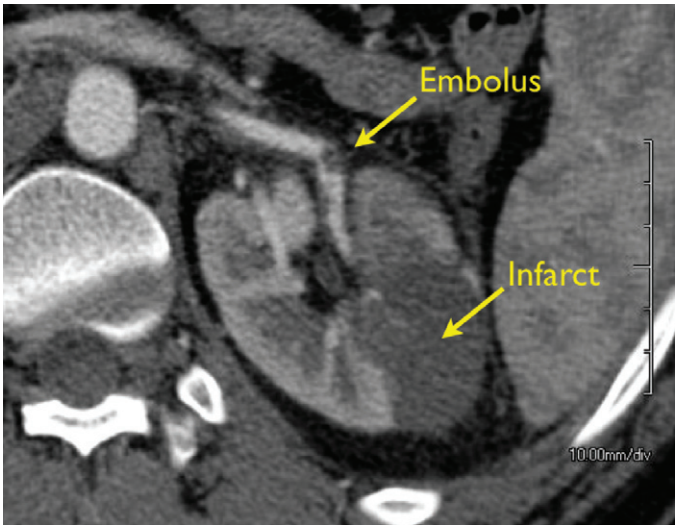

FIGURE 127-3. Computed tomography demonstrating a clot in the main renal artery and segmental renal infarction.

CLINICAL MANIFESTATIONS

The clinical presentation of renal vascular disease can be variable, and the diagnosis is often confused with more common disorders such as renal colic. Occlusion of a primary or secondary branch of the renal artery in a patient with preexisting disease and established collateral circulation, such as in long-standing renal artery stenosis, may produce little or no infarction and minimal symptoms. Acute thrombosis and infarction may cause the sudden onset of flank pain, fever, nausea, vomiting, and, on occasion, hematuria. Pain may be localized to the abdomen, back, or even the chest, but pain is absent in more than 50% of cases. Hypertension, which occurs with infarction as a result of the release of renin from the ischemic renal parenchyma, may be severe.

Anuria suggests bilateral involvement or occlusion of the artery to a solitary kidney. Urinalysis usually, but not always, reveals microscopic hematuria, and mild proteinuria may be seen.

If infarction occurs, leukocytosis usually develops, and serum enzyme levels of aspartate aminotransferase, lactate dehydrogenase, and alkaline phosphatase may be elevated. These laboratory findings are nonspecific, but elevation of the urinary lactate dehydrogenase level is more specific because its concentration should be normal in extrarenal disorders. Blood urea nitrogen and creatinine levels typically increase transiently with unilateral infarction, but more severe and protracted renal dysfunction may follow bilateral renal infarction or infarction of a solitary kidney.

DIAGNOSIS

The diagnosis of renal artery occlusion is most reliably established by CT with and without contrast. CT is accurate, can be performed rapidly, and can identify associated traumatic injury. Findings may include filling defects in the main or segmental renal arteries, as well as the absence of enhancement of renal tissue, indicating a lack of perfusion (Fig. 127-3). The complication of contrast nephropathy is a major concern in patients with a creatinine level of 2.0 mg/dL or greater or an estimated GFR less than 60 mg/dL. Alternatives to contrast administration should be considered in patients with chronic kidney disease, acute renal failure, or diabetes mellitus and in elderly patients. MRA has a high diagnostic accuracy and may be preferable to contrast CT in the elderly or in patients with diabetes mellitus, although it is contraindicated in patients with renal insufficiency. Radioisotope renograms, excretion urograms, and duplex ultrasound scanning are not recommended for the diagnosis of acute occlusions. Invasive angiography carries inherent risks but is occasionally required if the diagnosis remains uncertain or if percutaneous reperfusion is considered.

In patients with suspected embolic renal artery occlusion, echocardiography is indicated to search for a possible intracardiac thrombus. In nontraumatic thrombotic occlusion, evaluation for thrombophilia (Chapter 179), vasculitides (Chapter 278), or progressive atherosclerosis (Chapter 70) should be considered.

TREATMENT Rx

The human kidney can tolerate 60 to 90 minutes of warm ischemia, although the presence of collateral circulation may permit longer ischemic times. As a result, acute renal artery thrombosis requires urgent treatment in an attempt to reopen the artery. Treatment options for nontraumatic renal artery occlusion include systemic anticoagulation with unfractionated heparin (see Table 81-4 in Chapter 81) or low-molecular-weight heparin (see Table 37-3 in Chapter 37 and Table 81-3 in Chapter 81), followed by oral warfarin (Coumadin) to maintain an international normalized ratio of 2.0 to 3.0, or intra-arterial thrombolytic therapy. Surgical revascularization has been associated with higher mortality than medical therapy, without improved renal salvage rates; it is not recommended as primary therapy but can be considered for patients with bilateral renal artery occlusion or occlusion of the renal artery of a solitary kidney. Percutaneous endovascular therapies (e.g., local thrombolysis, thrombectomy, stent placement) have also been successful in acute renal artery occlusion. For iatrogenic occlusion of the renal artery as a result of angiographic manipulations or angioplasty, intra-arterial stent placement may be considered. For traumatic renal artery thrombosis, surgery is the treatment of choice, but it typically can salvage renal function only if accomplished immediately.

Patients with renal artery thrombosis also require close medical care, often with multiple parenteral agents (see Table 67-8 in Chapter 67), to control their hypertension and achieve a blood pressure between 140/90 and 110/70 mm Hg. Adequate hydration is also imperative.

PROGNOSIS

Mortality is high, especially in patients who require hemodialysis, and it correlates with the severity of underlying conditions. For patients undergoing surgical revascularization for complete acute renal artery occlusion, the mortality rate is 11 to 25%. The risk of losing renal function is variable, and rates of 0 to greater than 50% have been reported. Hypertension, which may develop as a late sequela of renal artery occlusion, is preferably treated with ACE inhibitors, ARBs, or nondihydropyridine calcium-channel blockers (see Table 67-5 in Chapter 67).

ARTERIOLES AND MICROVASCULATURE

Atheroembolic Disease of the Renal Arteries

EPIDEMIOLOGY AND PATHOBIOLOGY

Cholesterol crystal embolization is a potential complication of widespread atherosclerosis. The risk factors are similar to those for all atherosclerotic

disease (Chapter 51), including smoking, hypertension, hyperlipidemia, diabetes, and age. Atheroembolic disease appears to be more common in whites, but the condition may be underdiagnosed in African Americans owing to the difficulty of assessing livedo reticularis in this population.

The most common triggering events are manipulation of a thrombus or of the abdominal aorta or renal arteries during angiography or transluminal angioplasty. It is therefore not unusual for cholesterol crystal embolization to be mistaken for contrast-induced nephropathy. Atheroemboli can also be associated with anticoagulant or thrombolytic therapy and may be accompanied by the finding of a cyanotic toe on physical examination. Spontaneous atheroembolism after detachment of a mural plaque is uncommon. Cholesterol crystals typically do not occlude arterial flow but induce an inflammatory response and subsequent endothelial proliferation, so the clinical manifestations may occur some time after the initial insult.

CLINICAL MANIFESTATIONS

Although all organ systems can be affected (Chapter 80), the kidneys are most commonly involved, followed by the spleen and gastrointestinal tract. Renal insufficiency, hypertension, or both typically occur. Nonspecific complaints may include fever, myalgias, headaches, and weight loss. Evidence of cholesterol embolization may be present in the retina, muscles, or skin, where livedo reticularis (see Fig. 80-1 in Chapter 80) or blue toes may be seen. Embolization can also result in cerebrovascular events, acute pancreatitis, ischemic bowel, and gangrene of the extremities (Chapter 79).

DIAGNOSIS

Although most atheroembolic events are diagnosed because of an acute clinical change, clinically silent, chronic, low-grade embolization may be overlooked because patients at risk for this complication often have other chronic illnesses associated with renal failure, hypertension, and atherosclerosis. Urinalysis may not be helpful because cholesterol crystals often are not present, although mild proteinuria, eosinophiluria, and increased cellularity are frequently observed. Transient eosinophilia is common, and an elevated erythrocyte sedimentation rate, hypocomplementemia, anemia, and leukocytosis may also be present. As many as 80% of patients may have a serum creatinine level exceeding 2 mg/dL.

Although the demonstration of cholesterol crystals in the renal microvasculature with subsequent vessel occlusion is considered a diagnostic feature, a kidney biopsy generally is not necessary for patients with typical clinical features, including livedo reticularis and violaceous mottling of the toes, eosinophilia, and an elevated erythrocyte sedimentation rate. When uncertainty exists, noninvasive biopsy of the skin of the lower extremity, muscle of the calf or thigh, or gastric mucosa can be diagnostic in up to 80% of patients.

TREATMENT Rx

There is no curative therapy for atheroembolic disease, so supportive care is often all that can be offered. Aggressive control of dyslipidemia with statins (Chapter 213) is recommended and may have the added benefit of stabilizing the endothelial surface. Anticoagulants are of no value and may delay the healing of ulcerating atherosclerotic lesions; if possible, anticoagulant therapy should be discontinued. Adequate hydration is important to sustain renal perfusion. Hypertension should be treated (see Table 67-5 in Chapter 67) with angiotensin II antagonists and vasodilators, and volume should be controlled with diuretics, while being careful not to cause hypotension. Intravascular radiologic procedures and vascular surgery should be avoided if possible.

PROGNOSIS

Recent series suggest up to 80% survival at 1 year. Most patients die of cardiovascular complications. With adequate blood pressure control for several months or years, renal function may recover sufficiently to avoid dialysis. Patients who develop end-stage renal disease have a significantly higher mortality.

Hypertensive Arteriolar Nephrosclerosis

EPIDEMIOLOGY

The risk of nephrosclerosis among hypertensive patients is a function of the severity and duration of hypertension (Chapter 67). Although only a small percentage of patients with hypertensive nephrosclerosis progress to end-stage renal disease, the high prevalence of this condition makes it an important cause. The availability of effective antihypertensive medications has sharply reduced the occurrence of this devastating disorder. However, both benign and malignant hypertensive renal disease and the sequelae of these disorders appear to be more prevalent in African Americans.

PATHOBIOLOGY

The renal vasculature is exquisitely sensitive to damage caused by systemic hypertension when elevated blood pressure is transmitted to the glomerular capillary bed. Unopposed or sustained increases in glomerular capillary hydrostatic pressure eventually result in sclerosis. In benign nephrosclerosis, the kidney is the victim of the adverse effects of chronic hypertension. In malignant or accelerated hypertension, intimal changes in the renal arterial vessels lead to ischemia, increased production of renin, and exacerbation of hypertension, potentially resulting in acute renal failure that, if not treated successfully, will result in end-stage renal disease. Renal vascular lesions similar to those seen in malignant hypertension are also observed in scleroderma (Chapter 275), thrombotic microangiopathy (Chapter 123), and renal transplant rejection (Chapter 133). *MYH9* (myosin, heavy chain 9, nonmuscle) gene polymorphisms are associated with a spectrum of kidney diseases in African Americans with essential hypertension and nephropathy attributed to hypertension, focal segmental glomerulosclerosis, or HIV-associated nephropathy; these data suggest that much of the excess risk of end-stage renal disease in African Americans is linked to genetic susceptibility.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Typically, patients with benign hypertensive nephrosclerosis have been hypertensive for more than 10 to 15 years. Kidney size is usually reduced, and the urine sediment is unremarkable except for proteinuria, which is generally less than 1.5 g/day. The sudden development of malignant or accelerated hypertension (Chapter 67), either in patients with previously established mild to moderate hypertension or in patients with no previous diagnosis of hypertension, manifests as an abrupt increase in blood pressure (diastolic usually >130 mm Hg). Hypertensive retinopathy (see Fig. 67-1 in Chapter 67) is common, papilledema (see Fig. 431-27) may develop, and renal function may decline rapidly. The kidneys may be enlarged, the urinary sediment may show gross or microscopic hematuria, and proteinuria is often in the nephrotic range. Microangiopathic hemolytic anemia may be present. Abnormalities in the central nervous system are usually evident and include headaches, cerebrovascular accidents, generalized seizures, and coma.

TREATMENT Rx

In benign hypertensive nephrosclerosis, the renal outcome depends on the timely initiation of effective therapy, patient adherence, and careful follow-up. The primary goal is a blood pressure of 130/80 mm Hg or less (Chapter 67). Medications that provide renal protection include ACE inhibitors and ARBs (see Table 67-5 in Chapter 67). Nondihydropyridine calcium-channel blockers do not afford protection from progression of renal insufficiency and should be used only in patients who cannot tolerate ACE inhibitor or ARB therapy. For malignant hypertension, more aggressive therapy is required (see Table 67-8 in Chapter 67).

PROGNOSIS

With the skillful selection of renal-specific antihypertensive agents and control of blood pressure, progression of kidney disease can usually be avoided. Unfortunately, such measures may not be initiated sufficiently early or may not be successful in preventing progression to end-stage renal disease.

SYSTEMIC DISORDERS AFFECTING THE RENAL MICROVASCULATURE

Hemolytic-Uremic Syndrome and Thrombotic Thrombocytopenic Purpura

Renal failure is a common consequence of both hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) (Chapter 175). These conditions are characterized by platelet and fibrin thrombi within the renal microvasculature, accompanied by thrombocytopenia and microangiopathic hemolytic anemia.

TTP is suggested by the co-occurrence of hemolysis, thrombocytopenia, fever, purpura, and alternating mental status changes. HUS may be associated with acute renal failure, thrombocytopenia, and microangiopathic hemolytic

anemia, most commonly in children after an acute diarrheal illness. Either disorder may be observed in the setting of cancer and infection and while administering chemotherapeutic agents. In addition to specific therapies (Chapter 175), acute implementation of renal replacement therapy has significantly improved survival.

Scleroderma

The clinical features and progression of scleroderma are highly variable, but mild proteinuria without loss of renal function or evidence of glomerular disease is the most common sign of renal disease (Chapter 275). Significant renal involvement, which has been reported in 50% of patients with systemic sclerosis of 20 or more years' duration, is the most dreaded complication and has the poorest prognosis. A renal crisis may be associated with the use of corticosteroids and can be precipitated in situations that compromise renal blood flow (e.g., dehydration). An increase in vasomotor tone at the level of the renal vasculature contributes to a reduction in renal blood flow, hypertension, and progressive impairment in renal function. The resulting increase in renin and angiotensin II contributes to the development of worsening hypertension and hypertensive nephrosclerosis. Once azotemia develops, hypertension may become more difficult to manage, and dialysis is required within 1 to 2 years. Conversely, patients may initially come to medical attention with a "renal crisis" manifested by the abrupt onset of malignant hypertension and renal failure, commonly associated with heart failure and microangiopathic hemolytic anemia. This manifestation is seen in approximately 2.8% of all patients with scleroderma but in 14 to 18% of those with diffuse cutaneous disease.

TREATMENT Rx

Therapy should be directed primarily toward controlling hypertension, which may require several drugs in combination, such as ACE inhibitors or ARBs, nondihydropyridine calcium-channel blockers, vasodilators (e.g., minoxidil), and other agents (see Table 67-5 in Chapter 67). Renal crisis is an emergency that usually requires intravenous antihypertensive therapy (see Table 67-8 in Chapter 67). Some patients follow a progressive course despite blood pressure control. Patients with an initial serum creatinine level of 3.0 mg/dL or greater have a poorer prognosis. If dialysis is required, aggressive management of hypertension may allow a small but significant percentage of patients to regain sufficient renal function to allow cessation of renal replacement therapy.

Sickle Cell Nephropathy

PATHOBIOLOGY

The hypoxemic and hypertonic environment of the renal medulla (vasa recta) encourages the sickling of red blood cells circulating through this region (Chapter 166). When sickle hemoglobin desaturates, polymerization of hemoglobin can impair or interrupt capillary flow. The major manifestations of sickle cell nephropathy can all be explained by the development of papillary infarction.

CLINICAL MANIFESTATIONS

A defect in urinary concentration results in a tendency toward volume depletion in sickle cell disease and in sickle cell trait. A defect in urinary acidification is common and is manifested as distal renal tubular acidosis with hyperkalemia and hyperchloremic metabolic acidosis (type 4 renal tubular acidosis; Chapter 120). The acidification defect is usually not observed in patients with sickle trait. Microscopic hematuria occurs in most patients with sickle cell anemia. Painless gross hematuria occurs in up to 50% of patients with sickle cell nephropathy and also occurs in patients with hemoglobin SC disease. With recurrent papillary infarction, papillary necrosis can occur and progress. Sickle cell "crisis," dehydration, hypoxemia, and the use of nonsteroidal anti-inflammatory drugs predispose to papillary necrosis. Renal papillary necrosis is often silent, but it may progress to chronic renal insufficiency and predispose the patient to repeated urinary tract infections. Nephrotic syndrome may develop in approximately 4% of patients with sickle glomerulopathy. Findings on renal biopsy usually indicate membranoproliferative glomerulopathy (Chapter 123) with segmental and global sclerosis. As this disorder progresses, glomerulopathy results in sclerosis and progressive loss of glomerular function. In contrast, papillary infarction can result in persistent hematuria.

TREATMENT Rx

Volume depletion should be corrected by the intravenous administration of isotonic or hypotonic saline, as dictated by the serum sodium concentration. Hyperkalemia may require potassium exchange resin (sodium polystyrene [Kayexalate] 50 g in 70% sorbitol) per rectum or orally (15 g in water or 70% sorbitol). When acidosis accompanies the hyperkalemia, alkali may help correct both. Long-term administration of Shohl solution (15 mL two or three times daily) or sodium bicarbonate tablets (two 650-mg [7.6-mEq] tablets orally twice a day) may be necessary, and loop diuretics may be helpful. Potassium-sparing diuretics, nonsteroidal anti-inflammatory drugs, and potassium supplements should be strictly avoided. Rarely, small doses of ε-aminocaproic acid may be necessary for life-threatening hematuria, but this can result in thrombosis or ureteral obstruction.

RENAL VEINS

Renal Vein Thrombosis

EPIDEMIOLOGY

Unilateral or bilateral thrombosis of the major renal veins or their segments is often a subtle disorder that can develop in a variety of conditions (Table 127-3), but especially with nephrotic syndrome (Chapter 123) or renal malignancies (Chapter 203). Cases have also been associated with trauma, oral contraceptive use, hypovolemia, renal transplantation (Chapter 133), and thrombophilic states (Chapter 179). The reported incidence of renal vein thrombosis ranges from 5 to 62% in patients with nephrotic syndrome, including those with membranous nephropathy, membranoproliferative glomerulonephritis, focal glomerular sclerosis, sickle cell nephropathy, amyloidosis, diabetic nephropathy, renal vasculitis, and lupus nephritis. Spontaneous renal vein thrombosis is unusual in patients without underlying risk factors.

PATHOBIOLOGY

The precipitating factors are apparently abnormalities in coagulation or fibrinolysis. Antithrombin III and plasminogen levels may be depressed as a result of urinary excretion of antithrombin III in patients with nephrotic syndrome. Thrombocytosis, increased platelet activation, hyperfibrinogenemia, inhibition of plasminogen activation, and altered circulating levels of proteins S and C in nephrotic syndrome contribute to thromboembolic complications.

Extrinsic compression of the renal veins from retroperitoneal sources such as lymph nodes, fibrosis, abscess, aortic aneurysm, or tumor may cause renal vein thrombosis as a result of sluggish renal venous flow. Acute pancreatitis, trauma, and retroperitoneal surgery also may predispose to renal vein thrombosis. Renal cell carcinoma characteristically invades the renal vein and compromises venous flow, resulting in renal vein thrombosis. Renal vein thrombosis in the setting of severe volume depletion and impaired renal blood flow has been described in young adults.

CLINICAL MANIFESTATIONS

The manifestations of renal vein thrombosis depend on the extent and rapidity of the development of the occlusion. Patients with acute renal vein thrombosis may have nausea, vomiting, flank pain, leukocytosis, hematuria, compromised renal function, and an increase in kidney size. These features may be confused with renal colic or pyelonephritis. Adult patients with nephrotic syndrome and chronic renal vein thrombosis may have more subtle findings, such as a dramatic increase in proteinuria or evidence of tubular dysfunction, including glycosuria, aminoaciduria, phosphaturia, and impaired urinary acidification. Chronic renal vein thrombosis may first present in association with a pulmonary embolus.

TABLE 127-3 CAUSES OF RENAL VEIN THROMBOSIS

Nephrotic syndrome
Renal cell carcinoma with renal vein invasion
Pregnancy or estrogen therapy
Volume depletion (especially in infants)
Extrinsic compression (lymph nodes, tumor, retroperitoneal fibrosis, aortic aneurysm)
Corticosteroids

DIAGNOSIS

For acute renal vein thrombosis, which is typically associated with thrombophilia, contrast-enhanced CT shows an enlarged kidney, stretching of the calyces, and notching of the ureters. A venogram is rarely required but can be considered in cases of acute renal failure in which thrombectomy or thrombolysis is considered. In chronic renal vein thrombosis, an incidentally noted renal vein thrombus may be seen on imaging studies ordered for other reasons. Routine screening for thrombus is not recommended for those with nephrotic syndrome, but contrast-enhanced CT is recommended in patients with suggestive clinical manifestations.

TREATMENT

Rx

The most widely accepted form of therapy for both acute and chronic renal vein thrombosis is anticoagulation with low-molecular-weight heparin (see Table 81-3 in Chapter 81) or unfractionated heparin (see Table 81-4 in Chapter 81), which can be converted to oral warfarin after 7 to 10 days and should continue for at least 1 year and to an international normalized ratio of 2.0 to 3.0. In patients with ongoing risk factors, such as persistent nephrotic syndrome, or recurrent thrombosis, anticoagulation should be continued indefinitely. Fibrinolytic therapy may be considered in patients with acute renal vein thrombosis associated with acute renal failure.

PROGNOSIS

The prognosis of renal vein thrombosis depends entirely on the underlying condition causing or associated with it. Renal vein thrombosis associated with membranous glomerulonephritis and nephrotic syndrome (Chapter 123) usually resolves if the underlying condition responds to therapy or spontaneously resolves. In contrast, renal vein thrombosis associated with renal cell carcinoma (Chapter 203) has a very poor prognosis. Renal vein thrombosis associated with trauma or hypovolemia may resolve after appropriate therapy.

128

NEPHROLITHIASIS

GARY C. CURHAN

DEFINITION

A kidney stone is a crystalline mass that is formed in the kidney and that is of sufficient size to be clinically detectable, either by symptoms or by imaging. The composition of different types of kidney stones determines the clinical evaluation, treatment, and prognosis. The most common component is calcium oxalate; other types are calcium phosphate, uric acid, struvite, and cystine stones (Fig. 128-1). Infrequently, stones may be composed of medications, including acyclovir, indinavir, and triamterene.

EPIDEMIOLOGY

The prevalence of a history of kidney stone disease increased between the early 1970s and 1990 in both men and women and in whites and blacks. Nephrolithiasis accounts for nearly 2 million physician office visits with estimated annual health care costs of approximately $2 billion. The lifetime risk of stone formation in the United States is approximately 12% in men and 6% in women. The risk in blacks is one fourth that of whites.

Among men who have never had a stone, the incidence is 3 to 4 cases per 1000 men per year between the ages of 30 and 60 years and then slowly declines with age. For women, the incidence is 2 cases per 1000 women per year between the ages of 20 and 30 and then declines to approximately 1 per 1000 women per year for the next four decades.

The risk of recurrent stone formation in untreated patients after the first stone remains uncertain. Earlier studies reported stone recurrence rates ranging from 30 to 50% at 5 years. However, control groups in recent randomized controlled trials of incident calcium oxalate stone formers experienced substantially lower rates of first recurrence (2 to 5 per 100 person years). Unfortunately, no information on sex-specific rates is available from these trials.

Risk Factors

Dietary Factors

Nutrients

Dietary factors that appear to increase the risk for nephrolithiasis include animal protein, oxalate, sodium, sucrose, fructose, and vitamin C. Higher intake of potassium and phytate reduces the risk.

Low dietary calcium intake increases the risk for stone formation. Although the mechanism is uncertain, low calcium intake increases the gastrointestinal absorption and urinary excretion of oxalate. It is also possible that other factors in dairy products, the major source of dietary calcium, may reduce the risk for stone formation. In contrast, calcium supplements appear to increase the risk of incident stone formation. Thus, they should be used with caution in individuals with a history of calcium stone disease.

Higher animal protein intake may raise urinary excretion of calcium and uric acid and decrease urinary excretion of citrate, thereby increasing the risk for stone formation. Higher sodium or sucrose intake increases urinary

calcium excretion, and potassium supplementation decreases calcium excretion. In prospective studies, an increased risk for stone formation has been observed in men with higher intakes of animal protein, whereas a decreased risk for stones has been observed with higher potassium intake. Phytate, which is found in cold cereals, dark bread, and beans, can substantially reduce the likelihood of stone formation in younger women. These studies suggest that risk factors may vary by age and gender.

Although calcium oxalate is the most common stone and urine oxalate is clearly an important risk factor for stone formation, the role of dietary oxalate in the pathogenesis of calcium oxalate nephrolithiasis appears to be limited. The proportion of dietary oxalate that is absorbed from the gastrointestinal tract is estimated to range from 10 to 50%. Factors influencing absorption likely include other dietary components (e.g., calcium), genetic factors, and possibly intestinal flora. In addition, the bioavailability of oxalate in food is unknown. Urinary oxalate is also derived from the endogenous metabolism of glycine, glycolate, hydroxyproline, and vitamin C. Individuals who have Crohn's disease (Chapter 143) or who have had gastrointestinal bypass surgery often have very high urinary oxalate values owing to an increased absorption of dietary oxalate.

Fluid Intake

Fluid intake is the primary determinant of urinary volume, and daily urine volume is a crucial factor in stone formation, particularly when urine output is less than 1 L/day. The important protective role of fluid intake has been demonstrated in observational studies and was confirmed in a randomized controlled trial. Because the concentrations, not just the total amounts, of relevant urinary factors are the key determinants of stone formation, fluid intake and subsequent urinary volume are critical.

Systemic Conditions

Systemic conditions that increase the risk for formation of calcium-containing stones include primary hyperparathyroidism (Chapter 253) and renal tubular acidosis (Table 128-1). Primary hyperparathyroidism is found in less than 5% of stone formers. Obesity, gout, and diabetes mellitus are independently associated with stone formation, as are Crohn's disease and surgical treatments for obesity, such as gastric bypass surgery.

PATHOBIOLOGY

Genetics

Individuals with a family history of stone disease have a two-fold higher risk of becoming stone formers. Rare monogenic causes of nephrolithiasis include Dent's disease and cystinuria (Chapter 130). A recent genome-wide association study suggested that a single nucleotide polymorphism in the claudin-14 gene is associated with a higher risk of stone formation. Conversely, studies of specific genes involved in calcium metabolism, such as the calcium-sensing receptor and the vitamin D receptor, have not been conclusive in humans.

Pathogenesis

Supersaturation

Stone formation is the result of a complex physicochemical process that leads to crystallization. Although normal individuals can have crystalluria and not actual stones, the presence of crystalluria substantially increases the likelihood of stone formation. Formation of crystals in urine is largely a function of supersaturation, a concentration above a material's solubility in water.

Evidence suggests that the initial crystal nidus of calcium oxalate stones forms in the *medullary interstitium* and is composed of calcium phosphate. The calcium phosphate crystals then erode through the papilla, forming the classic Randall's plaque, where they act as a nidus for the deposition of calcium oxalate.

TABLE 128-1 SYSTEMIC DISORDERS ASSOCIATED WITH A HIGHER RISK FOR STONE FORMATION

Crohn's disease
Primary hyperparathyroidism
Gout
Diabetes mellitus
Obesity
Gastric bypass procedure
Renal tubular acidosis

Most stones do not contain one single type of crystal but rather are a mixture with one or two types that predominate. Furthermore, kidney stones also contain protein in the stone matrix.

Modifiable factors that influence supersaturation include pH, volume, and inhibitors. Crystallization of uric acid and calcium phosphate is strongly influenced by urinary pH, which has little effect on calcium oxalate. For all types of stones, supersaturation is dependent on urinary volume; increasing daily urine volume (ideally to greater than 2 L) is of practical benefit in reducing the supersaturation and incidence of stones.

The urine of most individuals is supersaturated with respect to calcium oxalate and calcium phosphate. The remarkable ability of urine to inhibit crystallization prevents most of the population from continuously forming stones. The compounds that stabilize and prevent crystallization within the tubules and the urinary tract are incompletely characterized but include citrate and urinary proteins.

Hypercalciuria

The common definition of hypercalciuria is urine calcium excretion greater than 300 mg/day in men, greater than 250 mg/day in women, or greater than 4 mg/kg/day on a 1000-mg/day calcium diet. Although this higher cutoff for men is reasonable from a calcium balance perspective, it is not relevant for stone formation because urine volumes in men and women are similar. Second, a definition based on weight is problematic. For example, if an individual gains 20 kg in weight, the amount of calcium that that person would be "allowed" to excrete would increase by 80 mg, but the risk of forming stones would rise.

Hyperoxaluria

Hyperoxaluria is often defined as urinary oxalate excretion of more than 45 mg/day, but the risk of stone formation begins well below this level. Elevated urinary oxalate excretion may be present in up to 40% of male and 10% of female stone formers, but hyperoxaluria is also frequently found in individuals who do not have a history of stone disease.

Hyperuricosuria

Persons with gout (Chapter 281) have an increased frequency of stone disease, and a double-blind trial about 25 years ago showed that allopurinol successfully decreased recurrence rates of calcium stones in patients with hyperuricosuria, often defined as more than 800 mg/day in men or more than 750 mg/day in women. However, a large study did not find a correlation of 24-hour urine uric acid excretion with an increased risk of calcium oxalate stone formation. Although hyperuricosuria is a risk factor for uric acid stones, its role in calcium oxalate stones is uncertain, and any protective benefit of allopurinol may be through a mechanism other than the lower urine urate.

Hypocitraturia

Citrate inhibits the growth and aggregation of crystals, and individuals with hypocitraturia (<320 mg/day for men and women) are at increased risk for stone formation. It is likely that an increase of urinary citrate above the normal range provides additional protection against stones. Although citrate in normal individuals is influenced by foods that are high in alkali (e.g., fruits, vegetables) or that generate acid (e.g., nondairy animal protein), they do not completely account for the higher renal tubular reabsorption of citrate in patients who have hypocitraturia and idiopathic calcium stones.

Formation of Non-Calcium-Containing Stones

Uric Acid Stones

Although uric acid excretion is important, the major driver of uric acid supersaturation and subsequent uric acid stone formation is low urinary pH. Many patients who form uric acid stones do not have markedly elevated urinary uric acid excretion (defined previously), but they do have persistently acid urine with the urinary pH typically below 5.5 throughout the day. Factors that contribute to lower urinary pH include obesity, type 2 diabetes mellitus, and high nondairy animal protein intake.

Struvite Stones

Struvite stones, also known as infection or triple-phosphate stones, form only when the upper urinary tract is infected with urease-producing bacteria such as *Proteus mirabilis, Klebsiella pneumoniae,* or *Providencia* species. Hydrolysis of urea by urease results in a supraphysiologic urine pH higher than 8.0 and the formation of struvite [$(NH_4)MgPO_4 \cdot 6(H_2O)$]. If the infection is

inadequately treated, struvite stones may grow quickly, fill the renal collecting system, and result in a staghorn calculus.

Cystine Stones

Cystine stones form in individuals with an uncommon autosomal recessive disorder of defective proximal renal tubular reabsorption of filtered dibasic amino acids. Cystine is clinically significant because of its poor solubility in urine. Normal cystine excretion is less than 18 mg/day, but heterozygotes with hypercystinuria (Chapter 130) may excrete up to 100 mg/day, and homozygotes may excrete more than 1 g/day. Cystine solubility is about 250 mg/L, so heterozygotes typically do not form cystine stones. Cystine stones are visible on plain radiographs and will often be manifested as staghorn calculi or multiple bilateral stones.

CLINICAL MANIFESTATIONS

A kidney stone takes weeks to months (and often much longer) to grow to a clinically detectable size. Although the passage of a stone is a dramatic event, a stone's formation and growth are typically clinically silent. A stone can remain asymptomatic in the kidney for years or even decades. Signs (e.g., hematuria) and symptoms may not become apparent until years after the stone has formed. Thus, it is important to remember that onset of symptoms, typically attributable to a stone moving into the ureter, does not provide insight into when the stone actually formed. The precipitants of movement of a stone are unknown.

Acute Renal Colic

When a stone moves from the renal pelvis into the ureter, the typical symptom is the sudden onset of unilateral flank pain of sufficient severity that the individual eventually seeks medical attention, often at an emergency department. Although the term *colic* is used, the pain does not completely remit but rather waxes and wanes. The pain, which is often accompanied by nausea and occasionally by vomiting, may radiate differently, depending on the location of the stone. If the stone lodges in the upper part of the ureter, pain may radiate anteriorly; if the stone is in the lower part of the ureter, pain can radiate to the ipsilateral testicle in men or the ipsilateral labium in women; and if lodged at the ureterovesical junction, the major symptoms may be urinary frequency and urgency. Occasionally, a patient will have gross hematuria without pain.

DIAGNOSIS

Physical examination alone will rarely make the diagnosis, but it may uncover clues to guide the evaluation. The patient will typically be in obvious pain and unable to find a comfortable position. Ipsilateral costovertebral tenderness is common. If the stone causes urinary obstruction, signs of infection and sepsis may be found. Occasionally, the examination may reveal findings associated with stone formation, such as tophi, but the physical examination rarely is diagnostic for stone disease.

Serum chemistry findings are typically normal, but the white blood cell count may be elevated. Urinalysis will classically reveal red and white blood cells and occasionally crystals. The absence of hematuria does not exclude a stone because no urine will be flowing from a ureter that is completely obstructed by a stone.

The diagnosis often is so clear, based on the history, physical examination, and urinalysis, that urgent radiographic confirmation is not required for acute care to be started. When such stable patients respond to analgesic therapy, imaging studies can be deferred for 2 to 3 weeks and performed only in patients whose stones do not pass or symptoms resolve.■

Diagnosis is confirmed by an appropriate imaging study (Fig. 128-2), preferably helical computed tomography (CT) because of its high sensitivity, ability to visualize uric acid stones (traditionally considered "radiolucent"), and ability to avoid radiocontrast. Helical CT detects stones as small as 1 mm, thus identifying small stones that may be missed by intravenous urography. Typically, helical CT will reveal a ureteral stone or evidence of recent passage (e.g., perinephric stranding or hydronephrosis), whereas a plain abdominal radiograph (kidney-ureters-bladder) can miss a stone in the ureter or kidney, even if radiopaque, and provides no information on obstruction. Although abdominal ultrasound has the advantage of avoiding radiation, this technique can image only the kidney and possibly the proximal segment of the ureter, so it misses most ureteral stones.

Differential Diagnosis

Because stone disease is common, a stone in the renal pelvis does not alone confirm the diagnosis in a patient with acute abdominal or flank pain.

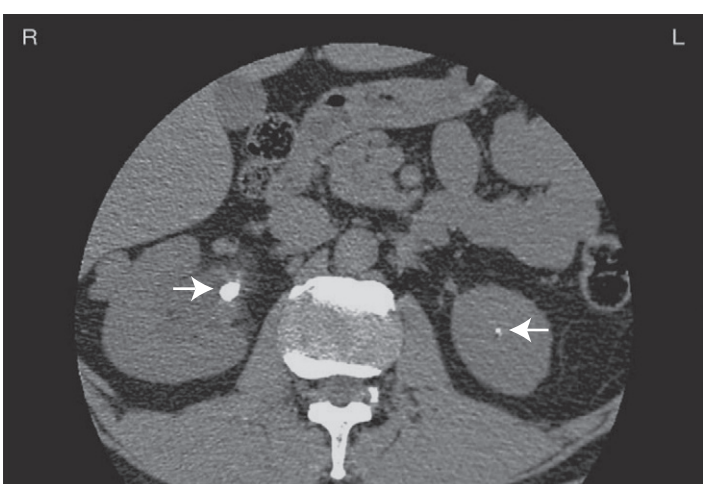

FIGURE 128-2. **High-resolution helical computed tomographic (CT) scan of the upper part of the abdomen demonstrating a stone in the right renal pelvis and a smaller stone in the left kidney *(arrowheads)*.** There is no hydronephrosis. (From Curhan GC. Clinical crossroads: a 44-year-old woman with kidney stones. *JAMA*. 2005;293:1107-1114.)

A stone lodged at the right ureteropelvic junction may mimic acute cholecystitis (Chapter 158), a stone in the distal right ureter may mimic acute appendicitis (Chapter 144), a stone at the ureterovesical junction may mimic acute cystitis (Chapter 292), and a stone in the distal left ureter may mimic diverticulitis (Chapter 144). An obstructing stone with proximal infection may mimic acute pyelonephritis (Chapter 292). Infection in the setting of ureteral obstruction is a medical emergency ("pus under pressure") that requires immediate drainage by placement of either a ureteral stent or a percutaneous nephrostomy tube. Other conditions to consider in the differential diagnosis include muscular or skeletal pain, herpes zoster (Chapter 383), duodenal ulcer (Chapter 141), abdominal aortic aneurysm (Chapter 144), gynecologic causes, ureteral stricture, and ureteral obstruction by materials other than a stone, such as a blood clot or sloughed papilla. Although extraluminal processes, such as extensions of gynecologic malignancies (Chapter 205) or retroperitoneal fibrosis (Chapter 284), can lead to ureteral obstruction, patients with these conditions tend not to have colic because of the usually gradual onset of the obstruction.

Chronic Nephrolithiasis

Among individuals with a documented history of nephrolithiasis, chronic back or flank pain is not infrequently encountered. Clinically, patients with an asymptomatic renal stone often have microscopic hematuria. Because stone disease itself is rarely a cause of chronic pain, the goal should be to determine the source of the pain. The differential diagnosis includes musculoskeletal pain, other intra-abdominal and pelvic conditions, and drug seeking. A thorough urologic evaluation, including appropriate radiologic studies, may curtail the long-term use of narcotics and avert frequent trips to the emergency room.

TREATMENT Rx

Medical Therapy

Renal colic can cause excruciating pain, so pain control is a priority after the definitive diagnosis has been made (Fig. 128-3). Nausea and vomiting often prevent the use of oral medication, so parenteral medication is typically required. Narcotics and parenteral nonsteroidal anti-inflammatory drugs (NSAIDs) have been demonstrated to be equally effective, and NSAIDs are preferred because of fewer side effects.■ Ketorolac, 30 mg given intravenously (IV), is the usual adult dose. If oral NSAIDs are selected, ibuprofen is the most common choice. Morphine (5 to 10 mg IV) and hydromorphone (1 to 2 mg IV) are the most commonly used parenteral narcotics in adults. Oral oxycodone may be given for pain control after discharge. If antiemetics are required, ondansetron (2 to 4 mg IV) is often used because it is not sedating. However, the risk of parenteral NSAIDs may be increased in the setting of dehydration, decreased renal function, or the use of radiocontrast. Alkalinization of urine may be effective for the acute treatment of ureteral uric acid stones, but these are not nearly as common as calcium stones. Intravenous

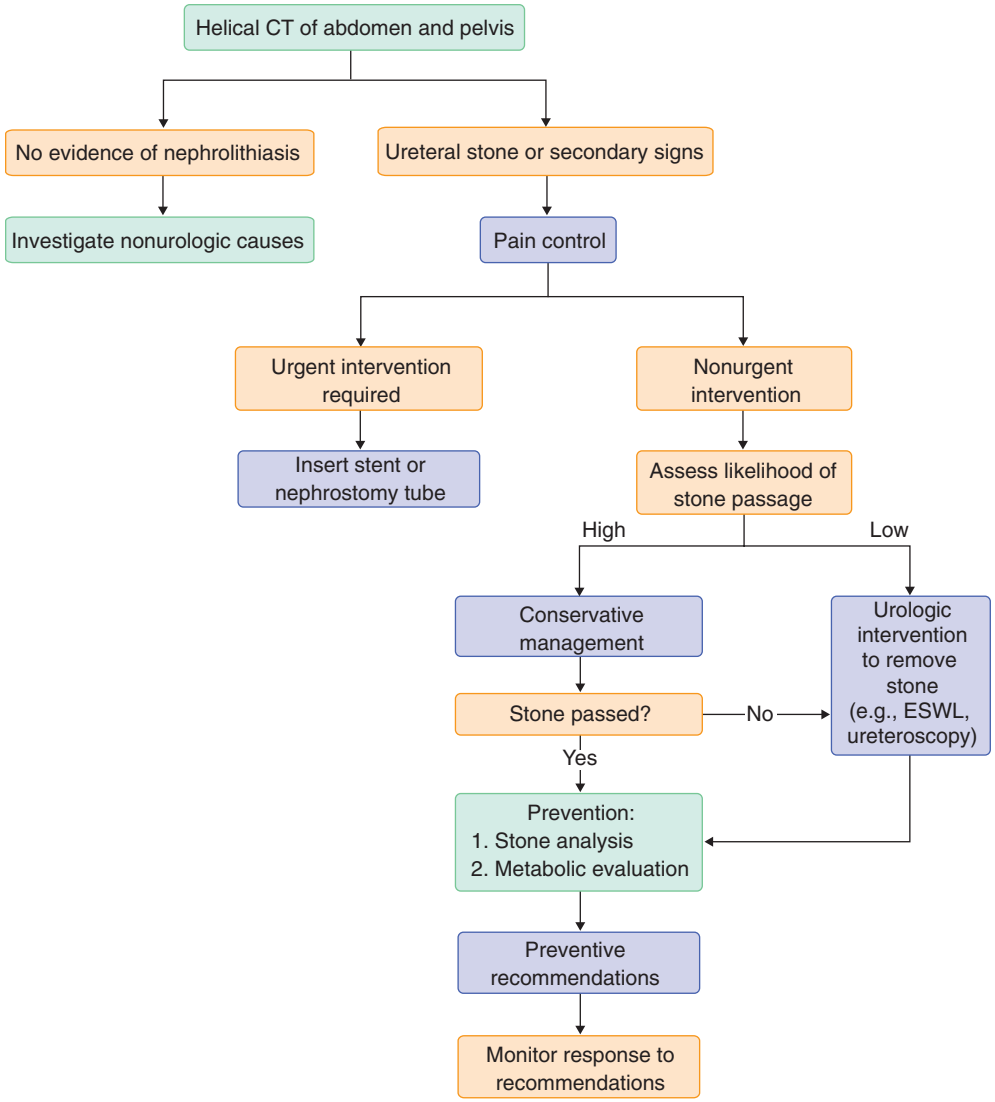

FIGURE 128-3. Algorithm for evaluation of suspected renal colic. ESWL = extracorporeal shock wave lithotripsy.

fluids are routinely given in the hope that increased ureteral flow will increase the likelihood that the stone will pass, but hydration status has little, if any, impact on stone passage.[3] Maintenance intravenous fluid replacement, such as half-normal saline with dextrose at 50 to 75 mL/hour, is reasonable for patients who are not able to take fluids orally.

A patient who is able to tolerate oral analgesics does not require admission, but instructions should be given to return if fever or uncontrollable pain develops. A urologist should be involved if infection is suspected, if the patient has persistent or uncontrollable pain, if the stone is not passed within 1 week, if urinary extravasation is detected by imaging, if there is high-grade obstruction with a large stone, or if the patient has a solitary kidney or is pregnant. For distal ureteral stones, meta-analysis suggests that oral calcium-channel blockers (e.g., nifedipine, 30 mg slow-release daily) or α-blockers (e.g., tamsulosin, 0.4 mg daily) administered for up to 28 days can increase the rate of spontaneous stone passage by 65%.[4]

Surgical Therapy

Most urologists usually wait several days before intervening unless there is evidence of urinary tract infection, a low probability of spontaneous stone passage (e.g., stone >6 mm or an anatomic abnormality), or intractable pain. Relief of obstruction is critical. A ureteral stent may be placed cystoscopically, but general anesthesia is typically required. Although the stent can be quite uncomfortable and may cause gross hematuria, it may help with stone passage.

The approach to removing a stone is dictated by its size, location, and composition; urinary tract anatomy; availability of technology; and the experience of the urologist. The least invasive approach is extracorporeal shock wave lithotripsy (ESWL). The ESWL procedure uses shock waves that are generated outside the body and that are focused on the stone using fluoroscopy or ultrasound. The shock waves fragment the stone into smaller pieces that then can be passed more easily. The strength of the shock waves, which is determined by the model of lithotripter machine used, determines the type of anesthesia required. ESWL can be used in the acute setting for upper tract stones,[5] but the success rate depends on the size, location, and composition of the stone. Cystoscopic stone removal, either by basket extraction or by laser fragmentation, is more invasive than ESWL but has a higher success rate, especially for ureteral stones, and is as good as ESWL for removing lower pole renal caliceal stones less than 1 cm in diameter.[6] Percutaneous nephrostolithotomy has the highest likelihood of making a patient stone free but is more invasive than cystoscopic methods. These endoscopic approaches have virtually eliminated the need for open surgical procedures such as ureterolithotomy or pyelolithotomy.

Asymptomatic Stones

With the increasing use of imaging, more incidental stones are being found. The best approach for asymptomatic renal stones is unsettled. Slightly less than 50% of individuals with radiologically documented asymptomatic stones will become symptomatic over a 5-year period. Most urologists would not consider removal of a stone that is 6 mm or smaller. For stones that are 10 mm or larger, many would recommend "prophylactic lithotripsy," but there are no data to support this approach.

Struvite Stones

Struvite stones require urologic intervention to ensure complete removal. The recommended approach is a combination of percutaneous nephrolithotomy and extracorporeal shock wave lithotripsy. Prolonged use of antibiotics alone may slow stone growth but rarely eradicates the infection. Although the medication acetohydroxamic acid inhibits bacterial urease, it is rarely used because of frequent and serious side effects.

PREVENTION

Evaluation after the First Stone

A complete history should include the pace and severity of all prior stone episodes as well as information regarding previous imaging studies (to

TABLE 128-2 LABORATORY EVALUATION

Spot urinalysis	Measure pH and examine the sediment for RBC, WBC, and crystals
24-Hour urine collection	Perform at least two at baseline; measure total volume, calcium, oxalate, citrate, uric acid, sodium, potassium, and creatinine If patient with cystine stones, also measure cystine
Blood	Electrolytes, calcium, phosphorus, BUN, creatinine If urine calcium or serum calcium is high, then measure PTH; if PTH is elevated, measure 25-hydroxyvitamin D to rule out secondary hyperparathyroidism If history of gout or considering use of a thiazide, measure serum uric acid If history of cystine stones, CBC and liver function tests should be performed before starting tiopronin

BUN = blood urea nitrogen; CBC = complete blood count; PTH = parathyroid hormone; RBC = red blood cells; WBC = white blood cells.

TABLE 128-3 DIETARY PRESCRIPTION FOR CALCIUM STONE PREVENTION ACCORDING TO URINARY RISK FACTOR

URINARY ABNORMALITY	DIETARY CHANGES
High calcium	Adequate dietary calcium intake Reduce nondairy animal protein intake (5-7 servings of meat, fish, or poultry/week) Reduce sodium intake to <2.4 g/day Reduce sucrose intake
High uric acid	Reduce purine intake
High oxalate	Avoid high-oxalate foods Avoid vitamin C supplements Adequate dietary calcium intake
Low citrate	Increase fruit and vegetable intake Reduce nondairy animal protein intake
Low volume	Increase total fluid intake to maintain urine volume to >2 L/day

Taylor EN, Curhan GC. Diet and fluid prescription in stone disease. *Kidney Int.* 2006;70:835-839.

distinguish stone passage events from actual new stone formation), surgical interventions, urinary tract infections, bowel disease or surgery, diarrhea or laxative abuse, family history of stone disease, and signs or symptoms suggestive of hyperparathyroidism (Chapter 253). In addition, information should be collected on dietary intake and the use of vitamins (e.g., C and D), minerals, and other supplements, as well as medications (e.g., carbonic anhydrase inhibitors, diuretics). The evaluation should also include appropriate clinical and laboratory evaluation to identify derangements and predict the likelihood of recurrence. Advice should be deferred until after the evaluation is complete; specifically, patients should be encouraged to resume their usual dietary habits while laboratory studies are completed.

Metabolic Evaluation

Every effort should be made to recover a stone that has passed or was removed, and its chemical composition should be analyzed by modern crystallographic methods. Even if the content of the stone is known, the metabolic evaluation for first-time and recurrent stone formers (Table 128-2) should include a serum chemistry profile and two 24-hour urine collections (because of substantial day-to-day variability).

Blood studies should include measurements of creatinine, calcium, phosphorus, albumin, uric acid, potassium, and total CO_2. Measurement of plasma parathyroid hormone level is recommended if serum or urine calcium levels are elevated.

The 24-hour urinary studies should be performed at least 6 weeks after the stone episode to ensure that patients have resumed their usual diet. The 24-hour measurements should include calcium, oxalate, uric acid, citrate, sodium, total volume, and creatinine. The urinary sediment should be examined for crystalluria in a freshly voided sample.

The 24-hour urine composition provides important prognostic information and directs recommendations for stone prevention. Traditionally, patients have been categorized into "normal" and "abnormal" with respect to the amount of lithogenic substances excreted. However, the measured values for the urinary factors are continuous variables, so dichotomization into normal and abnormal is somewhat artificial and potentially misleading. Second, stone formation is a disease of *concentration,* not just absolute amounts. Although a patient may have a normal amount of calcium in the urine over 24 hours, if the volume is low, the concentration of calcium would be abnormally high.

Patients with hypercalciuria can be divided into those with *absorptive* hypercalciuria (increased gastrointestinal calcium absorption), *resorptive* hypercalciuria (increased bone resorption), or *renal* hypercalciuria. However, a substantial proportion of patients do not fit into one category, an individual's classification may change over time, low bone mineral density may not be causally related to stone formation, and this classification approach rarely affects therapy.

All Stones

Dietary Modification

The observed increasing prevalence of nephrolithiasis and the physiologic impact of dietary factors have focused attention on the role of diet in stone formation (Table 128-3). In addition, the strong associations found in prospective studies of diet and initial stone formation (see earlier) suggest that dietary factors play an important role.

Fluid Intake

Stone formation is strongly influenced by urinary concentration, so the risk for stone formation decreases with increasing urine output. A general target is to encourage patients to drink enough fluid to produce more than 2 L of urine each day. The composition of the fluid ingested may be important, and observational studies suggest that higher intakes of coffee, tea, or alcoholic beverages are associated with a decreased risk for stone formation, perhaps because of the known diuretic action of these beverages.

Dietary Measures

Calcium Stones

The most controversial topic in dietary intervention for patients with nephrolithiasis is calcium intake. A low-calcium diet is often inappropriately recommended despite evidence that a low-calcium diet may in fact be *harmful* by increasing oxalate absorption from the intestine and also by leading to negative calcium balance and bone mineral loss. For example, in a randomized trial in men with hypercalciuria and recurrent calcium oxalate stones, a diet containing 1200 mg of calcium with a low intake of sodium and animal protein significantly reduced subsequent stone formation compared with a low-calcium diet (400 mg day).[7] The protective role for adequate dietary calcium intake does not extend to calcium from supplements, which either have no effect or slightly increase the risk of stone formation, and a very high calcium intake (>2 to 3 g/day) should be discouraged. Although the bioavailability of calcium is the same in dairy and calcium supplements, it is possible that dairy products, the major source of dietary calcium, contain some unidentified protective factor.

Other Dietary Factors

Restriction of nondairy animal protein (e.g., meat, chicken, seafood) is a reasonable option and may result in higher excretion of citrate and lower excretion of uric acid and calcium. For patients with high oxalate excretion, restriction of dietary oxalate may be beneficial. Reliable and complete data on the oxalate content of many commonly consumed foods are now available (*https://regepi.bwh.harvard.edu/health/Oxalate/files*). Spinach should be avoided because it is the highest oxalate-containing food. Reducing sodium intake to less than 3 g/day may decrease the obligatory, concurrent urinary excretion of calcium and may be particularly important for patients prescribed a thiazide. Sucrose intake, which may increase urinary calcium excretion, should be minimized. In contrast, potassium-rich foods should be encouraged. Dietary recommendations should be tailored to the patient's urinary chemistry profile, and the impact of the recommendations can be monitored by repeating the urine collections.

Uric Acid Stones

The mainstay of treatment to prevent uric acid stones is increasing urine pH by dietary modification, which should focus on decreasing acid production by reducing the intake of animal flesh and increasing the intake of alkali-rich foods, specifically fruits and vegetables. If dietary modification is unsuccessful, alkalinization with oral bicarbonate, typically requiring 20 to 30 mEq

three times per day, or a bicarbonate precursor (e.g., potassium citrate, 20 to 30 mEq three times per day) should be started. The pH goal is 6 to 7 throughout the day and night. Alkali three or four times a day is typically needed to match the endogenous acid production of approximately 1 mEq/kg per 24 hours. However, a urine pH greater than 7 should be avoided to minimize the likelihood of inducing calcium phosphate crystallization. Allopurinol (100 to 300 mg/day) should be prescribed for patients in whom alkalinization fails.

Cystine Stones

The total amount of cystine excreted cannot be easily modified, so treatment is directed at decreasing the urinary cystine concentration below the limit of solubility. Increasing urinary volume is the first approach, but some patients would need more than 4 L of urine per day, which is impractical. Increasing urine pH above 7.5 using oral alkali, such as 20 to 30 mEq of potassium citrate twice daily, will slightly increase cystine solubility, but this pH is often difficult to maintain in the long term. Tiopronin, typically 300 mg orally three times per day, will bind cystine and reduce urine supersaturation. Although side effects are common, tiopronin is first-line therapy in patients with recurrent cystine stone formation because there are no other alternatives.

Medical Prevention

Although nephrolithiasis is a common disease, surprisingly few well-designed prospective double-blind controlled trials have been conducted. Some medications may improve the urinary chemistry profile but not cure the underlying abnormality. Thus, the decision to start medication requires consideration of efficacy, side effects, cost, and adherence of the patient. Certainly, if new stone formation occurs despite dietary recommendations, medication should be prescribed. If urine calcium levels are elevated, a thiazide diuretic is recommended. For patients with hypocitraturia or hyperuricosuria as a sole finding, potassium citrate and allopurinol can be used, respectively. Unfortunately, the optimal duration of treatment is unclear, and long-term adherence remains suboptimal.

Thiazides

Thiazide diuretics, such as hydrochlorothiazide and chlorthalidone, increase calcium reabsorption in the proximal convoluted tubule and distal tubule and effectively lower urinary calcium excretion by 20 to 50%. In some patients, urine calcium levels may rise after a year despite continued therapy. Thiazides can also increase the mineral content of bone. About 30 years ago, two trials showed that thiazides reduced the risk of recurrent calcium oxalate stones in otherwise unclassified patients. The doses required for urinary calcium reduction (25 to 100 mg/day) are higher than those needed for treating hypertension. Side effects are reported in 8 to 35% of patients. Thiazide-induced hypokalemia can be treated with potassium citrate (20 mEq per day) or amiloride (2.5 to 5.0 mg per day). Because of its potential to precipitate in the urine, triamterene should be avoided in these patients. Indapamide (2.5 mg per day), although not strictly a thiazide, will also reduce urine calcium. Monitoring the urine calcium response with subsequent dosage adjustment is recommended.

Allopurinol

Allopurinol (300 mg per day) can reduce urine uric acid excretion by up to 50%, and it was shown 25 years ago to reduce stone recurrence in individuals with hyperuricosuric calcium oxalate stone disease. In patients without hyperuricosuria, allopurinol has no benefit when compared with placebo.

Potassium Citrate

Systemic alkalinization of the urine with bicarbonate (typically 30 mEq twice daily) or citrate (typically 30 mEq twice daily) will lead to an increase in urinary citrate excretion. The most commonly used salt is potassium citrate, which avoids the calciuric effect of a sodium load and restores any potassium deficiency. Citrate supplementation reduces recurrent calcium oxalate stones compared with placebo, but adherence to prescribed dosing is suboptimal.

Magnesium

Oral magnesium from supplements may reduce stone risk by forming soluble complexes with oxalate in the bowel or urine. However, in a 3-year double-blind trial, magnesium was no more effective than placebo. Thus, the role of magnesium supplementation remains uncertain.

Other Genitourinary Stones

Stones can form in other parts of the genitourinary tract, including the bladder and rarely the prostate. In the United States, the most common type of bladder stone is uric acid. Bladder stones are much more common in men because the primary risk factors are urinary stasis owing to bladder outlet obstruction and a persistently low urine pH. As with uric acid stones that form in the kidney, hyperuricosuria is not always present, but the low urine pH dramatically reduces the solubility of uric acid in the urine. Patients with bladder stones often pass stones frequently, sometimes on a daily basis. The stones can range in size from "sand" or "gravel" to several centimeters. Stones of sufficient size are characteristically round because of the rolling that can occur in the bladder. Bladder stones do not cause renal colic but can cause partial or complete acute urinary retention by obstructing the urethra. The rate of stone formation can be dramatically reduced or even halted by improving urine flow by medications or surgery (Chapter 131) or through alkalinization of the urine. Potassium citrate, typically 20 to 30 mEq three times daily, is sufficient to stop stone formation.

CYSTIC KIDNEY DISEASES

M. AMIN ARNAOUT

DEFINITION AND EPIDEMIOLOGY

The term *cystic kidney diseases* refers to a heterogeneous group of hereditary and acquired disorders characterized by the presence of unilateral or bilateral renal cysts. When acquired singly or in small numbers and in the absence of any other pathology, renal cysts are termed *simple cysts*, which are present in approximately 50% of individuals older than 40 years, are usually not loculated, and tend to bulge out from the renal surface (Fig. 129-1). The *polycystic kidney diseases* (PKDs), by comparison, constitute a clinically important group of genetically mediated disorders characterized by prominent, expanding, bilateral renal cysts. PKDs are classified as dominant, recessive, or X-linked, based on their pattern of inheritance. Autosomal dominant PKD (ADPKD), with a prevalence rate between 1 : 400 and 1 : 1000, is the most common monogenic disease in humans and accounts for about 10% of all end-stage renal disease (ESRD) in the United States. ADPKD develops in an age-dependent manner and affects mainly adults. Autosomal recessive PKD (ARPKD), by contrast, is a relatively rare childhood disorder that appears in 1 in every 6000 to 50,000 live births. Renal cysts are also seen in several other rare hereditary kidney diseases and in several syndromic PKDs (Table 129-1). Collectively, the hereditary PKDs generally affect both genders and all races equally and cost more than $1 billion annually to manage in the

The cysts bulge out from the surface of a normal-sized kidney. **B,** Sagittal cross section of a kidney from an adult with autosomal dominant polycystic kidney disease (ADPKD). Multiple macroscopic cysts have resulted in an enlarged but still reniform kidney (note the evidence of prior hemorrhage within some of the cysts). **C,** Sagittal cross section of a kidney segment from a neonate with autosomal recessive polycystic kidney disease (ARPKD). The kidney is enlarged, with numerous small cysts. (Courtesy Dr. Robert Colvin, Massachusetts General Hospital.)

United States alone. *Acquired cystic kidney disease* refers to the multiple bilateral renal cysts that develop in patients who already have kidney disease. Cysts occur in 90% of patients who have been receiving renal replacement therapy for 8 years or longer and are associated with increased rates of renal cell carcinoma.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

PATHOBIOLOGY

ADPKD is a systemic disorder characterized by cyst formation in multiple organs, including the kidneys, other ductal organs, and the cardiovascular system. Renal cysts originate as outpouchings of tubules and may affect any portion of the nephron, with up to 1% of nephrons involved. The outpouchings expand and eventually separate from the parent tubules, yielding cysts (Fig. 129-2). Expansion of cysts is caused by proliferation of the cyst lining cells, by chloride-driven fluid secretion that outpaces absorption, and by remodeling of the extracellular matrix. The kidneys become massively enlarged.

Genetics

Heterogeneous mutations in two genes, *PKD1* and *PKD2,* cause ADPKD. Mutations in *PKD1* account for approximately 85% of cases of ADPKD. Heterogeneous mutations in *PKD2* contribute an additional 10 to 15% of cases. The onset and severity of the disease are dramatically affected by the developmental stage at which gene inactivation occurs. In a minority of ADPKD cases, no demonstrable *PKD1* or *PKD2* mutations are found, suggesting that a third gene may be involved.

PKD1 is 54 kb long and is located on chromosome 16p13.3, adjacent to the tuberous sclerosis 2 (*TSC2*) gene. *PKD1* has 46 exons, generates a 14-kb transcript, and encodes a 4302- residue protein called polycystin-1, the first described member of an expanding group of polycystins. The 5′ region of human *PKD1* (to exon 33) is replicated on the same chromosome, resulting in approximately six copies of *PKD1*-like pseudogenes, which must be distinguished from the *PKD1* gene in direct mutational analysis. To date, more than 330 truncating mutations have been identified throughout the gene, but especially in the 3′ half. Mutations in the 5′ half of the gene are associated with more severe disease, with only 19% of patients retaining adequate renal function at 60 years of age (vs. 40% of those with 3′ mutations), and they are more likely to be associated with intracerebral aneurysms and aneurysm rupture.

The 68-kb *PKD2* gene is located on chromosome 4q13-23, transcribes 15 exons, and generates a 5-kb transcript, which encodes a protein of 968 residues called polycystin-2. Ninety-five heterogeneous mutations in *PKD2* have been identified to date.

Large intrafamilial variability in the onset and severity of ADPKD may be caused by bilineal inheritance of *PKD1* and *PKD2* mutant alleles or of hypomorphic variants of either gene. Mosaicism in a parent in whom a mutation has arisen de novo could result in one sibling having the disease while another is disease free, despite sharing the identical inherited haplotype at the *PKD* gene. Concomitant mutations affecting other genes can also result in ADPKD in infancy. Because cysts appear from a small number of nephrons, somatic inactivation of the normal allele has been proposed as the main mechanism of disease. *PKD1* or *PKD2* haplo-insufficiency and gene dose effects are associated with a high frequency of genomic instability, which likely increases the incidence of somatic second hits in ADPKD. Genomic instability may also explain the increased rate of apoptosis and the low incidence of renal cell carcinoma in this disease.

PATHOGENESIS

Polycystin-1 comprises a large extracellular modular ectodomain, followed by an 11-pass transmembrane segment and a short cytoplasmic carboxyl terminus (E-Fig. 129-1). The polycystin-1 ectodomain contains multiple functional motifs, suggesting a role in cell-cell and/or cell-matrix adhesion. Polycystin-2 is a six-membrane spanner that acts as a nonselective voltage-dependent, calcium-permeable ion channel with cytoplasmic amino and carboxyl termini. Its six-transmembrane segment bears a topologic and sequence similarity to the carboxyl terminal six-transmembrane segment of polycystin-1. The coiled-coil domains within the carboxyl termini of polycystin-1 and polycystin-2 interact to stabilize the channel activity of polycystin-2 and facilitate its translocation to the plasma membrane. In addition, polycystin-1 interacts with intermediate filaments, E-cadherin, focal adhesion proteins, β-catenin, and tuberin. Polycystin-1 and polycystin-2 also interact with a number of other proteins, and each of these interactions could serve as a modifier of the polycystins' functions.

Polycystin-1 and polycystin-2 are widely expressed in tissues, with some overlap consistent with their direct interaction. Polycystin-1 is found at multiple membrane sites, including adherens junctions, desmosomes and focal adhesions, primary cilia, and intracellular vesicles. Polycystin-2 is found in primary cilia as well as the basolateral membrane, endoplasmic reticulum, centrosome, and mitotic spindles in dividing cells. Both polycystin-1 and polycystin-2 are also found in urinary vesicles. Levels of polycystin-1 expression are highest in fetal tissue and progressively decline thereafter, whereas polycystin-2 levels are maintained throughout development.

Cyst Formation

Both polycystin-1 and polycystin-2 localize to primary cilia, which are found on the apical surface of all renal cells except intercalated cells. The primary cilium consists of an axoneme comprising nine microtubular doublets surrounded by a cell membrane. It is assembled during the interphase from the mother centriole (basal body), which serves as a microtubule-organizing center just beneath the plasma membrane. Transition fibers associated with the basal body regulate protein entry and exit into the cilium. Because cell division requires both centrioles to form the mitotic spindle, the cell is unable to divide until its cilium is resorbed, linking the structural integrity of the cilium to cell cycle regulation. A mechanosensitive cilium is normally deflected by the tubular flow of urine, thereby activating polycystin-1– and polycystin-2–mediated calcium influx, which is amplified by calcium released from internal stores. How this process translates into regulation of tube diameter (cyst formation) is still unclear. It is proposed that calcium influx through normal primary cilia favors the noncanonical Wnt pathway (also known as planar cell polarity) over the mitogenic canonical (β-catenin–dependent) Wnt pathway, thereby maintaining cell polarity and suppressing proliferation. Planar cell polarity couples polarized cell movement and cell division for proper control of tube diameter size during tube elongation. Loss of polycystin-1 or polycystin-2 disrupts this structural link, causing cysts.

Regulation of calcium influx by polycystin-1 and polycystin-2 may not be restricted to the cilium. For example, polycystin signaling also activates the JAK/STAT pathway. Polycystin-1– and polycystin-2–mediated calcium influx suppresses intracellular cyclic adenosine monophosphate (cAMP) signaling by inhibiting adenylyl cyclase and stimulating cAMP phosphodiesterase (E-Fig. 129-2). Loss of the polycystin-1 and polycystin-2 calcium signal may lead to a buildup of cAMP, promoting cell proliferation.

TABLE 129-1 COMPARISON OF CLINICAL FEATURES OF CYSTIC KIDNEY DISEASES

DISEASE	INHERITANCE	FREQUENCY	GENE PRODUCT	AGE OF ONSET	CYST ORIGIN	RENOMEGALY	CAUSE OF ESRD	OTHER MANIFESTATIONS
ADPKD	AD	1 : 400–1000	Polycystin-1 Polycystin-2	20s and 30s	Anywhere (including Bowman's capsule)	Yes	Yes	Liver cysts Cerebral aneurysms Hypertension Mitral valve prolapse Kidney stones UTIs
ARPKD	AR	1 : 6000–10,000	Fibrocystin/ polyductin	First year of life	Distal nephron, CD	Yes	Yes	Hepatic fibrosis Pulmonary hypoplasia Hypertension
ACKD	No	90% of ESRD patients at 8 yr	None*	Years after onset of ESRD	Proximal and distal tubules	Rarely	No	None
Simple cysts	No	50% in those older than 40 yr	None*	Adulthood	Anywhere (usually cortical)	No	No	None
Nephronophthisis	AR	1 : 80,000	Nephrocystins (NPHP1–9)	Childhood or adolescence	Medullary DCT	No	Yes	Retinal degeneration; neurologic, skeletal, hepatic, cardiac malformations
MCKD	AD	Rare	Uromodulin, others	Adulthood	Medullary DCT	No	Yes	Hyperuricemia, gout
MSK	No	1 : 5000–20,000	None*	30s	Medullary CD	No	No	Kidney stones Hypercalciuria
Tuberous sclerosis	AD	1 : 10,000	Hamartin (TSC1), tuberin (TSC2)	Childhood	Loop of Henle, DCT	Rarely	Rarely	Renal cell carcinoma Tubers, seizures Angiomyolipoma Hypertension
VHL syndrome	AD	1 : 40,000	VHL protein	20s	Cortical nephrons	Rarely	Rarely	Retinal angioma, CNS hemangioblastoma, renal cell carcinoma, pheochromocytoma
Oral-facial-digital syndrome-1	XD	1 : 250,000	OFD1 protein	Childhood or adulthood	Renal glomeruli	Rarely	Yes	Malformation of the face, oral cavity, and digits; liver cysts; mental retardation
Bardet-Biedl syndrome	AR	1 : 65,000–160,000	BBS 1-14	Adulthood	Renal calyces	Rarely	Yes	Syn- and polydactyly, obesity, retinal dystrophy, male hypogenitalism, hypertension, mental retardation

*No known genetic susceptibility.
ACKD = acquired cystic kidney disease; AD = autosomal dominant; ADPKD = autosomal dominant polycystic kidney disease; AR = autosomal recessive; ARPKD = autosomal recessive polycystic kidney disease; CD = collecting duct; CNS = central nervous system; DCT = distal convoluted tubule; ESRD = end-stage renal disease; MCKD = medullary cystic kidney disease; MSK = medullary sponge kidney; UTI = urinary tract infection; VHL = von Hippel-Lindau; XD = X-linked dominant.

CLINICAL MANIFESTATIONS

ADPKD has a highly variable presentation, even within families. The clinical features of *PKD2*-associated ADPKD are indistinguishable from those of *PKD1*-associated disease. However, *PKD2* disease is milder, with an older average age of onset—74 years versus about 54 years for *PKD1*-associated disease—owing to the development of fewer cysts at an early age rather than to a slower cyst growth rate.

Despite an estimated 100% penetrance by age 90 years, only half the individuals with heterozygous mutations in *PKD1* or *PKD2* are ever diagnosed clinically with ADPKD. Of these patients, the majority present in the third or fourth decade of life with symptoms referable to renal cystic disease. However, ADPKD can develop at any age, including infancy, and it can have a nonrenal presentation. Renomegaly may predominate the clinical picture, with abdominal distention, discomfort, or pain; however, renomegaly can also be discovered incidentally on physical examination or after radiographic studies of the abdomen.

Nocturia, which is one of the earliest signs of abnormal renal function in ADPKD, reflects the early impairment in urinary concentration. The urinary pH is typically low, with hypocitric aciduria. Hematuria is typical, but proteinuria is less prominent than in many other renal diseases. Anemia features less prominently than in other renal diseases, probably because of the relatively well-preserved erythropoietin secretion. Recurrent cyst infection, usually by common urinary tract–infecting organisms, is characterized by flank or abdominal pain, fever, rigors, leukocytosis, and occasionally sepsis. Cyst hemorrhage and sometimes rupture, which can occur spontaneously or after trauma, present as sharp pain and hematuria.

Arterial hypertension is present in approximately 70% of cases before renal dysfunction is detected. Enhanced vascular smooth muscle contractility, reduced endothelial-dependent vasorelaxation, lower constitutive nitric oxide synthase activity, activation of the intrarenal renin-angiotensin system, and increased sympathetic nerve activity are likely causes of the accompanying arterial hypertension. Development of hypertension at a young age is associated with a four-fold increased risk of ESRD and increased cardiovascular morbidity. The risk for preeclampsia is also higher than in the general population.

An estimated 4 to 15% of individuals with ADPKD develop saccular cerebral aneurysms (Chapter 415), a prevalence rate that is 4 to 10 times greater than in the general population. These aneurysms tend to segregate in families, making ADPKD one of a group of diseases characterized by autosomal dominant inheritance of cerebral aneurysms. ADPKD-associated aneurysms tend to rupture at a smaller size and in younger individuals—on average, 10 years younger than among the general population. Although usually clinically silent, intact cerebral aneurysms can present with focal neurologic symptoms and headaches. By contrast, aneurysms that rupture lead to subarachnoid hemorrhage (Chapter 415) and have dramatic presentations that include severe headaches, seizures, altered sensorium, and death. Aortic and coronary

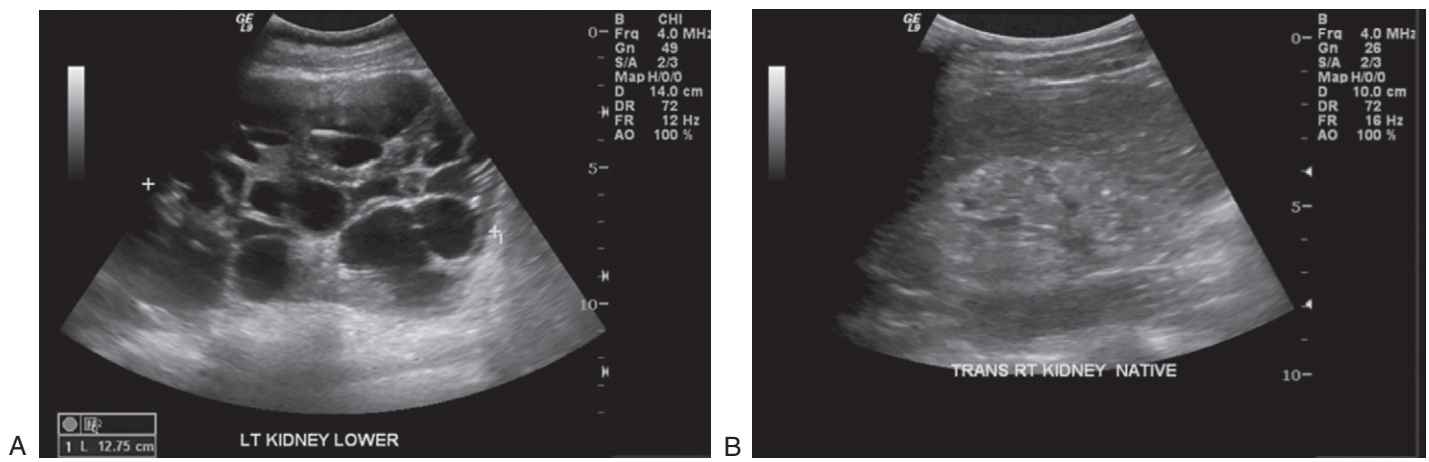

FIGURE 129-3. **A,** Ultrasound images of a kidney from a patient with autosomal dominant polycystic kidney disease. **B,** Ultrasound images of a kidney from a patient with autosomal recessive polycystic kidney disease. (Courtesy Dr. Javier M. Romero and Jennifer A. McDowell, Massachusetts General Hospital.)

artery aneurysms are also more prevalent in patients with ADPKD, and the frequency of aortic insufficiency is increased.

Although almost never severe enough to cause end-stage liver disease, age-dependent hepatic cysts occur in 30 to 80% of patients with ADPKD and can lead to signs and symptoms of mass effect, infection, hemorrhage, and rupture. Estrogen intake and multiparity in women are risk factors in developing larger and more symptomatic cysts. The cysts that occasionally form in other organs, such as the pancreas, spleen, brain, ovaries, epididymis, and prostate, are usually asymptomatic. Sperm abnormalities and defective motility may occur but rarely cause male infertility. Bronchiectasis (Chapter 90) is three-fold more common, inguinal hernias may be more prevalent, and colonic diverticulosis and diverticulitis are more common in ESRD patients with ADPKD.

DIAGNOSIS

The specific diagnosis of ADPKD requires a consideration of associated extrarenal manifestations, age at presentation, and family history. Because only about 60% of individuals give a family history of PKD, ultrasound screening of asymptomatic parents or grandparents may be required to uncover diagnostically relevant silent PKD. To account for the common age-dependent appearance of simple cysts, ADPKD is diagnosed if at least three renal cysts (distributed in one or both kidneys) are present in individuals 15 to 39 years old, if at least two renal cysts are present in each kidney in individuals aged 40 to 59 years, or if at least four renal cysts are present in each kidney in individuals 60 years and older (Fig. 129-3A). Fewer than two renal cysts in an individual aged 40 years or older from an ADPKD family with an unknown genotype, or the absence of renal cysts in such an individual aged 30 to 39 years, is sufficient to exclude the disease, with negative predictive values of 100 and 99.3%, respectively. A negative ultrasound is less accurate in excluding disease in individuals younger than 30 years, so computed tomography (CT) or magnetic resonance imaging (MRI) is recommended. When a young relative is being considered as a potential kidney donor to a family member with end-stage ADPKD, contrast-enhanced, three-dimensional CT or magnetic resonance angiography (MRA) is required because these tests can detect 3-mm cysts, compared with ultrasound's ability to detect 10-mm cysts.

DNA-based diagnosis of ADPKD by means of direct sequencing is commercially available and detects mutations in more than 90% of affected individuals. Such testing is expensive, however, and the marked allelic

heterogeneity of the *PKD1* and *PKD2* mutations, as well as the paucity of phenotype-genotype correlations, contributes to the complexity of DNA-based diagnostics. Testing is recommended when imaging studies are equivocal, in a young transplant donor from an ADPKD family when imaging studies are negative, or to facilitate preimplantation genetic diagnosis.

Monitoring Disease Progression

Despite ongoing renal cyst expansion, the glomerular filtration rate (GFR) and the serum creatinine level are generally maintained within the normal range in ADPKD patients until the fourth to sixth decade of life. As a result, these markers are insensitive for monitoring disease progression, especially in the young. Estimating kidney volume from measurements of kidney length, width, and thickness using MRI, CT, or ultrasonography can reliably monitor disease progression in the early stages of ADPKD, when the GFR is still in the normal range. Although gadolinium-enhanced MRI provides excellent detail of kidney structures, MRI without gadolinium is recommended to monitor kidney volume, especially in ADPKD patients with a reduced GFR, because of concern about nephrogenic systemic fibrosis (Chapter 275) and further impairment of renal function associated with its use. The combined kidney volume in ADPKD patients progressively increases in most cases, but at widely differing rates, ranging from less than 1% to more than 10%. Combined kidney volumes greater than 1500 mL are frequently associated with a decreased GFR and gross hematuria and invariably with arterial hypertension.

PREVENTION AND TREATMENT

Rx

Management strategies are aimed at monitoring for complications of ADPKD and treating them, as well as providing counseling. Frequent blood pressure monitoring is recommended because hypertension accelerates the decline in renal function. The goals of blood pressure control are the same as for other patients with renal disease, including the attainment of a symptom-free blood pressure of 125/75 mm Hg or less. Although all available antihypertensive agents have been used with roughly equivalent success, theoretical considerations and preliminary data suggest that angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) combined with salt restriction may be more efficient in slowing the rate of progression to ESRD (see Tables 67-5 and 67-7 in Chapter 67). If these drugs fail to lower blood pressure sufficiently owing to the associated plasma volume expansion, thiazides or loop diuretics may be added (see Table 67-5 in Chapter 67).

Treatment of urinary tract infection (Chapter 292) and prevention of nephrolithiasis (Chapter 128) are the same as in the general population and include standard antimicrobial therapy and increased fluid intake, respectively. Renal or hepatic cyst infections are optimally treated with lipophilic antibiotics that possess cyst-penetrating capabilities, including ciprofloxacin, trimethoprim, clindamycin, and vancomycin. Blood or urine cultures and sensitivities are used to guide the choice of antibiotic therapy.

Cyst hemorrhage and rupture, with resultant pain and hematuria, are usually managed conservatively with rest and analgesics; nonsteroidal anti-inflammatory drugs (NSAIDs) are avoided, owing to their antiplatelet action and potential renal toxicity. Alternatives include acetaminophen 500 mg up to every 4 hours for mild to moderate pain, nonopiates such as tramadol 50 mg up to every 4 hours for moderate to severe pain, and the addition of an oral or transdermal opioid (see Table 29-4 in Chapter 29) as needed. Patients with enlarged kidneys should be advised to avoid playing contact sports, and those with massively enlarged kidneys should refrain from wearing belts and seatbelts. Some patients with unusually painful cysts respond to cyst fluid aspiration, cyst deroofing, or ethanol-induced sclerosis.

Nephrectomy is rarely indicated before the onset of ESRD. Renal replacement therapies, including renal transplantation (Chapter 133), are at least as effective as in other causes of ESRD.

The massive cystic enlargement of the liver commonly seen by midlife in women with ADPKD makes it prudent to avoid estrogen intake and repeated pregnancies. Partial hepatectomy has been successful in improving the quality of life in patients with massive liver enlargement.

Screening MRA is not routinely recommended for asymptomatic patients without a family history of cerebral aneurysm or subarachnoid hemorrhage, but it is recommended for patients with a positive family history and may be considered in those with high-risk occupations, such as airline pilots, or with incapacitating anxiety. The risk of a patient with a positive family history developing a new aneurysm after an initially negative magnetic resonance angiogram is 2.6% at a mean follow-up of 9.8 years, so rescreening every 5 to 10 years in such cases may be appropriate, especially in patients with early-onset hypertension or a history of heavy smoking. Individuals shown to have cerebral aneurysms should be referred to a neurosurgeon for consideration of clipping (Chapter 415). Annual MRA screening is recommended in all patients with untreated aneurysms to assess for aneurysmal growth.

Patients should be advised that their children have a 50% probability of inheriting a disease-causing germline mutation. DNA-based diagnostics are most useful in identifying the germline mutation prenatally or preimplantation. As DNA-based diagnostics become more widely available and less expensive, and as promising new treatment options are developed, counseling will become an increasingly important component of prevention.

Experimental Therapies

The better understanding of the pathobiology of ADPKD raises the hope of directed therapies to halt or slow the progression of disease. The metabolically stable somatostatin analogue octreotide (at a dose of 40 mg intravenously every 28 days) halted the expansion of renal cysts but did not have a beneficial effect on the GFR in a small trial of ADPKD patients.[1] Neither sirolimus[2] nor everolimus[3] slowed the decline of renal function in ADPKD patients, although everolimus slowed the increase in kidney volume. These data suggest that cyst growth may not be the key determinant of renal function decline. ACE inhibitors and ARBs are currently being tested in large clinical trials, and the vasopressin V2 receptor inhibitor tolvaptan is being evaluated in phase III clinical trials.

PROGNOSIS

The rate of progression of renal disease is highest in men with poorly controlled hypertension, an early age at diagnosis, and mutations in *PKD1*. The presence of one affected family member who developed ESRD by age 60 years is highly predictive of PKD1 disease (positive predictive value, 100%; sensitivity, 75%), whereas the development of ESRD after age 70 years in a family member is highly predictive of PKD2 disease (positive predictive value, 95%; sensitivity, 75%). Approximately 5% of all ADPKD patients with cerebral aneurysms die from aneurysmal rupture.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

DEFINITION AND EPIDEMIOLOGY

ARPKD is a multisystem childhood disorder characterized by severe and early PKD dominated by dilation of the kidney collecting ducts, biliary ductal plate dysgenesis in neonates, and portal tract fibrosis in older children.

PATHOBIOLOGY

ARPKD has been linked to heterogeneous mutations in a single gene, *PKHD1* (polycystic kidney and hepatic disease 1). Located on chromosome 6q21, *PKHD1* has 67 exons and spans a genomic region of approximately 470 kb, the longest open reading frame of which is 12,222 base pairs long. *PKHD1* encodes a unique type I membrane protein, fibrocystin/polyductin, comprising 4074 amino acids, with a large extracellular segment and a short cytoplasmic carboxyl terminus. The precise physiologic function of fibrocystin/polyductin in collecting duct and biliary duct epithelium is not clear, but its domains are known to mediate cell motility and invasion, extracellular protein and carbohydrate binding, and catalysis of polysaccharide hydrolysis. Alternatively-spliced transcripts of *PKHD1* encode a membrane protein with variable extracellular domains, as well as forms lacking the transmembrane segment. Homozygous truncating mutations in *PKHD1* are associated with perinatal renal disease, whereas patients with homozygous missense mutations present later because some functional protein is produced.

PKHD1 messenger RNA is detected mostly in the cortical and medullary collecting ducts and the thick ascending limbs of Henle, but it is also found to a lesser degree in the pancreas, liver, and lungs, which are also affected in ARPKD. In common with many cystogenic proteins, the fibrocystin/polyductin protein is found in basal bodies and primary apical cilia, suggesting that it is important in maintaining the structural integrity of cilia.

Loss of the fibrocystin/polyductin protein downregulates polycystin-2, which is the deficient protein in one form of ADPKD. Fibrocystin/polyductin–polycystin-2 interactions may regulate calcium influx mediated by polycystin-2. These findings suggest that cystogenesis in ADPKD and ARPKD share a common mechanism, with the variability in the ARPKD phenotype traced to the degree of polycystin-2 expression among patients. However, renal cysts can originate from any part of the nephron and are detached from the nephron proper in ADPKD, whereas they originate from and remain attached to the distal nephron in ARPKD, suggesting that additional signaling pathways specific for each disease and gene product likely explain these anatomic differences.

CLINICAL MANIFESTATIONS

Although ARPKD can present as renal cysts discovered radiographically either antenatally or during adulthood, it usually manifests as bilateral abdominal masses and renal insufficiency in infancy. It carries a 30% mortality owing to severe pulmonary hypoplasia; oligohydramnios, presumably linked to in utero renal disease, likely accounts for the pulmonary hypoplasia. Hypertension is almost universal, typically develops before renal impairment is apparent, and probably accelerates the decline in renal function. Findings related to renal tubular dysfunction may be present and include polyuria, enuresis, hyponatremia, and hyperchloremic metabolic acidosis. Cystic complications related to infection and rupture also occur, although hematuria is an infrequent finding. ESRD can take up to 20 years to develop, and in rare instances, it never occurs.

Hepatic fibrosis, secondary to dilation of the intrahepatic and extrahepatic bile ducts, manifests as recurrent ascending cholangitis (Chapter 158) and portal hypertension with splenomegaly and esophageal varices. Pancreatic fibrosis is rarely a clinical concern.

DIAGNOSIS

The demonstration by abdominal ultrasound (Fig. 129-3B) or CT of symmetrically enlarged polycystic kidneys that retain their reniform shape (owing to uniform microcystic dilation of collecting ducts) and hepatic fibrosis is sufficient to diagnose ARPKD. In contrast to ADPKD cysts, ARPKD cysts tend to retain their connections with the originating nephron. Aside from an occasional affected sibling, a family history is often not elicited. Distinguishing ARPKD from ADPKD, especially in patients presenting in childhood or adulthood, may require a liver biopsy to document otherwise undetectable hepatic fibrosis. Gene-based diagnostics in ARPKD are helpful in making a firm diagnosis, especially in patients with late-onset disease, and they are useful in preimplantation and in prenatal diagnosis.

PREVENTION AND TREATMENT Rx

In the absence of specific therapy for ARPKD, management goals focus on early detection and treatment of the complications of hypertension, urinary tract or cyst infection, ESRD, and portal hypertension. Kidney transplantation may be necessary in late childhood in ARPKD patients who present with renal disease perinatally. Treatment of portal hypertension may require liver transplantation or portosystemic shunting (Chapter 157). Treatment of hypertension begins with ACE inhibitors and ARBs (see Tables 67-5 and 67-7 in Chapter 67), which are generally effective. As in all children with ESRD, attention to nutrition and renal osteodystrophy is paramount (Chapter 132). With improving sensitivity of gene-based diagnostics, genetic counseling will play a more active role in prevention.

PROGNOSIS

For patients with ARPKD, the highest mortality rates occur during the first year of life. Approximately 50 to 80% of patients survive to 15 years of age.

NEPHRONOPHTHISIS

DEFINITION AND EPIDEMIOLOGY

The autosomal recessive disorder nephronophthisis is characterized pathologically by renal interstitial fibrosis, tubular atrophy with basement membrane thickening and disruption, and renal cysts and diverticula that are largely restricted to the loops of Henle and distal tubules at the corticomedullary junctions. Nephronophthisis is the most common genetic cause of ESRD in childhood and adolescence, accounting for 5 to 15% of cases. Kidney size is generally normal or reduced, except in the rare infantile form of nephronophthisis that leads to ESRD by 5 years of age.

Patients exhibit extrarenal anomalies, with missense mutations causing a milder phenotype and truncating mutations causing severe disease. The most frequently associated extrarenal abnormalities are retinal degeneration secondary to photoreceptor cell defects (Senior-Loken syndrome), seen in 15% of cases; cerebellar ataxia (Joubert's syndrome and related diseases), observed in 10 to 15% of cases; and hepatic fibrosis (Boichis disease), seen in 5% of cases.

The clinical syndrome of nephronophthisis is caused by recessively acquired homozygotic and compound heterozygotic mutations in nine known genes (*NPHP1* through *NPHP9*), which account for only about 30% of cases, indicating the presence of yet-to-be-discovered genes. Expression of the encoded proteins, called nephrocystins, at extrarenal sites accounts for the associated retinal, neural, liver, and skeletal abnormalities. Each of the nine genes is associated with a somewhat different phenotype, although some share common phenotypes, explained by protein-protein interactions between two or more gene products. Most of the encoded proteins localize to centrosomes or cilia, but some also localize to adherens junctions and/or focal adhesions in epithelia.

CLINICAL MANIFESTATIONS

Presenting symptoms include polyuria, growth failure, and anemia. Polyuria occurs early, owing to reduced urinary concentrating ability and to salt wasting. Decreased growth rate is related to chronic dehydration, and growth failure and anemia occur with the onset of ESRD. Blood pressure is normal and edema is absent before the onset of renal failure. Hematuria and proteinuria are absent or minimal. Patients with mutations in specific nephronophthisis genes may also present with eye defects, oculomotor apraxia, congenital amaurosis, retinitis pigmentosa, neural anomalies, cerebellar ataxia, seizures, liver fibrosis, skeletal defects, scoliosis, cleft palate, and situs inversus.

DIAGNOSIS

Diagnosis relies on clinical suspicion of the disorder in a pediatric or adolescent patient who presents with ESRD and extrarenal manifestations such as abnormal eye movements, blindness, mental retardation, and polydactyly. Abdominal ultrasound, MRI (without gadolinium), electroretinogram, and full neurologic and ophthalmologic evaluations should assess the patient's renal, liver, retinal, and neurologic status. A renal ultrasound showing loss of corticomedullary differentiation, increased parenchymal echogenicity, and occasionally small medullary or corticomedullary cysts in normal-sized or moderately small kidneys is highly suggestive of juvenile nephronophthisis in a child with severe uremia. Genetic testing may be required for a conclusive diagnosis. A renal biopsy showing evidence of chronic tubulointerstitial nephritis may be necessary to confirm the diagnosis if genetic testing is not available.

PREVENTION AND TREATMENT Rx

Treatment is largely supportive, focusing on the progressive renal failure and the need for dialysis and transplantation. Vasopressin V2 receptor antagonists and rapamycin show promise in animal models, but clinical trials are needed to assess these treatments in patients.

Prenatal genetic testing in families with a genetic diagnosis of nephronophthisis is feasible. DNA-based diagnostics are most useful in identifying the germline mutation prenatally or preimplantation.

MEDULLARY CYSTIC KIDNEY DISEASE

Medullary cystic kidney disease is an autosomal dominant interstitial kidney disease that results in renal failure after the fourth decade of life. It is rarer than autosomal recessive nephronophthisis, with which it shares a number of histologic features, including tubular basement membrane disintegration, tubular cyst formation, and tubulointerstitial inflammation and fibrosis.

At least two genes, *MCKD1* and *MCKD2*, cause medullary cystic kidney disease. *MCKD2* encodes an 85-kD nonciliary protein, uromodulin, which is secreted by the thick ascending limb of the loop of Henle and is the most abundant protein in human urine. The *MCKD1* gene has not yet been identified, but some studies have linked it to chromosome 1q21.

Mutations in *MCKD1* and *MCKD2* result in a similar clinical picture, except for an earlier onset of ESRD and precocious gout with mutations in *MCKD2*. Polyuria and anemia are usually not clinically present in the early stages, and renal failure generally occurs after the fourth decade of life. Hypertension is likely secondary to renal failure.

Corticomedullary cysts, which are present in most adult patients, cannot always be recognized on ultrasonography or CT because they tend to be very small. Except for the treatment of gout (Chapter 281), management is similar to that of patients with nephronophthisis.

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney, which is a rare disorder of unknown pathogenesis, is characterized by congenitally acquired inner medullary and papillary collecting duct dilations, hypercalciuria, and a mild defect in urinary

concentration and acidification owing to tubular dysfunction. Patients present with hematuria and recurrent kidney stones, usually by the second or third decade of life. Medullary sponge kidney may also be an incidental finding on an intravenous pyelogram that shows the characteristic pooling of contrast material within the cystic collecting ducts. ESRD is uncommon, and the long-term prognosis is excellent.

OTHER INHERITED CYSTIC SYNDROMES

Bardet-Biedl syndrome is an autosomal recessive disorder characterized by obesity, hypertension, and dystrophy of the hands, eyes, kidneys, and male genitalia. Mutations in 14 different genes encoding proteins that localize to basal bodies have been identified. Calyceal cysts and calyceal clubbing predominate the renal lesion and are best diagnosed by intravenous urography rather than ultrasound. Renal impairment is frequent and is an important cause of death.

Oral-facial-digital syndrome is characterized by malformations of the face, oral cavity, and digits. It is inherited in an X-linked pattern and is caused by defects in the *OFD1* gene, which encodes OFD1 protein expressed in basal bodies but otherwise has an undetermined function. Renal (primarily glomerular) cysts are found in as many as 50% of patients, all of whom are females; males carrying the mutation die in utero. ESRD has been reported in affected females ranging in age from 11 to 72 years.

Autosomal dominant renal cyst formation is also seen in tuberous sclerosis and von Hippel-Lindau syndrome (Chapter 426). In tuberous sclerosis, cyst formation is commonly associated with hypertension; this disorder can resemble ADPKD and is associated with about a 5% incidence of renal cell carcinoma. In von Hippel-Lindau syndrome, cyst formation can also lead to features of ADPKD; more importantly, the syndrome is associated with a 25% incidence of renal cell carcinoma.

ACQUIRED CYSTIC KIDNEY DISEASE

Acquired cystic kidney disease is largely confined to the ESRD population on dialysis (Chapter 133). Cysts arise from proximal and distal tubule dilations in small end-stage kidneys regardless of cause, mode of dialysis, or presence of a functioning kidney transplant. Identifiable risk factors include duration of ESRD, older age, large cysts, male gender, black race, and chronic hypokalemia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Acquired cystic kidney disease is usually asymptomatic, but it occasionally leads to enlarged kidneys with associated abdominal discomfort and pain. Cyst hemorrhage, which is more common than cyst infection, presents with flank pain, anemia, or hematuria. The most significant complication of acquired cystic kidney disease is malignant conversion of cysts into renal cell carcinoma (Chapter 203). Carcinomas commonly present as hematuria and are 2 to 200 times more common in patients with acquired cystic kidney disease than in the general dialysis population.

Acquired cystic kidney disease is diagnosed by ultrasound or CT demonstrating multiple and bilateral renal cysts in a patient with preexisting chronic renal failure or ESRD. In contrast to ADPKD and ARPKD, the kidneys are usually not enlarged, and there is no family history of PKD. Renal CT or MRI is preferable to detect cysts in small kidneys and to assess for malignant conversion.

PREVENTION AND TREATMENT

Rx

There are no strategies to prevent the appearance or delay the expansion of renal cysts in patients on hemodialysis, but cysts may stabilize or regress following successful renal transplantation. New or frank hematuria raises the concern of renal cell carcinoma (Chapter 203), which should be assessed using ultrasound and contrast-enhanced CT. Any evidence of septa formation, solid material, or contrast enhancement within a cyst is suspicious for renal cell carcinoma and warrants consideration of nephrectomy.

PROGNOSIS

Asymptomatic acquired cystic kidney disease does not affect survival. The incidence of renal cell carcinoma in patients with acquired cystic kidney disease is approximately 0.18% per year. Although metastasis is less common at the time of diagnosis in patients with acquired cystic kidney disease than in other patients with renal cell carcinoma, the 5-year mortality rates are higher, likely related to the almost invariable coexistence of ESRD.

HEREDITARY NEPHROPATHIES AND DEVELOPMENTAL ABNORMALITIES OF THE URINARY TRACT

LISA M. GUAY-WOODFORD

HEREDITARY NEPHROPATHIES

The proximal tubule is responsible for reclaiming most of the filtered glucose, amino acids, uric acid, phosphate, bicarbonate, and low-molecular-weight proteins. The loop of Henle and the distal nephron reabsorb approximately 30% of the filtered sodium chloride and 50% of the filtered divalent cations. The collecting duct, under the regulatory control of aldosterone, fine-tunes sodium reabsorption and secretes hydrogen and potassium ions. In the terminal collecting duct, antidiuretic hormone regulates water reabsorption and urinary concentration.

Inherited renal tubular disorders are a group of conditions in which the normal renal tubular reabsorption of ions, organic solutes, and water (Chapter 118) is disrupted. These defects can be categorized by the nephron segment affected (Table 130-1).

Disorders of Proximal Tubule Function

CYSTINURIA

Cystinuria is characterized by defective proximal tubular reabsorption of cystine and dibasic amino acids, resulting in the formation of urinary calculi (Chapter 128). This autosomal recessive trait has an estimated prevalence of 1 in 7000 individuals. Two cystinuria genes have been identified: *SLC7A9,* which encodes the luminal transport channel itself, and *SLC3A1,* which encodes the transporter regulatory subunit. Several large studies indicate that mutations in *SLC3A1* are more common than mutations in *SLC7A9.* Mutations in *SLC3A1* cause cystinuria type A, mutations in *SLC7A9* cause cystinuria type B, and mutations in both genes (compound heterozygotes) cause cystinuria type AB.

Although the severity of the disease is similar in all types of cystinurias, the clinical presentation can be quite variable, and the onset of disease may occur from infancy to the seventh decade of life. Affected children can be identified by elevated urinary cystine levels, but testing must be performed after tubular transport has fully matured (at age 2 years). Cystine stones are radiopaque and often form the nidus for secondary calcium oxalate stones. Symptoms include renal colic, which may be associated with urinary tract obstruction and/or infection. Conservative therapy with high urine volume and urinary alkalinization is sufficient for many patients with cystinuria, but recurrent stone formation may cause renal damage and warrants treatment with thiol agents (e.g., D-penicillamine: pediatric dose, 15 to 20 mg/kg/day; adult dose, 2 g/day in four divided doses) or α-mercaptopropionylglycine

(pediatric dose, 10 to15 mg/kg/day; adult dose, 1 to 2 g/day in two divided doses) to form soluble mixed disulfides with cystine and maintain free urine cystine levels below 200 mg/g of creatinine.

CYSTINOSIS

Cystinosis is the most common inherited cause of renal Fanconi's syndrome; it also affects the eyes, muscles, central nervous system, lungs, and various endocrine organs. Cystinosis is an autosomal recessive disorder caused by mutations in the gene *CTNS,* which encodes cystinosin, a lysosomal cystine transporter. Defects in this transporter lead to the accumulation of intralysosomal cystine crystals and widespread cellular destruction.

Three clinical presentations have been described. The most severe is infantile (classic) cystinosis, which manifests in the first year of life with renal tubular acidosis, impaired growth, and evidence of renal Fanconi's syndrome, including aminoaciduria, glucosuria, phosphaturia, and low-molecular-weight proteinuria. Progressive renal failure reaches end-stage renal disease in childhood. A less severe, late-onset (juvenile or intermediate) form causes renal dysfunction in adolescence and involves cystine deposits in the cornea. The mildest form, an ocular, non-nephropathic form, features photophobia but no renal problems.

The mainstay of cystinosis therapy is oral cysteamine (adult dose, 500 mg four times daily), an aminothiol that can lower intracellular cystine content by 90%. In well-treated adolescent and young adult patients, cysteamine delays renal glomerular deterioration, enhances growth, prevents hypothyroidism, and lowers muscle cystine content. Therefore, early diagnosis and prompt, proper treatment are critical for preventing or significantly delaying the complications of cystinosis.

Disorders of Loop of Henle and Distal Tubule Function

THE BARTTER-GITELMAN DISORDERS

The Bartter-Gitelman syndromes are a group of disorders characterized by markedly reduced salt transport in the thick ascending limb of Henle (Bartter's syndrome) or in the distal convoluted tubule (Gitelman's syndrome).

Most patients with Gitelman's syndrome have defects in *SLC12A3,* the gene encoding the sodium-chloride cotransporter NCCT. However, a minority of patients with the Gitelman phenotype have mutations in *CLCNKB.*

Bartter's syndrome can be caused by mutations in one of four genes—*SLC12A2,* encoding the sodium-potassium-chloride cotransporter NKCC2;

TABLE 130-2 FEATURES OF THE INHERITED RENAL TUBULAR ACIDOSES (RTAs)

DISORDER	RENAL TRANSPORT DEFECT	MINIMAL URINE pH DURING ACIDOSIS	ALKALI SUPPLEMENTATION (HCO_3^-)	UAG DURING ACIDOSIS*
Proximal RTA	↓Proximal bicarbonate reabsorption	<5.5	Children: 10-15 mEq/kg/day	0 or +
Carbonic anhydrase II deficiency	↓Proximal bicarbonate reabsorption and ↓distal acidification	Variable	Variable	0 or +
Distal RTA	↓Distal acidification	>5.5	Adults: 1-3 mEq/kg/day Children: 3-6 mEq/kg/day	0 or +

*In RTA, the UAG is usually 0 or positive, whereas in metabolic acidosis associated with diarrheal illness, the UAG is negative.
HCO_3^- = bicarbonate; UAG = urinary anion gap ($[Na^+] + [K^+] - [Cl^-]$).

KCNJ1, encoding the ROMK1 potassium ion channel; *CLCNKB,* encoding the ClC-Kb basolateral chloride ion channel; and *BSND,* encoding barttin, a regulatory subunit required for basolateral chloride channel targeting to the membrane. These mutations cause autosomal recessive Bartter's syndrome types I, II, III, and IV, respectively. Defects in any of these genes disrupt salt transport in the thick ascending limb, causing a furosemide-like effect (E-Fig. 130-1). In addition, severe gain-in-function mutations in *CASR,* the gene encoding the extracellular calcium ion–sensing receptor CaSR, can cause a Bartter-like phenotype (referred to as Bartter's type V) that is distinguished from the others by autosomal dominant transmission and associated hypocalcemic hypercalciuria.

Individuals with Bartter's syndrome exhibit renal salt wasting, lowered blood pressure, polyuria, hypokalemic metabolic alkalosis, and hypercalciuria with a variable risk of nephrocalcinosis. In comparison, individuals with Gitelman's syndrome exhibit milder renal salt wasting, normal blood pressure, hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria. This clinical disorder resembles the effects of long-term thiazide administration. Clinical differences between Bartter's and Gitelman's syndromes relate to the severity of salt wasting, whereas phenotypic differences among Bartter's types I through V correlate with the specific physiologic roles played by the individual transporters or channels in the kidney and other organs.

The mainstay of treatment includes replacing salt and water losses and providing potassium supplementation to maintain serum levels greater than 3 mEq/dL. In patients with perinatal (type I or II) Bartter's syndrome, cyclooxygenase inhibitors (e.g., indomethacin 2-4 mg/kg/day in two to four divided doses) may be beneficial. In patients with Gitelman's syndrome and some patients with Bartter's syndrome type III, oral magnesium supplementation may be required to maintain serum levels above 1.2 mg/dL.

Disorders of Collecting Duct Function

LIDDLE'S SYNDROME (PSEUDOALDOSTERONISM)

Liddle's syndrome, which is an autosomal dominant form of salt-sensitive hypertension (Chapter 67), is caused by mutations in the α, β, or γ subunits of the epithelial sodium channel, which is expressed at the apical surface of collecting duct cells and plays a critical role in maintaining salt balance and blood pressure. Both the β and the γ subunits regulate the channel activity of the α subunit. Mutations in either of these regulatory subunits result in increased epithelial sodium channel activity and Liddle's syndrome.

Severe hypertension typically manifests in childhood, with features of hypokalemic metabolic alkalosis that resemble primary aldosteronism. However, renin and aldosterone secretion is suppressed in this disorder. The clinical abnormalities can be ameliorated by a low-salt diet plus a potassium-sparing diuretic (e.g., amiloride 5 to 10 mg/day), which acts as an antagonist of the epithelial sodium channel.

DISTAL RENAL TUBULAR ACIDOSIS

Distal renal tubular acidosis (dRTA) results from failure of the collecting duct α-intercalated cells to excrete fixed acids (see Fig. 120-1 in Chapter 120). Both autosomal dominant and autosomal recessive forms of dRTA have been described. These heritable disorders include mutations in genes encoding carbonic anhydrase II, the chloride-bicarbonate exchanger AE1, and subunits of the hydrogen–adenosine triphosphatase (H^+-ATPase) proton pump. Mutations in the *SLC4A1* gene encoding AE1 cause autosomal dominant dRTA and are rarely associated with recessive forms of the disease. Mutations in subunits of H^+-ATPase are the primary causes of autosomal recessive dRTA. Vacuolar H^+-ATPases (V-type ATPases) are ubiquitous, multi-subunit protein complexes that mediate the ATP-dependent transport of protons. In the kidney, V-type ATPases are the major proton-secreting pumps in the distal nephron and are involved in net proton secretion (bicarbonate generation) or proton reabsorption (net bicarbonate secretion). Defects in two genes, *ATP6B1* and *ATP6N1B,* cause dRTA with or without associated sensorineural deafness.

Clinical consequences include hypokalemic, hyperchloremic metabolic acidosis; impaired growth; hypercalciuria; hypocitraturia; nephrocalcinosis; nephrolithiasis; rickets in children; and osteomalacia in adults. Classic dRTA can be distinguished from other metabolic acidoses by an inappropriately high urine pH (>5.5), diminished net acid excretion, positive urinary anion gap, and low urinary ammonium concentration (Table 130-2). Treatment with alkali supplementation (1 to 3 mEq/kg/day in adults and 3 to 6 mEq/kg/day in children) is usually effective in correcting the acidosis. In contrast to proximal RTA, urinary potassium wasting can be ameliorated with alkali therapy alone.

DEVELOPMENT OF THE KIDNEY AND URINARY TRACT

The human kidney and urogenital tract develop from three principal embryonic structures: the metanephric mesenchyme, the mesonephric (wolffian) duct, and the cloaca (Fig. 130-1). At 4 to 5 weeks of gestation, the ureteric bud originates as a diverticulum of the mesonephric duct. Reciprocal interactions between the branching ureteric bud and the metanephric mesenchyme induce kidney development, with the metanephros undergoing an epithelial transformation to form the glomeruli and the proximal and distal tubules. The ureteric bud branches give rise to the collecting ducts, the renal pelvis, the ureter, and the bladder trigone. Nephrogenesis is completed by 34 weeks of gestation.

Concurrent with the initial nephrogenic events, the urorectal fold divides the cloaca into the urogenital sinus and the future rectum. The mesonephric duct opening into the bladder becomes the vesicoureteric orifice of the trigone. Between 5 and 6 weeks of gestation, the second genital duct (müllerian duct) appears and runs in parallel with the wolffian duct. In males, the müllerian duct subsequently regresses, the wolffian duct proceeds to form the epididymis, the vas deferens, the seminal vesicle, and the ejaculatory duct. In females, the wolffian duct regresses, and the müllerian ducts fuse to form the ureterovaginal primordium, which merges with the urogenital sinus and eventually gives rise to the uterus, the oviducts, and the proximal vagina. The remnants of the allantois form the urachus, a fibrous cord that connects the bladder to the umbilicus.

Congenital abnormalities of the kidney and urinary tract occur in 1 in 500 newborns and account for approximately 20 to 30% of all anomalies identified in the prenatal period. Some urinary tract anomalies are asymptomatic and inconsequential, but many renal tract malformations are important causes of infant mortality as well as morbidity in older children and adults, including the progression to renal failure.

ABNORMALITIES OF THE URINARY TRACT

Renal Parenchymal Malformations

Congenital defects in renal development may result in the absence of a kidney (agenesis) or abnormalities in kidney size, structure, or position. Irregularities in the renal contour may arise from the persistence of fetal lobulation or

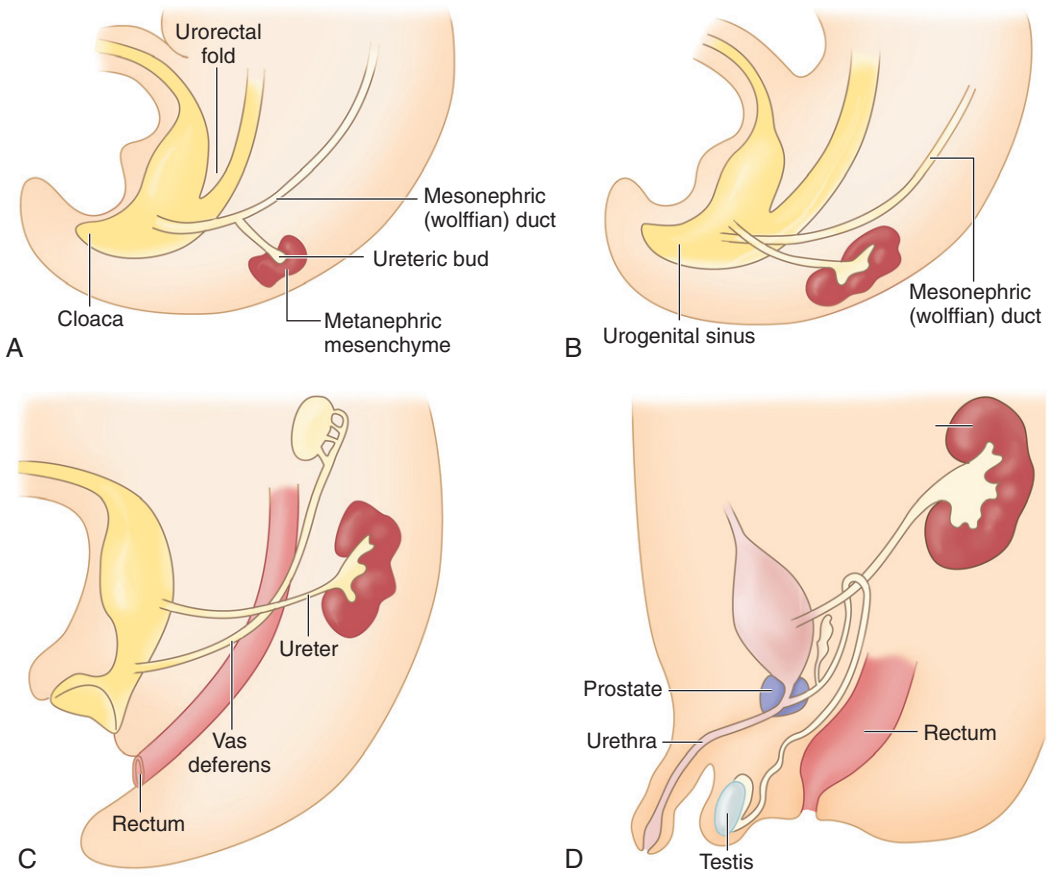

FIGURE 130-1. Key events in the development of the urinary tract. In the 4-week embryo, the ureteric bud emerges from the wolffian duct (**A**). Reciprocal interactions between the branching ureteric bud and the metanephric mesenchyme induce kidney development. Concurrently, the cloaca is divided by the urorectal fold into the urogenital sinus and the future rectum (**B**). In the 8-week male embryo, the wolffian duct begins to give rise to the epididymis, the seminal vesicles, and the caudal part of the vas deferens (**C**). By 9 weeks, axial growth of the fetal spine prompts the developing kidney to ascend from the pelvis to its final lumbar position. The external genitalia develop between 8 and 16 weeks, and testicular descent begins in month 7 of gestation (**D**).

a depression in the midpole of the left kidney caused by the spleen (a "dromedary hump"). Neither irregularity impairs renal function.

RENAL AGENESIS

Renal agenesis reflects a complete failure of nephrogenesis. Unilateral agenesis can occur as an isolated abnormality or as a component of syndromic disorders, such as Turner's syndrome (Chapter 241). As an isolated entity, the complete absence of one kidney occurs in 1 in 5000 individuals. The incidence is higher in males and occurs somewhat more frequently on the left side; in about half the patients, the ipsilateral ureter and hemitrigone are also absent. The remaining kidney is usually enlarged owing to compensatory hypertrophy, but it may be ectopic or malrotated. Vesicoureteral reflux is observed on the contralateral side in about 30% of patients.

Renal agenesis is commonly associated with genital anomalies, suggesting that it represents a developmental field defect. In females, absence of the ipsilateral oviduct and malformation of the uterus and vagina result from maldevelopment of the müllerian duct, whereas in males, wolffian duct–derived structures, such as the vas deferens and the seminal vesicles, are often absent. Other associated anomalies can include cardiovascular malformations, vertebral defects, and imperforate anus.

Bilateral renal agenesis has an estimated incidence of 1 in 10,000 births and is associated with the Potter phenotype, which includes pulmonary hypoplasia, a characteristic facies, and deformities of the spine and limbs. At birth, these neonates have a critical degree of pulmonary hypoplasia that is incompatible with survival. The familial association of unilateral and bilateral renal agenesis, renal dysplasia, and congenital hydronephrosis occurs in hereditary renal adysplasia syndrome (Online Mendelian Inheritance in Man entry 191830), a rare autosomal dominant disorder with variable penetrance.

RENAL HYPOPLASIA

The term *renal hypoplasia* describes small kidneys with normally differentiated nephrons that are reduced in number. *Oligomeganephronia* describes a form of bilateral renal hypoplasia with a marked reduction in nephron number and associated hypertrophy of individual glomeruli and tubules. This abnormality occurs sporadically as an isolated developmental defect that must be differentiated from acquired renal atrophy and the nephronophthisis–medullary cystic disease complex. Renal function declines slowly, with progression to end-stage renal failure in the second to third decade of life.

RENAL DYSPLASIA

Renal dysplasia, which can be associated with various abnormalities of kidney size, results from abnormal metanephric differentiation that causes anomalous and/or incompletely differentiated renal elements. Small dysplastic kidneys are commonly referred to as *aplastic*. Large dysplastic kidneys are often cystic; the most extreme type is referred to as *multicystic dysplastic kidney*.

Unilateral dysplasia may be asymptomatic well into adult life. Small aplastic and large multicystic dysplastic kidneys are nonfunctioning and can be distinguished from renal agenesis by imaging studies. The ipsilateral ureter is typically atretic. Contralateral malformations, including obstruction and vesicoureteral reflux, are common. Unilateral multicystic kidneys involute over time and often disappear. Unilateral aplasia and multicystic dysplasia may be manifestations of the hereditary renal adysplasia syndrome. Bilateral multicystic dysplastic kidneys are incompatible with neonatal survival.

Renal and Ureteral Structural Abnormalities

RENAL MALROTATION AND ECTOPIA

Metanephric kidney development begins caudally. By 9 weeks of gestation, the kidney has ascended to its normal level (L1-L3), and the renal pelvis has rotated 90 degrees toward the midline. Anomalies of ascent and/or failure of rotation are common. Bilateral renal ectopia is often associated with kidney fusion. The most common fusion anomaly is the horseshoe kidney, which occurs in 1 in 500 newborns with a 2 : 1 male predominance. Renal ascent is prevented by the root of the inferior mesenteric artery (Fig. 130-2A). Crossed renal ectopia can occur with or without fusion. Supernumerary (extra) kidneys are typically ectopic and vary in location. Although almost one third of patients with renal ectopia remain asymptomatic, the associated malrotation of the renal pelvis increases the risk of hydronephrosis, infection, and stone formation.

PELVIURETERAL ABNORMALITIES

Obstruction of the ureteropelvic junction impedes the flow of urine from the renal pelvis into the ureter. It is one of the most frequently occurring urinary

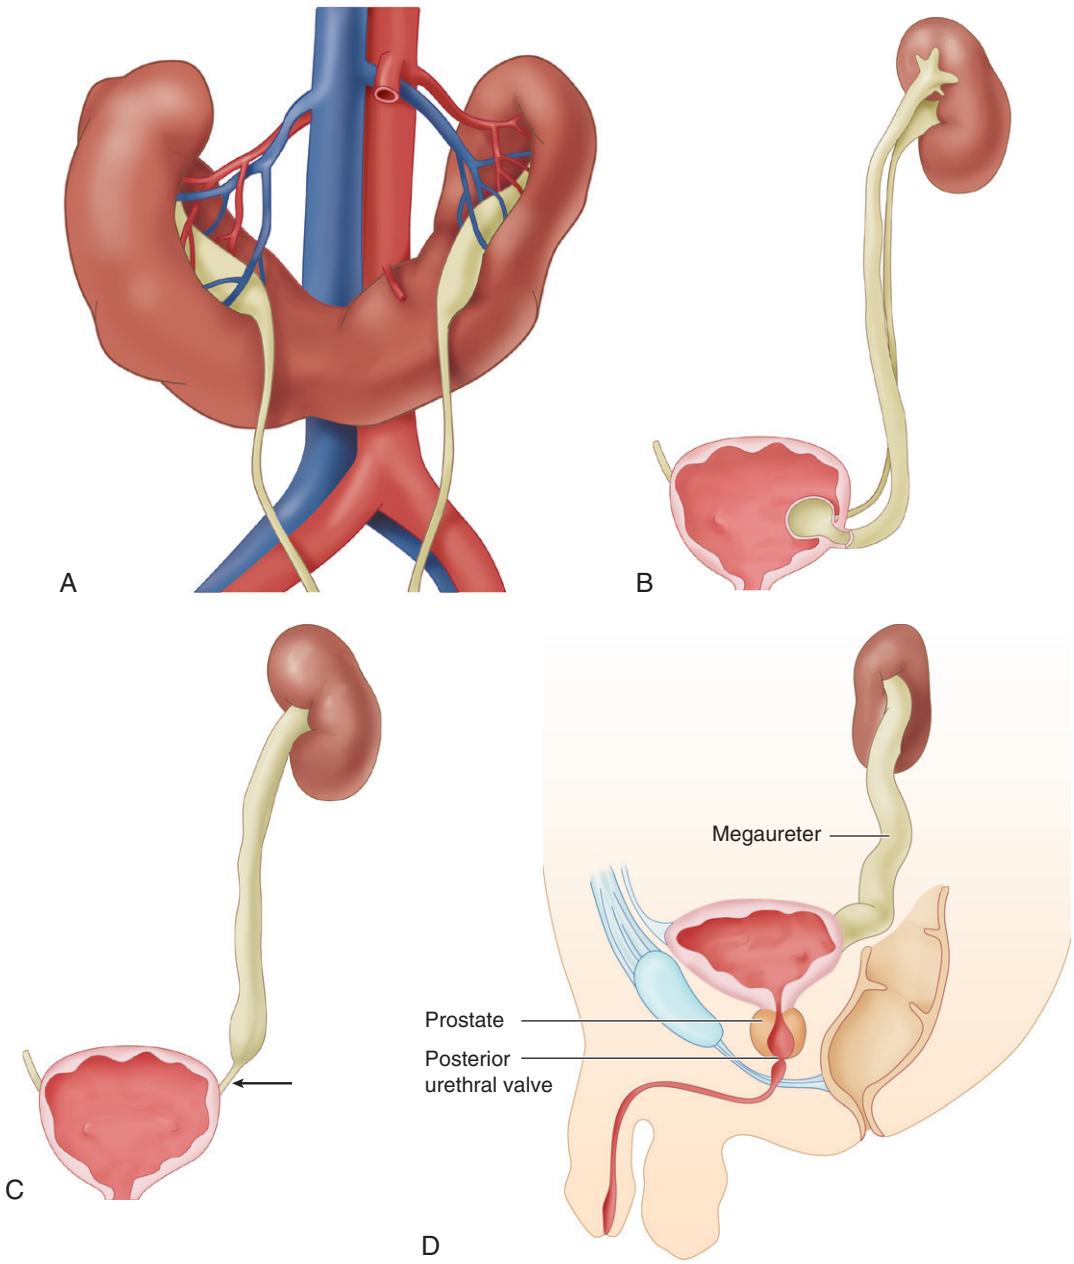

FIGURE 130-2. Developmental abnormalities of the urinary tract. A, Horseshoe kidney. **B,** Ectopic ureter associated with a ureterocele. **C,** Megaureter with the aperistaltic segment (arrow). **D,** Bladder outlet obstruction caused by posterior urethral valves.

tract anomalies in children and is the most common cause of collecting system dilation in the fetal kidney. In congenital obstruction of the ureteropelvic junction, urologic anomalies in the contralateral system are common, including renal agenesis, renal dysplasia, multicystic dysplasia, ureteropelvic junction obstruction, and vesicoureteral reflux. Ureteropelvic junction obstruction may occur in adults secondary to external compression, kinking, or stenosis of the proximal ureter. Surgical intervention is indicated if there is associated renal function impairment, pyelonephritis, stones, or pain.

Hydrocalyx or *hydrocalycosis* refers to dilation of a major calyx that occurs in the context of intrinsic obstruction, as in infundibular stenosis, or in the context of extrinsic compression of the pelvis, as caused by a vessel or a parapelvic cyst. In comparison, *megacalycosis* represents a nonobstructive, dysplastic lesion seen primarily in males, in which the calyces are dilated and usually increased in number. Associated renal medullary hypoplasia causes malformation of the renal papillae.

Calyceal diverticula are cystic structures connected by a narrow channel to an adjacent minor calyx. In imaging studies, these diverticula typically fill with contrast material, which distinguishes them from renal parenchymal cysts.

Partial duplication of the renal pelvis and ureter is a common anomaly that occurs more frequently in females, is typically unilateral, and is clinically insignificant.

URETERIC ANOMALIES

Ectopic ureters usually reflect complete ureteric and renal duplication. Approximately 10% are bilateral. The ectopic ureter typically drains the dysplastic upper pole of a duplex kidney and inserts below the normal vesicoureteral junction into the lower trigone or the proximal urethra. Ectopic ureters occur much more frequently in females, and the insertion sites can include the vagina and the vulva, with resulting incontinence. An ectopic ureter is often associated with a ureterocele, a cystic dilation of the terminal ureter (Fig. 130-2B). In children, ureteroceles can be associated with urinary tract infection and obstruction of the bladder neck or even of the contralateral ureter. In adults, the clinical presentation usually involves an associated infection, ureteric stones, or both.

A megaureter, or grossly dilated ureter, has multiple potential causes, including intrinsic ureteric obstruction by a stone, bladder outflow obstruction, vesicoureteral reflux, and external compression of the distal ureter. In contrast, primary megaureter results from a functional obstruction of the distal ureter caused by an aperistaltic segment (Fig. 130-2C).

VESICOURETERAL REFLUX

In the normal urinary tract, urinary reflux from the bladder into the ureters is prevented by a functional valve-like mechanism at the vesicoureteral junction. The competence of this valve is dependent on several critical factors,

such as the intramural length of the ureter, the position of the ureteric orifice in the bladder, and the integrity of the bladder wall musculature. Primary vesicoureteral reflux, with an estimated incidence of 1 to 2% in children, results from incompetence of the vesicoureteral junction owing to the shortened length of the ureter's submucosal segment and the lateral, ectopic position of its orifice. Genetic factors appear to contribute to the pathogenesis of primary vesicoureteral reflux, as there is a 30- to 50-fold increased risk in immediate relatives of an index case. As the intramural ureter lengthens with age, primary vesicoureteral reflux tends to remit or disappear. Vesicoureteral reflux can also occur secondary to obstructive maldevelopment of the lower urinary tract, such as in triad syndrome and posterior urethral valves.

In both primary and secondary vesicoureteral reflux, intrarenal reflux can lead to the development of reflux nephropathy, a tubulointerstitial lesion associated with gross scarring at the renal poles. In addition, the development of a glomerular lesion consistent with focal and segmental glomerulosclerosis can cause proteinuria, hypertension, and progressive loss of renal function.

In children younger than 18 years with prior urinary tract infections, daily treatment with trimethoprim (2 mg/kg/day) plus sulfamethoxazole (10 mg/kg/day) reduces recurrent infections by about 40%,■ but the value of long-term suppression is less clear.■ Although surgical correction is the current standard of care for severe grades of vesicoureteral reflux, particularly secondary forms associated with maldevelopment of the lower urinary tract, the long-term benefit of either endoscopic or surgical intervention appears to be small and is unlikely to prevent renal damage.■

Lower Urinary Tract Abnormalities

TRIAD SYNDROME (PRUNE-BELLY SYNDROME, EAGLE-BARRETT SYNDROME)

Triad syndrome, also referred to as prune-belly syndrome or Eagle-Barrett syndrome, involves a constellation of anomalies including congenital absence or deficiency of the abdominal wall musculature, gross ureteral dilation, bladder wall thickening, prostatic hypoplasia, and bilateral undescended testes (cryptorchidism). The full syndrome is expressed only in males, and surviving individuals are typically infertile. Patients with an incomplete syndrome can have anomalies of the abdominal wall musculature, bladder, and upper urinary tract; 3% of these patients are females. Although the specific molecular events have yet to be defined, defects in mesenchymal development appear to cause poor prostate and bladder differentiation, ureteral smooth muscle aplasia with consequent ureteral aperistalsis, and varying degrees of renal dysplasia. Three fourths of patients with triad syndrome have associated malformations in the cardiopulmonary system, gastrointestinal tract, and skeleton. In the immediate postnatal period, prognosis depends on the severity of extragenitourinary anomalies. Long-term outcome is based on the degree of renal dysplasia and the success of urodynamic management.

BLADDER ABNORMALITIES

Bladder exstrophy results from a midline closure defect involving the lower anterior abdominal wall, the bladder, and the external genitalia. These abnormalities have been attributed to a primary defect in the differentiation of the cloacal membrane, but the precise molecular events are unclear. In severe cases, bladder exstrophy may be associated with imperforate anus and rectal atresia. However, other congenital anomalies are rarely associated. Clinical studies indicate that there is a correlation between the success of bladder reconstruction and long-term preservation of renal function.

In adults, neuropathic or neurogenic bladder (Chapter 25) has numerous etiologic contributors, including central nervous system trauma, stroke, disorders such as Parkinson's disease, spinal trauma, multiple sclerosis, and peripheral nerve damage caused by trauma or surgery. In children, myelomeningocele (spina bifida) is the most common cause of neurogenic bladder dysfunction. Other forms of myelodysplasia, such as spinal dysraphism (spina bifida occulta) and sacral agenesis, are less common causes.

POSTERIOR URETHRAL VALVES

In male infants, posterior urethral valves are the most common cause of bladder outflow obstruction, with resulting bilateral hydronephrosis and megaureters. However, among all infants with hydronephrosis, only 10% have posterior urethral valves. The urethral obstruction results from defective reabsorption of mucosal folds in the posterior urethra, just distal to the verumontanum. As a result, dilation of the proximal urethra, bladder wall hypertrophy and trabeculation, associated vesicoureteral reflux, and varying degrees of renal dysplasia are present (Fig. 130-2D). Surgical management strategies are dictated by the age of the child and the degree of associated renal insufficiency. Survival and long-term renal outcome depend on the severity of the associated renal dysplasia.

BENIGN PROSTATIC HYPERPLASIA AND PROSTATITIS

MICHAEL J. BARRY AND MARY MCNAUGHTON COLLINS

The prostate gland, the largest accessory gland in the male reproductive system, surrounds the prostatic urethra below the bladder. Superiorly, its base is contiguous with the bladder neck; inferiorly, its apex adjoins the urogenital diaphragm. The prostatic urethra is angulated at the verumontanum, the union with the two ejaculatory ducts. In younger men, the prostate weighs about 20 g. As men age, the prostate enlarges and develops a characteristic zonal anatomy (Fig. 131-1). Its acini, which communicate with the urethra via prostatic ducts, supply about 20% of semen volume. Prostatic fluid is rich in citrate, zinc, and polyamines, although their roles in reproduction are poorly defined.

BENIGN PROSTATIC HYPERPLASIA

DEFINITION

Benign prostatic hyperplasia (BPH) is defined histologically by hyperplasia of both epithelial and stromal cells, beginning in the periurethral area. With aging, multiple small hyperplastic nodules grow, coalesce, and compress normal tissue outward against the true prostatic capsule, creating a surgical capsule that bounds the expanding adenoma.

EPIDEMIOLOGY

The hyperplastic process often begins in the third decade of life; by age 80 years, 85% of men have BPH. The age-specific prevalence of BPH at autopsy is remarkably similar among men of different ethnicities. Aging and functioning testes are the dominant risk factors. The onset of clinical manifestations of BPH before age 65 in a first-degree relative is also a risk factor. The prevalence of clinical manifestations is uncertain because of a lack of consensus on a working definition. Nevertheless, in the United States, about one third of men aged 40 to 79 years have moderate to severe lower urinary tract symptoms, a majority of which are attributable to BPH.

PATHOBIOLOGY

Testosterone is converted by the 5α-reductase enzyme into dihydrotestosterone, the major intraprostatic androgen. BPH does not develop in men who are castrated before puberty or who have 5α-reductase deficiency. Although the type 2 isoenzyme predominates in the prostate, the type 1 isoenzyme predominates elsewhere. An array of peptide growth factors, along with dihydrotestosterone, mediates stromal-epithelial interactions that alter the balance of cell proliferation and apoptosis and thereby lead to BPH. The mechanisms are poorly understood.

The genetics of BPH are also unclear. An autosomal dominant hereditary form may account for less than 10% of cases.

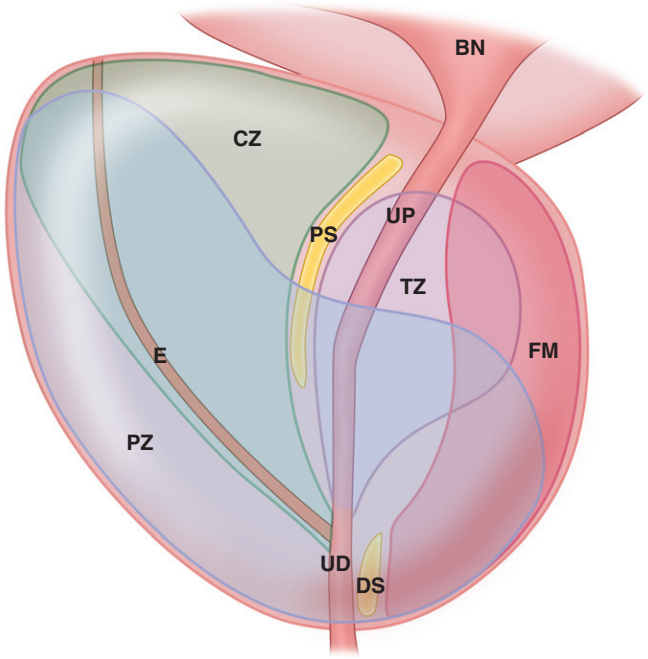

FIGURE 131-1. Anatomy of the prostate. Sagittal diagram of the distal prostatic urethral segment (UD), proximal urethral segment (UP), and ejaculatory ducts (E), showing their relationships to a sagittal section of the anteromedial nonglandular tissues: the bladder neck (BN), anterior fibromuscular stroma (FM), preprostatic sphincter (PS), and distal striated sphincter (DS). These structures are shown in relation to a three-dimensional representation of the glandular prostate: central zone (CZ), peripheral zone (PZ), and transitional zone (TZ). (From McNeal J. Normal histology of the prostate. *Am J Surg Pathol.* 1988;12:619-633.)

CLINICAL MANIFESTATIONS

The morbidity of BPH is conferred through bothersome lower urinary tract symptoms. Traditionally, voiding symptoms such as hesitancy, straining, a sense of incomplete emptying, intermittency, a weak stream, and postvoid dribbling were considered a consequence of mechanical bladder outlet obstruction. Filling symptoms, such as frequency, nocturia, urgency, and urge incontinence (Chapter 25), were thought to be caused by secondary uninhibited detrusor contractions. However, poor correlations among the severity of symptoms, prostatic size, degree of obstruction, and detrusor instability suggest that the pathophysiology is more complex. The key lower urinary tract symptoms of BPH can be quantified by asking the seven symptom questions in the International Prostate Symptom Score (IPSS) (Fig. 131-2).

Bladder outlet obstruction owing to BPH has both static and dynamic components. The static component is due to the enlarged prostate, whereas the dynamic component is due to increased adrenergic tone in the prostate, where α_2-adrenoreceptors predominate.

In the setting of obstruction, increased detrusor pressure can result in detrusor hypertrophy and, eventually, fibrosis. Complications of BPH include acute urinary retention, which may result from prostatic infarction. Postvoid residual urine probably increases the risk of urinary tract infection or stone formation. With long-standing obstruction, hydroureter and hydronephrosis may develop, and renal failure may eventually ensue. Men with BPH may have hematuria because of the complex of veins stretched over the enlarged prostate; however, other causes, especially malignancy (Chapter 203), need to be considered.

DIAGNOSIS

History

Symptoms are commonly attributed to BPH when an older man presents with lower urinary tract symptoms. IPSSs of 0 to 7 represent mild symptoms;

	Not at all	Less than 1 time in 5	Less than half the time	About half the time	More than half the time	Almost always
1. Over the past month or so, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
2. Over the past month or so, how often have you had to urinate again less than two hours after you finished urinating?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
3. Over the past month or so, how often have you found you stopped and started again several times when you urinated?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
4. Over the past month or so, how often have you found it difficult to postpone urination?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
5. Over the past month or so, how often have you had a weak urinary stream?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
6. Over the past month or so, how often have you had to push or strain to begin urination?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐

7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?

0 ☐ none	1 ☐ 1 time	2 ☐ 2 times	3 ☐ 3 times	4 ☐ 4 times	5 ☐ 5 or more times

Total IPSS Score = sum of questions 1–7 = _____

Quality of life due to urinary symptoms

If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?

Delighted	Pleased	Mostly satisfied	Mixed—about equally satisfied and dissatisfied	Mostly dissatisfied	Unhappy	Terrible
0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐	6 ☐

FIGURE 131-2. International Prostate Symptom Score (IPSS). The seven symptom questions constitute a scale initially developed by the American Urological Association. The eighth question about quality of life is scored separately. (From Barry MJ, Fowler FJ Jr, O'Leary MP, et al. The American Urological Association symptom index for benign prostatic hyperplasia: the Measurement Committee of the American Urological Association. *J Urol.* 1992;148:1549.)

8 to 19, moderate symptoms; and 20 to 35, severe symptoms (see Fig. 131-2). When frequency and nocturia are the dominant symptoms, a voiding diary, in which the patient records the times and amounts of each void over several days, may be helpful. For example, if the diary documents nocturnal polyuria alone, causes other than BPH should be strongly considered. Men with BPH tend to have a balance of voiding and filling symptoms that slowly progress with age. A complete list of medications should be obtained because many drugs, especially over-the-counter antihistamines, sympathomimetics, and anticholinergics, can affect the urinary tract.

Differential Diagnosis

Although lower urinary tract symptoms in older men are often due to BPH, the differential diagnosis includes systemic diseases that cause frequency and nocturia, such as diabetes (Chapter 236 and 237), hypercalcemia (Chapter 253), bladder outlet obstruction due to urethral strictures, and neurologic diseases affecting the bladder (Chapter 25). Rapid onset of symptoms, presentation before age 50, or filling symptoms without voiding symptoms are "red flags" that suggest these alternative causes. Older men can have overactive bladders either primarily or secondary to outlet obstruction. A general medical history and the pattern of symptoms should provide clues to systemic diseases. Men with strictures usually have undergone genitourinary instrumentation or have had sexually transmitted diseases (Chapter 293). Primary bladder problems should be suspected in men with previous stroke (Chapter 414), Parkinson's disease (Chapter 416), or diabetic neuropathy (Chapter 428).

Physical Examination

The physical examination should include a digital rectal examination and a focused neurologic examination to look for evidence of peripheral neuropathy or saddle-area anesthesia (the S2-S4 segments innervate the bladder), which might suggest an underlying neuropathic bladder. The digital rectal examination should assess the size and consistency of the prostate. Classically, BPH causes a symmetrically enlarged, firm prostate, with a consistency similar to that of the tip of the nose. Asymmetry or frank nodules suggest prostate cancer (Chapter 207), but prostate cancer can be present even when the prostate feels normal. Physicians tend to underestimate the prostate's size; if the prostate feels enlarged, it usually is.

Laboratory Findings

Urinalysis should assess possible pyuria or hematuria. Optional studies include measurement of the serum creatinine and prostate-specific antigen (PSA) levels. Peak urinary flow is often measured in urologists' offices, but results are unreliable with low voided volumes (<150 mL). Peak flows less than 10 mL/second are more suggestive of outlet obstruction, whereas peak flows greater than 15 mL/second are less suggestive. Unfortunately, men can have good flows with forceful bladder contractions despite obstruction, and they can have poor flows with weak bladder contractions in the absence of obstruction.

PSA results must be interpreted with caution. Generally, a level greater than 4 ng/mL should trigger an ultrasonography-guided prostate biopsy. About 50% of men with PSA levels greater than 10 ng/mL have prostate cancer at biopsy, about 25% with levels of 4.1 to 10 ng/mL have cancer, and 15% with levels of 4 ng/mL or less have cancer. Most authorities doubt the value of early detection of nonpalpable prostate cancer in men with a life expectancy of less than 10 years or those older than 75 years with average comorbidities. However, for medicolegal reasons, it is wise to discuss the possibility of an underlying prostate cancer with any older man who presents with lower urinary tract symptoms. A PSA level, probably by serving as a proxy for prostate size, can also help stratify the future risk of progression to surgery or acute urinary retention, with higher values predicting greater risk.

The "gold standard" test for the diagnosis of bladder outlet obstruction (Chapter 25) is the documentation of increased bladder pressure relative to urinary flow. Pressure-flow studies should be considered in men who have atypical presentations, diseases that increase their risk of primary bladder problems, or no response to adequate medical therapy.

PREVENTION

There are no documented effective strategies for the prevention of BPH. For the prevention of adverse outcomes from prostate cancer, which may present similarly to BPH, data are still evolving. A PSA level may detect prostate cancer in patients evaluated for suspected BPH, but the PSA level has relatively poor specificity in this situation. Early detection of prostate cancer with routine PSA testing may reduce prostate cancer–specific mortality somewhat, but at the expense, morbidity, and inconvenience of substantial false-positive and overtreatment rates (Chapter 207).

TREATMENT Rx

Men with IPSSs in the mild range are rarely bothered enough by their symptoms to warrant treatment. Similarly, an enlarged prostate alone is not an indication for treatment. The key step in decision making for men with moderate or severe symptoms is to assess the degree to which the patient is bothered. The last IPSS question—"If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?"—can serve as an entrée to this discussion.

For men whose symptoms cause little inconvenience, "watchful waiting" is appropriate. The patient's situation should be reassessed periodically. Avoidance of offending medications is also wise. Self-managed lifestyle changes, including fluid management (daily intake of 1500 to 2000 mL and fluid restriction before long journeys and within 2 hours of bedtime), avoiding caffeine, and the use of voiding techniques (double voiding, urethral milking, and bladder retraining) can improve symptoms and decrease the need for medical or surgical intervention substantially, at least over the short term.

Medical Therapy

Most men with bothersome symptoms initially choose medical therapy. α_1-Adrenergic blockers and 5α-reductase inhibitors are the prescription options in the United States. When men present with symptomatic BPH, an α-blocker is a reasonable first choice for medical therapy. Finasteride or dutasteride can also be offered to men with palpably enlarged prostates or higher PSA levels for added preventive benefit. Combination α_1-adrenergic blocker and antimuscarinic therapy, though not yet approved by the Food and Drug Administration (FDA), may be effective for men with BPH symptoms related to overactive bladder; however, men need to be monitored closely for acute urinary retention, particularly during the first month of therapy.

α-Blockers (Table 131-1), which attack the dynamic component of BPH, reduce symptoms significantly, independent of prostate size, but they do not significantly reduce the risks of acute retention or progression to surgery over 4 years. In general, doses should be increased toward the maximum until the therapeutic effect is optimal, unless side effects, including orthostatic hypotension, dizziness, and asthenia, are limiting. Tamsulosin, alfuzosin, and silodosin, which appear to be more specific for the α_{1a}-receptor subtype that dominates in the prostate, have little or no effect on blood pressure. However, because α-blocker-related dizziness and asthenia are not mediated primarily through hypotension, it is unclear whether these agents have advantages other than a lower risk of orthostatic hypotension. An intraoperative floppy iris syndrome can complicate cataract surgery in patients taking tamsulosin and other α_1-blockers; preoperative risk assessment (Chapter 439) should consider the use of these medications, but it is unclear whether discontinuation before surgery reduces the occurrence rate.

Finasteride and dutasteride are 5α-reductase inhibitors (see Table 131-1) that block the conversion of testosterone to dihydrotestosterone by the type 2 isoenzyme (finasteride) or both isoenzymes (dutasteride). Prostate size decreases by 15 to 20% over 1 year of treatment with either agent. Compared with placebo, finasteride and dutasteride reduce lower urinary tract symptoms for at least 2 to 4 years. Although relief of symptoms may be more modest than with α-blockers in some men, dutasteride monotherapy produces more symptom relief than tamsulosin alone in men with larger prostate glands. In addition, 5α-reductase inhibitors reduce the rate of progression to surgery or to acute urinary retention in men with larger prostates. The "number needed to treat" for 4 years to prevent an episode of acute retention or surgery is about 30 for men with PSA levels less than 1.4 ng/mL, about 20 for those with PSA levels of 1.4 to 3.2 ng/mL, and about 10 for those with PSA levels greater than 3.2 ng/mL. Given the different mechanisms of α-blockers and 5α-reductase inhibitors, it is not surprising that combination therapy is more effective than monotherapy in preventing progression of symptoms and disease.

The main side effect of finasteride and dutasteride is sexual or ejaculatory dysfunction, which occurs in about 5% of men. Both agents lower PSA levels by about 50% but do not appear to interfere with the detection of prostate cancer if the physician mentally doubles the measured PSA and then interprets this higher value as usual. Finasteride reduces the 7-year cumulative incidence of prostate cancer from 24 to 18% in men who are heavily screened, including routine end-of-study biopsies. However, concerns about the higher risk of high-grade prostate cancer observed in this trial have not been completely allayed.

Some short-term trials have suggested that daily use of a 5-phosphodiesterase inhibitor can reduce lower urinary tract symptoms, but these agents are not FDA approved for this purpose, and their role in the management of lower urinary tract symptoms due to BPH has yet to be defined. Although a variety of plant extracts, such as saw palmetto, have been suggested for the relief of lower urinary tract symptoms, recent results from a high-quality trial were disappointing.

Surgical Therapy

Transurethral prostatectomy (TURP) reduces symptoms significantly more than watchful waiting or any form of medical therapy, without any greater risk of sexual dysfunction or incontinence.■ Standard TURP, which uses a wire electrode to resect obstructing tissue, generally requires a brief hospital stay and an indwelling catheter for a few days or a week. Newer variations use a rolling electrode or laser energy to vaporize or resect prostate tissue. These procedures appear to result in less short-term bleeding and good short-term symptom improvement, but their long-term effectiveness is undefined.

Minimally invasive transurethral microwave thermotherapy (TUMT) heats and coagulates prostate tissue by using a microwave antenna surrounded by a cooling jacket to protect the urethra. Transurethral needle ablation (TUNA) uses radio frequency needles placed directly into the prostate to generate heat and cause coagulation. The mechanisms by which these treatments work are poorly understood. However, they appear to produce an initial level of symptom relief intermediate between drug therapy and TURP. Their long-term effectiveness remains unclear.

PROGNOSIS

Lower urinary tract symptoms attributable to BPH generally progress slowly over time, but individual experience varies. For example, in one study of men with symptom scores in the moderate range who elected watchful waiting, after 4 years of follow-up, 13% had only mild symptoms, 46% still had moderate symptoms, 17% had severe symptoms, and 24% had opted for surgery. The risk of acute urinary retention for such men is 1 to 2% per year. More serious complications appear to be exceedingly rare.

TABLE 131-1 MEDICATIONS USED IN THE TREATMENT OF MEN WITH LOWER URINARY TRACT SYMPTOMS ATTRIBUTED TO BENIGN PROSTATIC HYPERPLASIA

DRUG	TABLET/CAPSULE SIZE (mg)	RECOMMENDED DOSE STEPS
α-BLOCKERS		
Alfuzosin ER	10	10 mg qd
Doxazosin	1, 2, 4, 8	1, 2, 4, 8 mg qd
Doxazosin XL	4, 8	4, 8 mg qd
Silodosin	4,8	8 mg qd (4 mg qd for moderate renal impairment)
Tamsulosin	0.4	0.4, 0.8 mg qd
Terazosin	1, 2, 5, 10	1, 2, 5, 10 mg qd
5α-REDUCTASE INHIBITORS		
Finasteride	5	5 mg qd
Dutasteride	0.5	0.5 mg qd

PROSTATITIS

DEFINITION

The validity of the traditional etiology-based classification of prostatitis has never been confirmed. The current National Institutes of Health prostatitis classification system incorporates the term *chronic pelvic pain syndrome* to reflect uncertainty about whether chronic nonbacterial prostatitis and prostatodynia are actually related to the prostate (Table 131-2).

EPIDEMIOLOGY

Two million outpatient visits for prostatitis are made annually in the United States. The histologic prevalence ranges widely from 6 to 98%. The prevalence of current prostatitis-like symptoms or a previous physician's diagnosis of prostatitis is about 10%.

PATHOBIOLOGY

Both type I (acute bacterial) and type II (chronic bacterial) prostatitis account for 5 to 10% of cases. Like urinary tract infections, 80% are due to strains of *Escherichia coli*; 10 to 15% are due to *Pseudomonas aeruginosa*, *Serratia*, *Klebsiella*, and *Proteus* species; and 5 to 10% are due to enterococci. The remaining cases (>90%) are type III (chronic abacterial/chronic pelvic pain syndrome) prostatitis, for which the pathogenesis remains uncertain. Type III prostatitis is further divided into inflammatory (type IIIA) and noninflammatory (type IIIB) subtypes, based on the presence of leukocytes in expressed prostatic secretions and prostatic urine. Because there appears to be no correlation between the presence of leukocytes and symptoms, the subdivision into types IIIA and IIIB is controversial; many experts believe that both inflammatory and noninflammatory chronic prostatitis/chronic pelvic pain syndrome are the same noninfectious condition, which may or may not be related to the prostate gland.

Theories about the cause of type III prostatitis include infectious agents such as *Mycoplasma hominis, Ureaplasma urealyticum*, *Trichomonas vaginalis*, *Chlamydia trachomatis,* viruses, anaerobic bacteria, and coagulase-negative staphylococci; pro-inflammatory cytokines; autoimmune mechanisms; neurogenic processes; increased prostate tissue pressure; chemical irritation; and increased tension in the muscles of the bladder neck and prostatic urethra or from a tension myalgia of the pelvic floor. Psychological factors have also been implicated.

CLINICAL MANIFESTATIONS

Type I prostatitis is characterized by the acute onset of fever, chills, malaise, low back or perineal pain, and urinary symptoms, particularly dysuria, frequency, and urgency. The presentation is generally dramatic, and the patient may appear toxic. Digital rectal examination often reveals a markedly tender gland.

Type II prostatitis generally occurs in older men in association with recurrent urinary tract infections (Chapter 292). The presentation is less dramatic but involves similar lower urinary tract symptoms, pelvic pain, and sexual dysfunction. On digital rectal examination, the prostate may be normal, swollen, firm, or tender.

TABLE 131-2 CLASSIFICATION AND DEFINITION OF PROSTATITIS

Traditional Classification		*National Institute of Diabetes and Digestive and Kidney Diseases Classification*	
CATEGORY	**DEFINITION**	**CATEGORY**	**DEFINITION**
Acute bacterial prostatitis	Recovery of bacteria from prostatic fluid, purulence of fluid, and systemic signs of infectious illness (fever, chills, myalgia)	Type I (acute bacterial prostatitis)	Acute infection of the prostate
Chronic bacterial prostatitis	Recovery of bacteria in significant numbers from prostatic fluid in the absence of concomitant urinary infection or significant systemic signs (as in acute bacterial prostatitis)	Type II (chronic bacterial prostatitis) Type III (chronic abacterial prostatitis/chronic pelvic pain syndrome)	Recurrent infection of the prostate No demonstrable infection
Nonbacterial prostatitis	No recovery of significant numbers of bacteria from prostatic fluid, but the fluid consistently reveals microscopic purulence	Type IIIA (inflammatory chronic pelvic pain syndrome)	Leukocytes in semen, expressed prostatic secretions, or post–prostatic massage urine
Prostatodynia	No recovery of significant bacteria or purulence in the prostatic fluid, but patients have persistent pelvic pain and lower urinary tract symptoms	Type IIIB (noninflammatory chronic pelvic pain syndrome) Type IV (asymptomatic inflammatory prostatitis)	No leukocytes in semen, expressed prostatic secretions, or post–prostatic massage urine No subjective symptoms; detected by prostate biopsy or by the presence of leukocytes in expressed prostatic secretions or semen during evaluation for other disorders

NIH-Chronic Prostatitis Symptom Index (NIH-CPSI)

Pain or Discomfort

1. In the last week, have you experienced any pain or discomfort in the following areas?

	Yes	No
a. Area between rectum and testicles (perineum)	❑1	❑0
b. Testicles	❑1	❑0
c. Tip of the penis (not related to urination)	❑1	❑0
d. Below your waist, in your pubic or bladder area	❑1	❑0

2. In the last week, have you experienced:

	Yes	No
a. Pain or burning during urination?	❑1	❑0
b. Pain or discomfort during or after sexual climax (ejaculation)?	❑1	❑0
